Theoretic Models for Estimating Risk of Low-Dose Ionizing Radiation. Collective population dose is expressed as a person-rem (roentgen equivalent, man). Estimating a collective dose then enables an application of a "constant risk factor" to obtain a statistical estimate of the number of additional cancers (above background radiation) from that exposure. These computations apply to low doses–low dose rates only **(A).** Many propose the best fit is the linear no-threshold (LNT) model **(B).** The most common alternative to the LNT model is the linear-quadratic model. The quadratic term is the square of the dose. The linear term is equal to zero **(C).** The threshold model is a threshold below which there is *no* increase in cancer risk. Proponents of this model argue that because some toxic chemicals/materials exhibit such thresholds, radiation must also have a threshold. Their arguments are related to repair of the radiation damage caused by lower doses of radiation **(D).** Some evidence exists that low levels of radiation produce a higher level of risk per unit dose, which is called the supralinear model. The stochastic model is where effects are random and the events cannot be predicted **(E).** (Adapted from Makhijani A, Smith B, Thorne MC: *Science for the vulnerable: setting radiation and multiple exposure environmental health standards to protect those at most risk,* Takoma Park, Md, 2006, Institute for Energy and Environmental Research.)

Data from Hoel DG: *Ann N Y Acad Sci* 1076:309–331, 2006; Preston DL et al: *Radiat Res* 160:381–407, 2003.

Extrapolations from high dose or high dose rate down to very low doses and very low dose rates using these mathematical models may underestimate or overestimate cancer risks at low doses. Consequently, animal studies are also ongoing to experimentally understand the biology of low-dose radiation and low dose rates of radiation. The risks of low doses of radiation are controversial and the uncertainties associated with the best estimates are great.[196] The risk of neoplastic transformation in bystander cells remains unclear.

Ultraviolet Radiation

Ultraviolet sunlight *causes* basal cell carcinoma and squamous cell carcinoma (i.e., photocarcinogenesis), two common skin cancers found in white individuals (see following discussion about melanoma). Exposure to ultraviolet radiation (UVR) can emanate from natural and artificial sources; however, the principal source of exposure for most people is sunlight. With further depletion of the stratospheric ozone layer, people and the environment will be exposed to higher intensities of UVR. The degree of damage in skin depends on the intensity and wavelength content (i.e., ultraviolet A [UVA] or ultraviolet B [UVB]; ultraviolet C possess the highest energy but does not penetrate the atmosphere) and the depth of penetration. UV radiation is known to cause specific gene mutations; for example, squamous cell carcinoma involves mutation in the *TP53* gene, basal cell carcinoma in the *patched* gene, and melanoma in the CDKN2A/*p16* gene.[197] In addition, UV light induces the release of TNF-α in the epidermis, which may reduce immune surveillance against skin cancer.[198]

Skin exposure to UVR and ionizing radiation, as well as chemical (xenobiotic) agents/drugs, produces ROS in large quantities that can overwhelm tissue antioxidants and other oxygen-degrading pathways.[199] Uncontrolled release of ROS is an important contributor to skin carcinogenesis.[199] Healthy genes are needed to coordinate the levels of antioxidants and decrease harmful ROS. Imbalances in ROS and antioxidants can lead to oxidative stress, tissue injury, and direct DNA damage. ROS can induce a number of transcription factors (e.g., activator protein 1 [AP-1] and NF-κB)[200] and increase regulating genes that induce inflammation.[201,202] Inflammation is a critical component of tumor progression. The pathophysiology of skin carcinogenesis is discussed further in Chapter 46.

Basal cell carcinoma (BCC) commonly occurs on the head and neck. Individuals with these tumors generally have fair complexions, light-colored eyes, and fair hair. They tend to sunburn rather than tan and live in areas of high sunlight exposure. Usually these cancers arise on areas of the body that receive the greatest sun exposure, although they are not necessarily restricted to these skin sites. Squamous cell carcinoma (SCC) is found more commonly in men who work outdoors. These tumors are distributed over the head, neck, and exposed areas of the upper extremities (see Chapter 46).

The incidence of melanoma in the United States (from the most recent SEER data) has been increasing annually at a rate of about 2.8% from 1981 to 2008.[203] Because mortality rates have not risen as rapidly, however, controversy exists as to whether the incidence increase is a true increase in clinically significant melanoma or is a result of overdiagnosis.[204] Overdiagnosis may include lesions that are histologically malignant but biologically benign.[205] Melanomas most commonly affect whites, and the lower incidence of melanoma in darker-skinned individuals is thought to be the result of higher melanin densities in these individuals.[206] Established risk factors for melanoma are genetic and phenotypic traits; increasing age; fair skin and hair color; the presence of >20 nevi, ≥3 atypical nevi, or freckling; an increased likelihood of burning with sun exposure; a history of immunosuppression, previous psoralen UVA treatment, solar keratoses, squamous cell carcinoma, or xeroderma pigmentosum; and a family history of dysplastic nevi or melanoma.[207,208]

Environmental exposures important in melanoma include history of three or more episodes of sunburn, periodic excessive sunlight exposure (e.g., vacations with intense exposure), possibly long-term continuous sunlight exposure,[209] and UV exposure at tanning salons.[207] Other environmental factors, such as ozone depletion and latitudes closer to the equator, also may be related.[207] Sun exposure and the risk of melanoma remain complex. Melanomas can appear suddenly without warning but can arise from or near a mole (melanocytic nevus). When detected in the early stages, melanoma is highly curable.[210] About 20% of melanomas, however, are diagnosed at nonlocalized and advanced stages.[210] According to Sekulic and colleagues,[211] the failure of current diagnostic methods to accurately predict individual risk of disease progression and outcome challenges the ability to diagnose melanoma in early stages. Recent progress in understanding the molecular alterations in melanoma will likely advance its diagnosis, prognosis, and treatment.

Until 1998 a direct causal relationship between UVB light and melanoma in humans had not been established. Grafted newborn human foreskin (xenograft) onto RAG-1–immunodeficient mice showed such a relationship.[212] Melanocytic hyperplasia occurred in 73% of UVB-treated xenografts. One graft treated with 9,10-dimethylbenz[*a*]anthracene (DMBA) and UVB light developed a human malignant melanoma. This was the first experiment to show that exposure to both UVB light and an exogenous carcinogen could result in a new malignant melanoma. Recent evidence shows UV signature mutations in human melanoma.[213,214] (For further specific pathophysiology discussion, see Chapter 46.)

Increased understanding of the intricate cellular interactions in melanoma will further our knowledge of melanoma etiology and pathogenesis. This knowledge is essential for early detection and treatment.

Electromagnetic Radiation

Health risks associated with **radiofrequency electromagnetic radiation (RF-EMR)** are very controversial. RF-EMR is in the frequency range of 30 kHz to 300 GHz. Electromagnetic fields (EMFs) generated by RF sources couple with the body and result in induced electric and magnetic fields with associated currents inside tissue.[215] Exposure to electric and magnetic fields is widespread. Electric fields are shielded or weakened by walls and other objects; however, magnetic fields are not.[216] EMRs are a type of nonionizing, low-frequency radiation without enough energy to pull electrons from their orbits around

atoms and ionize (charge) the atoms. Microwaves, radar, mobile and cell phones, mobile phone base stations, appliances, power frequency radiation associated with electricity and radio waves, fluorescent lights, computers, and other electric equipment create EMRs of varying strength. The major debate for more than four decades has focused on the association of exposure to EMR and resultant health consequences, including cancer. Scientific evidence is accumulating although hampered by the availability of methods to accurately measure exposure, the lack of a clear dose-response relationship, and the difficulty in reproducing effects. In addition, with competing priorities such as convenience, financial interest, and health necessity, a consensus of the risk/benefit ratio of EMR exposure may be difficult to achieve, and safety standards significantly vary, up to 1000 times among countries.[217,218] In 1998, the National Institute of Environmental Health Sciences Electric and Magnetic Fields Working Group[219] recommended that low-frequency electromagnetic fields (EMFs) be classified as possible carcinogens. Overall, there is limited evidence that magnetic fields cause childhood leukemia[216] (see Chapter 14). Studies of magnetic field exposure from power lines and electric blankets in adults reveal little evidence of an association with leukemia, brain tumors, or breast cancer.[216]

Most exposure to EMF from occupational sources comes from near-field sources; the highest exposure to the general population comes from transmitters close to the body, such as hand-held devices like mobile telephones.[215] Epidemiologic evidence for an association between EMF and cancer has been derived from case-control, cohort, and time-trend studies. The most extensively studied exposure is from use of wireless telephones (mobile and cordless); other exposures include occupational settings and sources from the general environment[215] (also see Chapter 14). The one cohort study and five case-control studies judged by the WHO International Agency for Research on Cancer Monograph Working Group to offer potentially useful information about associations between wireless phones and glioma, with time-trend analyses, did not show an increased rate of brain tumors after the increase in mobile phone use. However, these studies had limitations because most of the analyses examined trends only in the early 2000s.[215] The INTERPHONE study,[220] a multicenter case-control study, is the largest study so far that studies the relationship between mobile phone use and brain tumors—glioma, acoustic neuroma, and meningioma. The pooled analyses included 2708 glioma cases and 2972 controls. The odds ratios (ORs) in terms of time spent on the phone showed that the highest time spent on the phone (>1640 hours of use) was related to glioma risk (OR 1.40; 95% confidence interval [CI] 1.03-1.89). There was a suggestion of increased risk of tumors on the same side of the head as the phone use (ipsilateral exposure) in the temporal lobe, where radiofrequency (RF) EMF exposure is highest.[215] The OR for glioma increased with increasing RF dose for exposure 7 years or more before diagnosis, and there was no association with estimated dose for exposure less than 7 years before diagnosis.[215] A Swedish investigative group performed a pooled analysis of two similar studies between the relationship of glioma, acoustic neuroma, and meningioma manifestation and mobile and cordless phone use.[221] Study participants who used a mobile phone for more than 1 year had an OR for glioma of 1.3 (95% CI 1.1-1.6). The OR increased with increasing time since first use and with total call time, 3.2 (2.0-5.1) for more than 2000 hours of use.[215] Ipsilateral use of the phone was associated with higher risk.[215] Similar findings were reported for cordless phones.[215] Although the INTERPHONE and Swedish studies were judged susceptible to bias, the Working Group concluded that the findings could not be dismissed because of bias alone and a causal relationship between phones and glioma is possible.[215] The Working Group concluded there is "limited evidence in humans" for the carcinogenicity of RF-EMF based on associations between glioma and acoustic neuroma and exposure to RF-EMF from wireless phones.[215] The Working Group reviewed animal studies and concluded there is "limited evidence" in experimental animals for the carcinogenicity of RF-EMF.[215]

The Working Group also reviewed numerous studies' endpoints relevant to mechanisms of carcinogenicity from RF-EMF.[215] The mechanisms included genotoxicity, effects on immune function, gene and protein expression, cell signaling, oxidative stress, and apoptosis. Additionally, studies on the possible effects of RF-EMF on the blood-brain barrier were analyzed. Overall, the Working Group reported there was evidence of RF-EMF on some of these endpoints, but they provided weak mechanistic evidence of RF-EMF–induced cancer in humans.[215] The outcome of the Working Group was to classify RF-EMF as "possibly carcinogenic to humans" (Group 2B).

There are no studies of adults who have used cell phones as children or adolescents. Concern is for children in whom the effects may be compounded because of increased vulnerability to radiation and their longer use of cell phones into adulthood. Ongoing unbiased research is desperately needed. Absolute proof of causation may be hindered because of the ethical questions of exposing individuals to potentially harmful interventions.[222] Chapter 14 discusses cancer in children.

Chemicals and Occupational Hazards as Carcinogens

An estimated 80,000 synthetic chemicals are used in the United States. Of those, only about 7% have been tested for their health effects.[223] It is disturbing that another 1000 are manufactured each year. Exposure to chemicals occurs every day—they are present in air, soil, food, water, household products, toys, personal care products, workplaces, and homes. The number of known carcinogens in experimental animals is large. It is suspected that most of these chemical carcinogens are potentially carcinogenic in humans but documentation is lacking. Table 13-1 provides a summary of the chemicals according to sufficient or limited evidence in humans by cancer site. Known and probable carcinogenic agents are updated by the International Agency for Research on Cancer (IARC). Chemical carcinogenesis involves the classical genotoxic mechanisms and exposure to genotoxic carcinogens might also involve a variety of nongenotoxic effects in cells.[224] Recently, a number of studies reported that the carcinogenic effects induced by several chemicals, including 2-acetylaminofluorene, tamoxifen, trichloroethylene,

aflatoxin B_1, ochratoxin, nickel, and chromium, do not follow a classic genotoxic carcinogenesis model, but rather involve a spectrum of cellular alterations encompassing epigenetic alterations.[225] These epigenetically reprogrammed cells show an epigenetic profile similar to that frequently observed in cancer cells, including altered histone patterns, hypomethylation of DNA repetitive elements, alterations in proto-oncogenes, and hypermethylation of tumor-suppressor genes. Altered epigenetic status confers genome instability and loss of controlled growth signals, typically observed in cancer cells.[226]

A substantial percentage of cancers of the upper respiratory passages, lung, bladder, and peritoneum are attributed to occupational factors; however, fewer studies of nonsmokers exist.[227] One notable occupational factor is **asbestos,** which increases the risk of mesothelioma and lung cancer. Asbestos was used in homes and buildings built before the 1970s to insulate ceiling tiles, flooring, and pipe covers. In Western Europe, the epidemic of mesothelioma in building workers and other workers born after 1940 did not become apparent until the 1990s because of long latency. No exposure to asbestos is without risk and a large number of countries still use, export, and import asbestos-containing products (see Table 13-1).

Carcinoma of the bladder has been linked with the manufacture of dyes, rubber, paint, and aromatic amines, especially β-naphthylamine and benzidine. Benzol inhalation is linked to leukemia in shoemakers and in workers in the rubber cement, explosives, and dyeing industries. Other notable occupational hazards include heavy metals (e.g., high-nickel alloy, chromium VI compounds, inorganic arsenic), silica, polycyclic aromatic hydrocarbons, sulfuric acid, and chloromethyl ether. Studies of occupational exposure to diesel exhaust indicate an increased risk of lung cancer.[228] Disentangling data related to lung cancer, air pollution, and occupational risks is complex, especially in combination with active and passive smoking and the interplay of environmental factors and genetic polymorphisms at multiple loci.

Air Pollution

In the United States, two types of air pollution are most important and widespread: ozone and particle pollution.[229] Other important air pollutants include carbon monoxide, lead, nitrogen dioxide, sulfur dioxide, mercury, arsenic, benzene, formaldehyde, and acid gases.[229] Ozone is an extremely reactive gas molecule composed of three oxygen atoms. It is the main ingredient in smog air pollution. The ozone layer found in the upper atmosphere (the stratosphere) is called ozone (O_3), or good ozone, and protects life on earth by absorbing UV radiation emitted from the sun. The heavy use of propellants, such as aerosols, has decreased the size of the good ozone layer, leading to the banning of chlorofluorocarbons. The accumulating ozone at the lower atmospheric level or ground level is a toxic air pollutant. This ground-level ozone is a gas formed by reactions with nitrogen oxides, volatile organic compounds (VOCs), and sunlight. This gas mixture is emitted from motor vehicle exhausts and industrial emissions. Nasty combinations of mixtures cause damage (i.e., ROS and inflammation) to lung tissue, especially in people with preexisting lung diseases. These mixtures can also affect healthy people when combined with other air pollutants, such as sulfur dioxide. Sulfur dioxide is produced by power plants burning oil and coal, copper smelting, and paper mills. Fine or ultrafine particles, those less than 10 micrometers in diameter, are considered the most harmful. Fine or ultrafine particles are easily absorbed by the lungs and phagocytosed by macrophages and neutrophils that release tissue-damaging inflammatory mediators. Acute exposure to diesel exhaust that contains fine particles is linked to lung, throat, and eye irritations; asthma attacks; and myocardial ischemia.[230] Importantly, according to the WHO diesel exhaust is carcinogenic and causes lung cancer.[231] Long-term exposure to other sources of air pollution may cause lung cancer.[232] Evidence for cancers, other than lung cancer and childhood cancer, is inconsistent.[233]

Indoor pollution generally is considered worse than outdoor pollution, partly because of cigarette smoke. Environmental tobacco smoke (ETS; passive smoking) can cause the formation of reactive oxygen free radicals and thus DNA damage. The IARC has classified ETS as a human carcinogen. Another significant indoor air pollutant is radon gas. **Radon** is a natural radioactive gas derived from the radioactive decay of uranium that is ubiquitous in rock and soil; it can become trapped in houses and gives rise to radioactive decay products known to be carcinogenic to humans. The most hazardous houses can be identified by testing and then by being modified to prevent further radon contamination. Exposure levels are greater from underground mines than from houses. Most of the lung cancers associated with radon are bronchogenic; however, small cell carcinoma does occur with greater frequency in underground miners. Radon increases the risk of lung cancer in underground miners whether they smoke or not.

In China, some regions report very high levels of lung cancer in women who spend much of their time indoors. Exposures from heating and cooking combustion sources (e.g., oil vapors, volatile toxicants) are identified as risk factors for lung cancer.[234,235] In addition, domestic coal use and ETS increase the risk of lung cancer in women and men.[236]

Inorganic arsenic (known as a carcinogen since the late 1960s), found principally in underground water (from 1000 to 4000 mcg/L), is found in many regions of the world. According to the IARC, strong evidence indicates an increased risk of bladder, skin, and lung cancers following consumption of water with high levels of arsenic (generally greater than 200 mcg/L).[237] Evidence for cancers of the liver, colon, and kidney is weaker. Other sources of inorganic arsenic are related to occupational exposures.

The central hypothesis, based on rat studies, for the mechanisms related to particle-induced lung carcinogenesis is that insoluble particles cause pulmonary inflammation (e.g., cytokine release, ROS), which leads to oxidative stress and oxidation of DNA, proliferative response, and tissue remodeling progressing toward fibrosis and tumor development. Additional research is needed to understand the surface chemistry and lung tissue remodeling in relation to insoluble particles, lung carcinogenesis, and other respiratory problems.

SUMMARY REVIEW

Genes, Epigenetics, Tissue

1. Cancer arises from a complicated and an interacting web of multiple causes. Avoiding high-risk behaviors and exposures to individual carcinogens, or cancer-causing substances, will prevent many types of cancer.
2. Lifestyle behaviors, dietary choices, and environmental factors, such as exposure to ultraviolet radiation and occupational carcinogens, contribute to the number of cancer cases and deaths.
3. Investigators are connecting the intricate web between genotype, phenotype, high-risk lifestyle behaviors, the environment, and carcinogenesis. The root cause of cancer is more than inherited or acquired genetic mutations and involves epigenetic changes that frequently precede and induce cancer-causing genetic mutations.
4. Cancer development and progression involves the tissue microenvironment or stroma.
5. The microenvironment participates in a complex signaling process that facilitates tumor promotion and metastases because stromal tissue has immune cells. Chronic inflammation from infiltrating immune cells can be caused by numerous environmental factors, for example, inhaling tobacco smoke.

Incidence and Mortality Trends

1. Cancer is reported to become a major cause of morbidity and mortality in the coming decades in all regions of the world.
2. Overall, cancer incidence rates in the United States for all racial and ethnic groups combined decreased by 0.8% per year during the most recent study period, 2003 to 2007.
3. Death rates from the periods 1998 to 2007 and 2003 to 2007 continued to decrease for 7 of the top 15 cancer types in both men and women (colorectal, brain, stomach, and kidney cancers; non-Hodgkin lymphoma; leukemia; and myeloma). Decreasing death rates for men also included lung, prostate, and the oral cavity, and for women breast and bladder cancers. Death rates continued to increase for cancers of the liver and pancreas among men and women, uterine cancer in women, and melanoma of the skin in men.

In Utero and Early Life Conditions

1. Accumulating data suggest early life events influence later susceptibility to certain chronic conditions, including cancer.
2. Developmental plasticity is the degree to which an organism's development is contingent on its environment. It requires stable gene expression that in part appears to be modulated by epigenetic processes such as DNA methylation, histone modification, and microRNAs.
3. Epidemiologic and animal studies reveal that small changes in the developmental environment can alter phenotypic changes, resulting in individual responses in adulthood.

Tobacco Use

1. Cigarette smoking is carcinogenic and the most important cause of cancer. The risk is greatest in those who begin to smoke when young and continue throughout life.
2. Cigarette smoking accounts for one of every five deaths each year in the United States. Yet it is the single most preventable cause of death and disease.
3. In addition, smoking causes even more deaths from vascular, respiratory, and other diseases than from cancer.
4. Smoking tobacco is linked to cancers of the lung, lower urinary tract, upper aerodigestive tract, liver, kidney, pancreas, cervix, and uterus and to myeloid leukemia.
5. Environmental tobacco smoke (ETS) is the combination of sidestream and mainstream smoke.
6. More than 60 chemicals in tobacco smoke are considered carcinogenic. Nonsmokers who live with smokers are at greatest risk for lung cancer, as well as other noncancerous conditions. In utero effects from maternal or paternal smoking and subsequent disease are being investigated.
7. Cigar or pipe smoking is strongly and causally related to cancers of the oral cavity, oropharynx, hypopharynx, larynx, esophagus, lung, and possibly the pancreas. Bidi smoking can cause cancers of the respiratory and digestive tracts and also increase the risk of heart attacks and chronic bronchitis.

Diet

1. Dietary sources of carcinogenic substances include compounds produced in the cooking of fat, meat, or protein, and naturally occurring carcinogens associated with plant food substances, such as alkaloids or mold byproducts.
2. Research is ongoing to understand the complexity of nutrition and genomics, epigenomics, transcription factors (transcriptomics), proteomics, and metabolic factors (metabolomics) and the effect on cancer risk of modifying one or more of these factors.
3. Nutrition directly influences epigenetic factors that silence genes that should be active or activate genes that should be silent. The expression of microRNAs in response to diet may be involved in several cancers.
4. Dietary components can act directly as mutagens or interfere with the elimination of mutagens.
5. Dietary factors may affect the cell cycle, differentiation, DNA damage and repair, stem cell renewal, hormonal axes, the balance of cellular proliferation and cell death, the microenvironment, cell signaling, inflammation, and immunity.
6. Xenobiotics that include toxic, mutagenic, and carcinogenic chemicals are found in the human diet.
7. Food and nutrition modify carcinogen metabolism and include the examples selenium, allyl sulfur, sulforaphane, and isoflavonoids.
8. *N*-Nitroso compounds can increase nitrogenous residues in the colon and cause DNA damage.
9. Undernutrition can be a factor in cancers caused by infectious agents, for example, cancers of the liver and cervix.
10. Future research is needed to define robust biomarkers of cancer risk.

SUMMARY REVIEW—cont'd

Obesity

1. Obesity has been increasing in most developed countries and in urban areas of developing countries.
2. Childhood obesity has been increasing. There is considerable concern for children with early onset of obesity.
3. The substantial suffering and long-term human and societal costs of obesity underlie the urgency to accelerate progress in obesity prevention.
4. Studies have significantly improved the understanding of the relationship between overweight/obesity, energy balance and cancer risk, cancer recurrence, and survival.
5. Consensus now exists that obesity is a risk factor for cancers of the endometrium, colorectum, kidney, esophagus, breast (postmenopausal), and pancreas. Evidence is evolving of the association of obesity with cancers of the thyroid, gallbladder, liver, and ovary and also with aggressive types of prostate cancer and non-Hodgkin lymphoma.
6. Obesity is recognized as a poor prognostic factor for several cancers.
7. Overall, the putative mechanisms whereby obesity drives the progression of cancer are not completely known and the process is complex.
8. Earlier studies centered on mostly hormonal effects; however, research now includes other mechanisms whereby energy balance may affect (a) genomic instability, (b) dysregulated growth signaling and cellular energetics, (c) inhibition of apoptosis and immune surveillance, and (d) angiogenesis.
9. Numerous signaling pathways and factors are involved in the acceleration of carcinogenesis. Data now exist for several factors, including energy-driven signaling from insulin, insulin-like growth factor 1 (IGF-1), phosphatidylinositol 3-kinase, and AMP-activated protein kinase and many others.
10. Adipose tissue is a source of inflammatory modulators and increasing evidence indicates that obesity is causally linked to inflammation
11. Cancers have altered metabolism. Tumors consume large quantities of glucose to make cellular building blocks, called the Warburg Effect. Yet, some tumors do use oxidative stress as a weapon to extract recycled nutrients from cancer-associated fibroblasts in stromal tissue (Reverse Warburg Effect).
12. Food metabolism and circadian cycles are linked and impairment of inner clock regulation results in dysregulated metabolism.
13. Overall, there are strong data supporting alcohol as a cause of cancers of the mouth, pharynx, larynx, esophagus, liver, colorectum, and breast.

Infection, Sexual and Reproductive Behavior, Human Papillomaviruses

1. Infection is an important contributor to cancer worldwide and the population attributable fraction (PAF) was 16.1% of cancers diagnosed in 2008 were caused by infection, or about 2 million new cases.
2. Infection and cancer rates vary widely by region, with a 7.4% rate for more developed regions and 22.9% rate for less developed regions. The highest PAF is for sub-Saharan Africa with a rate of 32.7%.
3. The four top notable infections and new cancer cases include HPV, *Helicobacter pylori (H. pylori),* hepatitis B virus, and hepatitis C virus.
4. Hepatitis B and C can infect the liver and together account for the large majority of liver cancer diagnoses.
5. It has been estimated that *H. pylori* accounts for about 75% of all stomach cancers.
6. *High-risk,* or oncogenic, *HPVs* can cause cancer. High-risk types of HPV are required for the development of most cervical cancers. HPV types 16 and 18 cause the majority of cancers.
7. HPV types 16 and 18 also have been found to cause almost half of vaginal, vulvar, and penile cancers. Recently, HPV infections have been found to cause cancer of the oropharynx (soft palate, base of the tongue, tonsils).
8. Factors that may increase the risk of developing cancer following a high-risk HPV infection include smoking, decreased immunity, having many children (for increased risk of cervical cancer), long-term oral contraceptive use (for increased risk of cervical cancer), poor oral hygiene (for increased risk of oropharyngeal cancer), and chronic inflammation.
9. HPVs infect epithelial cells that cover the inside and outside surfaces of the body, including the skin, throat, genital tract, and anus.

Physical Activity

1. Physical activity reduces the risk for breast cancer, colon cancer, and endometrial cancer, independent of weight changes.
2. Biologic mechanisms for the protective effects of exercise include decreasing insulin and IGF levels, decreasing obesity, increasing free-radical scavenger systems, changing inflammatory mediators, decreasing the levels of circulating sex hormones and metabolic hormones, improving immune function, and enhancing cytochrome P-450 function, thus modifying carcinogen activation and increasing gut motility.
3. Several reports suggest that implementing a physical activity program after a cancer diagnosis is associated with better cancer-specific outcomes and overall survival with early-stage breast, prostate, and colorectal cancers.
4. Many unanswered questions remain regarding the frequency, intensity, and duration of exercise required for optimal health benefits.

Ionizing Radiation

1. Much of the knowledge of the effects of ionizing radiation (IR) on human cancer has stemmed from observations of the Hiroshima and Nagasaki atomic bomb exposures, particularly the Life Span Study. Other evidence is derived from groups exposed for medical reasons, underground miners exposed to radon gas, and other occupational exposures.

SUMMARY REVIEW—cont'd

2. The atomic bomb exposures in Japan caused acute leukemias in adults and children and increased frequencies of thyroid and breast carcinomas. Lung, stomach, colon, esophageal, and urinary tract cancers and multiple myeloma have been added to the list.
3. Recent models of radiation carcinogenesis show ionizing radiation (IR) acts not only as an initiator of premalignant cell clones but also as a promoter of preexisting premalignant cell alterations.
4. Health risks from IR involve cancers, cardiovascular diseases, respiratory diseases, birth defects, and eye maladies.
5. In 2009 the National Council on Radiation Protection and Measurements reported Americans were exposed to more than seven times as much IR from medical procedures compared to IR exposure in the 1980s.
6. Ionizing radiation is a mutagen and carcinogen and can penetrate cells and tissues and deposit energy in tissues at random in the form of ionizations.
7. The past two decades have focused on cellular and molecular mechanisms that relate to the induction of cancer, including dose-response relationships for chromosome aberrations and for cell transformation; gene expression (genetic and epigenetic); alternative targets, such as membranes; mutagenesis in somatic cells; the biologic effects that occur in nonirradiated cells (i.e., nontargeted effects); and effects on the microenvironment.
8. Because models and underlying assumptions of IR and cell damage are incomplete, investigators are working hard to understand induced repair, adaptive responses, hormesis, low-dose hypersensitivity, nontargeted effects, signaling, exosomes, and long-term persistence of radiation damage and clonal heterogeneity.
9. A long held assumption is that cellular alterations—mutations and malignant transformation—occur only in cells directly radiated. It is now known that radiation may induce a type of genomic instability to the progeny of the directly irradiated cells over many cell generations and can affect so-called innocent bystander cells.
10. Epigenetic events after radiation include alterations in pathways affecting cell adhesion, extracellular matrix interactions, and cell-to-cell communication.

Ultraviolet Radiation

1. Ultraviolet radiation (UVR) causes basal cell carcinoma and squamous cell carcinoma. The principal source of UVR is sunlight.
2. The degree of damage in skin depends on the intensity and wavelength content—ultraviolet A (UVA) or ultraviolet B (UVB).
3. UVR is known to cause specific gene mutations; for example, squamous cell carcinoma involves mutation in the TP53 gene, basal cell carcinoma in the patched gene, and melanoma in the p16 gene.
4. Skin exposure to UVR produces ROS in large quantities that can overwhelm tissue antioxidants and other oxygen-degrading pathways. Imbalances in ROS can lead to oxidative stress, tissue injury, and direct DNA damage.
5. ROS can induce a number of transcription factors (e.g., activator protein 1 [AP-1] and NF-κB) and increase the levels of regulating genes that induce inflammation. Inflammation is a critical component of tumor progression.
6. The incidence of melanoma in the United States has been increasing annually at a rate of about 2.8% from 1981 to 2008. Because mortality rates have not risen as rapidly, however, controversy exists as to whether the incidence increase is a true increase in clinically significant melanoma or is a result of overdiagnosis.
7. The relationship between sun exposure and the risk of melanoma remains complex.
8. Increased understanding of the intricate cellular interactions in melanoma will enhance knowledge of melanoma etiology and pathogenesis. This knowledge is essential for early detection and treatment.

Electromagnetic Radiation

1. Health risks associated with electromagnetic radiation (EMR) are controversial. Exposure to electric and magnetic fields is widespread. EMRs are a type of nonionizing and low-frequency radiation.
2. EMRs generated by radiofrequency sources couple with the body and result in induced electric and magnetic fields with associated currents inside tissue.
3. Microwaves, radar, mobile and cell phones, mobile phone base stations, appliances, power frequency radiation associated with electricity and radio waves, fluorescent lights, computers, and other electric equipment create EMRs of varying strength.
4. Data measuring the relationships between EMR exposure and cancer are limited because of inadequate methods to accurately measure exposure, lack of clear dose-response relationships and reproduction of effects, financial interests, and other priorities such as convenience.
5. Most exposure to EMFs from occupational sources comes from near-field sources; the highest exposure to the general population comes from transmitters close to the body, such as hand-held devices like mobile telephones.
6. The WHO International Agency for Research on Cancer Monograph Working Group reported that the INTERPHONE and Swedish studies were judged susceptible to bias, the findings could not be dismissed because of bias alone, and a causal relationship between phones and glioma is possible.
7. The outcome of the Working Group was to classify RF-EMF as "possibly carcinogenic to humans" (Group 2B). The mechanisms included genotoxicity, effects on immune function, gene and protein expression, cell signaling, oxidative stress, apoptosis, and, possibly, the blood-brain barrier.
8. There are no studies of adults who have used cell phones as children or adolescents. Concern is for children in whom the effects may be compounded because of increased vulnerability to radiation and their longer use of cell phones into adulthood.

SUMMARY REVIEW—cont'd

Chemicals and Occupational Hazards

1. An estimated 80,000 synthetic chemicals are used in the United States. Of those, only about 7% have been tested for their health effects and another 1000 are synthesized each year.
2. Chemicals are present in air, soil, food, water, personal care products, toys, household products, medications, workplaces, and homes.
3. Known and probable carcinogenic agents are updated by the International Agency for Research on Cancer (IARC).
4. The number of known carcinogens in experimental animals is large. It is suspected that most of these chemical carcinogens are potentially carcinogenic in humans but documentation is lacking.
5. Chemical carcinogenesis involves the classic genotoxic mechanisms, and exposure to genotoxic carcinogens also might involve a variety of nongenotoxic effects, including epigenetic alterations in cells.
6. A number of studies reported that the carcinogenic effects induced by several chemicals do not follow a classic genotoxic carcinogenesis model, but rather involve a spectrum of cellular alterations encompassing epigenetic alterations.
7. A substantial percentage of cancers of the upper respiratory passages, lung, bladder, and peritoneum are attributed to occupational factors; however, fewer studies of nonsmokers exist.
8. Disentangling data related to lung cancer, air pollution, and occupational factors is complex, especially in combination with active and passive smoking, environmental factors, and multiple interacting genes.

Air Pollution

1. In the United States, two types of air pollution are most important and widespread: ozone and particle pollution. Other important air pollutants include carbon monoxide, lead, nitrogen dioxide, sulfur dioxide, mercury, arsenic, benzene, formaldehyde, and acid gases.
2. Ozone is the main ingredient in smog air pollution.
3. Ground-level ozone is a gas formed by reactions with nitrogen oxides, volatile organic compounds (VOCs), and sunlight. This gas mixture is emitted from motor vehicle exhausts and industrial emissions.
4. Fine or ultrafine particles are easily absorbed by the lungs and phagocytosed by macrophages and neutrophils that release tissue-damaging inflammatory mediators.
5. The indoor air pollution environmental tobacco smoke (ETS; passive smoking) can cause the formation of reactive oxygen free radicals and thus DNA damage. The IARC has classified ETS as a human carcinogen.
6. Strong evidence indicates an increased risk of bladder, skin, and lung cancers following consumption of water with high levels of arsenic (generally greater than 200 mcg/L).

- Review Questions and Answers

CHAPTER OUTLINE

Cancer in children is rare, but it is still the leading cause of death from disease in this patient population. The 5-year survival rates in children with cancer have improved from 59% in the 1970s to 83% today.[1] Some of the factors leading to improved cure rates in children with cancer include the use of combination chemotherapy, the utilization of immunotherapy, and the participation of many subjects in clinical trials.

INCIDENCE AND TYPES OF CANCER

In 2012, approximately 12,060 children (from birth to 14 years of age) in the United States will be diagnosed with cancer, and approximately 1340 will die from the disease, one third of these from leukemia.[1]

The types of malignancies in children are vastly different from those that affect adults. The most common types of cancer among adults include prostate, breast, lung, and colon. Children (birth to 14 years of age) with leukemias and brain tumors account for 61% of childhood cancers; neuroblastoma and soft tissue or bone sarcomas are less common. Although many adult cancers have associated lifestyle factors that could theoretically be avoided, such as smoking and lifetime exposure to sun, very few environmental factors have been linked to pediatric malignancies. Yet more data are emerging that the developing child may be affected by parental exposures before conception, exposures in utero, and the contents of breast milk.[2,3]

The incidence of cancer among adolescents and young adults represents only 2% of all invasive cancers. However, the malignancy rate in this age group (15- to 39-year-olds) is three times higher than that in children younger than 15 years. Each year about 70,000 adolescents and young adults will be diagnosed with cancer. The following are the most common cancers diagnosed among the 15- to 39-year-old population in the United States[3] (these cancers are discussed in the appropriate chapters):

- Hodgkin lymphoma
- Leukemia
- Germ cell tumors (particularly testicular)
- Central nervous system (CNS) tumors
- Non-Hodgkin lymphoma
- Thyroid cancer
- Melanoma
- Sarcomas
- Breast, cervical, liver, and colorectal cancers

Most childhood cancers originate from the **mesodermal germ layer** that gives rise to connective tissue, bone, cartilage, muscle, blood, blood vessels, gonads, kidney, and the lymphatic system. Thus the more common childhood cancers are leukemias, sarcomas, and embryonic tumors. **Embryonic tumors** originate during intrauterine life. These tumors contain abnormal cells that appear to be immature embryonic tissue, unable to mature or differentiate into fully developed functional cells. Embryonic tumors are diagnosed early in life (usually before 5 years of age). Embryonic tumors often contain the term **blast cell** in their name, which refers to the immature nature of the cells.

Leukemia is the most common malignancy in children and the most common type of leukemia is acute lymphoblastic leukemia (ALL), which represents approximately 75% of all pediatric leukemia cases. Although the presenting signs of the various types of leukemia may be similar, the treatment and response to treatment of childhood leukemias vary greatly (see Chapter 30).

CNS tumors are the most common types of solid tumors in children and account for 27% of all childhood cancers[1] (see Chapter 20). Not all brain tumors are diagnosed malignant by histologic studies, but even a benign tumor can have devastating effects, depending on the anatomic location. The treatment for brain tumors in children often presents difficulties because therapies, such as radiation, may have debilitating effects on the developing brain, particularly in children younger than 3 years of age.

Lymphoma, including non-Hodgkin lymphoma and Hodgkin lymphoma, is a malignancy that occurs in children and adults. However, the subtypes of lymphoma and treatments in the two populations often differ (see Chapter 30).

Many pediatric solid tumors usually develop only in children but in very rare instances may occur in adults. These tumors include neuroblastoma, Wilms tumor, rhabdomyosarcoma, retinoblastoma, osteosarcoma, and Ewing sarcoma.

Childhood cancers are most often diagnosed during peak times of physical growth. In general, they are extremely fast growing, with 80% having distant spread (metastases) at diagnosis. Overall, cancer is 10% to 25% more common in white than in black children. Boys are more likely to develop cancer than girls.

ETIOLOGY

The causes of cancer in children are largely unknown. A few environmental factors are known to predispose a child to cancer, but causal factors have not been established for most childhood cancers. A number of host factors, many of which are genetic risk factors or congenital conditions, have been implicated in the development of childhood cancer (Table 14-1). It is most likely the interaction of many factors that produces cancer, a concept referred to as multiple causation or **multifactorial etiology.** According to this premise, cancer develops because of the predisposing characteristics of the person and the interaction with environmental causes.

The **multiple causation** concept is useful when the results of epidemiologic studies are interpreted. For example, laboratory and epidemiologic studies may indicate that exposure to a certain chemical can cause leukemia, but not all children exposed to that chemical will develop leukemia. Additional studies will be needed to determine what other factors must interact with chemical exposure to cause the disease.

TABLE 14-1 CONGENITAL FACTORS ASSOCIATED WITH CHILDHOOD CANCER

SYNDROME	ASSOCIATED CHILDHOOD CANCER
Chromosomal Alterations	
Down syndrome	Acute leukemia
13q syndrome	Retinoblastoma
Chromosomal Instability	
Ataxia-telangiectasia	Lymphoma
Bloom syndrome	Acute leukemia, lymphoma, Wilms tumor
Fanconi anemia	Nonlymphocytic leukemia, myelodysplastic syndrome, hepatic tumors
Hereditary Syndromes	
Beckwith-Wiedemann syndrome	Wilms tumor, sarcoma, brain tumors, neuroblastoma, hepatoblastoma
Neurofibromatosis type 1	Brain tumors, sarcomas, neuroblastomas, Wilms tumor, nonlymphocytic leukemia
Neurofibromatosis type 2	Meningioma (malignant or benign), acoustic neuroma/schwannoma, gliomas, ependymomas
Tuberous sclerosis	Glial tumors
Li-Fraumeni syndrome	Sarcoma, adrenocortical carcinoma
von Hippel-Lindau disease	Cerebellar hemangioblastoma, retinal angioma, renal cell carcinoma, pheochromocytomas
Ataxia-telangiectasia	Leukemia, lymphoma, brain tumors
Gorlin syndrome	Medulloblastoma, skin tumors
Immune Deficiency Disorders	
Congenital	
Agammaglobulinemia	Lymphoma, leukemia, brain tumors
Immunoglobulin A (IgA) deficiency	Lymphoma, leukemia, brain tumors
Wiskott-Aldrich syndrome	Leukemia, lymphoma
Acquired	
Aplastic anemia	Leukemia
Organ transplantation	Leukemia, lymphoma
Congenital Malformation Syndromes	
Aniridia, hemihypertrophy, hamartoma, genitourinary anomalies	Wilms tumor
Cryptorchidism	Testicular tumor
Gonadal dysgenesis	Gonadoblastoma
Family Susceptibility	
Twin or sibling with leukemia	Leukemia

TABLE 14-2 SELECTED ONCOGENES AND TUMOR-SUPPRESSOR GENES ASSOCIATED WITH CHILDHOOD CANCER

GENE	ASSOCIATED PEDIATRIC TUMOR
Oncogenes	
bcr-abl	Acute lymphoblastic leukemia
N-myc	Neuroblastoma
c-myb	Neural tumors, leukemia, lymphoma, rhabdomyosarcoma, Wilms tumor, neuroblastoma
erb B	Glioblastomas
N-ras	Neuroblastoma, leukemia
H/K-ras	Neuroblastoma, rhabdomyosarcoma, leukemia
ATM	Lymphoma, leukemia
Tumor-Suppressor Genes	
Rb1	Retinoblastoma, sarcoma
WT1, WT2	Wilms tumor, leukemia
WTC	Wilms tumor
NF-1	Sarcoma, primitive neuroectodermal tumor, juvenile chronic myelocytic leukemia
NF-2	Brain tumors, melanoma, meningiomas
p16	Brain tumors, leukemia
TP53	Sarcoma, leukemia, brain tumors, lymphoma
DCC	Ewing sarcoma, rhabdomyosarcoma
$p16^{INK4a}$	Glioma, leukemia
$p15^{ARF}$	Glioblastoma, T-cell ALL
CDC2L1	Non-Hodgkin lymphoma, neuroblastoma

ALL, Acute lymphocytic leukemia.

Genetic Factors

Oncogenes and tumor-suppressor genes are associated with the development of childhood cancer (Table 14-2; also see Chapter 12). **Proto-oncogenes** code for proteins that help to regulate normal cell growth and differentiation. If mutated, proto-oncogenes become oncogenes that help to turn normal cells into cancer cells. Changes produced by specific oncogenes cause the cell cycle to become dysregulated. An example of an oncogene identified in pediatric cancer is *N-myc,* which is involved in neuroblastoma and glioblastoma. Tumor-suppressor genes arise from genes that normally suppress cancer cell proliferation but have lost their suppressor function, thus leading to uncontrolled growth. Some childhood cancers identified with tumor-suppressor genes include osteosarcoma, leukemia, rhabdomyosarcoma, retinoblastoma, and Wilms tumor.[4]

Other genetic factors involve chromosomal aberrations or single-gene defects. These chromosomal abnormalities include aneuploidy, amplifications, deletions, translocations, and susceptibility to breakage, known as fragility. A well-known chromosomal abnormality is the Philadelphia chromosome found in chronic and acute myelogenous leukemias.[5] Chromosomal deletions are often observed in retinoblastoma and osteosarcoma.

WHAT'S NEW?

Far Fewer Genetic Mutations in Pediatric Cancer

A collaborative study conducted at 20 different centers in the United States examined how DNA in medulloblastoma in children differs from the DNA in adult cancers. The investigators found that the tumors in children had 5 to 10 times fewer mutations than the tumors in adults. However, although the tumors in the children had fewer mutations, more than one third were known to disrupt gene function, which is a much higher percentage than that found in adult tumors.

The findings from this study suggest that childhood cancer is very different than adult cancers. As scientists better understand which genes are most important for causing and preventing cancer, they will be able to more readily identify the type of cancer a person has and also develop targeted therapies.

Data from Parsons DW et al: *Science* 331(6016):435–439, 2011.

Some chromosomal defects and congenital malformations are associated with the development of pediatric cancer. Trisomy 21 (Down syndrome) is the most common genetic defect linked to the development of acute leukemia. Children with Down syndrome have a 10- to 20-fold increased risk of developing acute lymphoblastic and myelogenous leukemias and a higher risk for developing acute megakaryocytic leukemia. The risk is highest between 1 and 4 years of age.[6] Wilms tumor is associated with several congenital syndromes: aniridia, or congenital absence of the iris of the eye; ambiguous genitalia and mental retardation (AGR), neurofibromatosis, and Beckwith-Wiedemann syndrome.[7] Retinoblastoma, a malignant embryonic tumor of the eye, occurs as an inherited defect or as an acquired mutation (see Chapter 20).

Several single-gene defects have been associated with the subsequent development of childhood cancers. Fanconi anemia and Bloom syndrome, two autosomal recessive conditions, are risk factors for the development of acute lymphocytic leukemia (ALL) (see Chapter 30).

Although not determined to be genetically transmitted, a child who has a sibling with leukemia has a risk for the development of leukemia that is two to four times greater than that for children with healthy siblings. The occurrence of leukemia in monozygous twins is estimated as being as high as 25%.

In families with a history of Li-Fraumeni syndrome (LFS) (an autosomal dominant disorder involving the *p53* tumor-suppressor gene), the risk of developing cancer as a child or adult is significantly higher than that seen in the unaffected population. Children and adults in these families are at risk for soft tissue sarcoma, breast cancer, leukemia, osteosarcoma, melanoma, and cancer of the colon, pancreas, adrenal cortex, and brain. Individuals with LFS are at increased risk for developing multiple primary cancers.[8] Overall, cancers in children are very different than adult cancers and are associated with far fewer genetic mutations (see What's New? Far Fewer Genetic Mutations in Pediatric Cancer).

Environmental Factors

Although many adult cancers are associated with environmental agents, few childhood tumors share a similar strong association. Because of the lengthy latency period required between

TABLE 14-3 DRUGS THAT MAY INCREASE RISK OF CHILDHOOD CANCER

DRUG CLASS	USES	CANCER RISK
Anabolic androgenic steroids	Stimulate bone growth and appetite Induce puberty Increase muscle mass and physical strength	Hepatocellular carcinoma Brain tumors
Cytotoxic chemotherapy	Used in cancer treatment	Leukemia
Immunosuppressive agents	Prevent organ rejection following transplantation surgery	Lymphoma

exposure and development of cancer, presumably early exposure to carcinogens does not result in cancer until the child is an adult. A recent meta-analysis of 1426 cases of neuroblastoma failed to show an association between paternal occupational exposure to pesticide and development of disease.[9]

Prenatal Exposure

Prenatal exposure to some drugs and pesticides has been linked to childhood cancers. The most well-described drug is diethylstilbestrol (DES), which was prescribed by physicians to prevent spontaneous miscarriage (in women with previous miscarriage). In 1971, DES was identified as a transplacental chemical carcinogen because a small percentage of the daughters of the women who took DES developed adenocarcinomas of the vagina and cervix. Since then, other studies have attempted to identify drugs taken by pregnant women that may cause cancer in their offspring, but no other drugs have been found. Prior research suggested an association between antenatal x-ray exposure and childhood cancer, but studies have not been replicated or supported in recent literature. In 2006 the Office of the U.S. Surgeon General suggested evidence of a causal relationship between childhood leukemia, lymphoma, and brain tumors and prenatal or postnatal environmental tobacco smoke exposure; the results have suggested an association between parental exposure to pesticides before or during pregnancy.[2] A recent study suggested that the risk of leukemia and lymphoma increased when the mother was exposed to pesticides in the prenatal period and the risk of brain tumors was correlated with paternal exposure (occupational or household use) either before or after birth.[10]

Childhood Exposure

Childhood exposure to ionizing radiation, drugs, or viruses has been associated with the risk of developing cancer. Retrospective research has shown a significant correlation between radiation-induced malignancies from radiotherapy (cancer treatment) or from radiation exposure from diagnostic imaging.[11] Few studies have followed children for a long enough period of time to determine whether there is an increased risk of cancer in adulthood, although there are current studies with more rigorous methodology to assess this risk[12] (see What's New? CT Scans in Childhood Appear to Increase Cancer Risk). In addition to the drug and environmental agents that are known to cause cancer in adults and therefore also are risks for exposure during childhood, a few drugs may particularly increase cancer risk during childhood (Table 14-3). Exposures during childhood to unspecified residential pesticides and insecticides have been associated with childhood leukemia.[13]

WHAT'S NEW?

CT Scans in Childhood Appear to Increase Cancer Risk

The findings from a recent study of 176,587 children suggest that those who had 2 or 3 computed tomography (CT) scans of the head before age 22 years were 3 times as likely to develop brain cancer as those in the general population, and the risk of developing leukemia was 3 times as great in those who received 5 to 10 CT scans. Previous studies have speculated that there may be increased risk from repeated CT scans, but this large study was the first to provide direct evidence. Although the risk remains low, it amounts to 1 additional case of brain cancer for every 30,000 children scanned or to 1 additional case of leukemia for every 10,000 persons who were scanned. Although it remains important for children to receive CT scans to detect head injuries, the results of this study suggest that children should only be scanned when necessary and also with the lowest dose of radiation possible.

Pearce MS et al: *The Lancet* 380(9840):499–505, 2012.

The relationship between childhood cancer and exposure to radon[14] and electromagnetic fields has been the focus of many epidemiologic studies, yet no conclusive evidence has been observed. In 2007 a task group of scientific experts convened by the World Health Organization (WHO) reported that it could not confirm the existence of any health consequences from exposure to low-level magnetic fields.[15]

The strongest association between viruses and the development of cancer in children has been the relationship between exposure to Epstein-Barr virus (EBV) and development of Burkitt lymphoma, nasopharyngeal carcinoma, and Hodgkin disease. Children with acquired immunodeficiency syndrome (AIDS) have an increased risk of developing non-Hodgkin lymphoma and Kaposi sarcoma. However, with the use of highly active antiretroviral therapy in the developed world, the incidence of AIDS-related malignancies has declined dramatically[16] (see Chapter 10).

PROGNOSIS

More than 80% of children diagnosed with cancer are cured. Mortality rates have declined from 6.5 per 100,000 in 1969 to 2.2 per 100,000 in 2008, largely because of advances in treatment and increased participation in clinical trials.[1]

Some of the factors leading to improved cure rates in pediatric oncology include the use of combination chemotherapy

and multimodal treatment for childhood solid tumors. Additionally, development of research centers for comprehensive childhood cancer treatment, cooperation among treatment institutions, and development of cooperative study groups enable the most efficient advancement of treatment regimens. Currently, clinical trials are being conducted by the Children's Oncology Group (COG) at more than 180 hospitals across the United States and are funded by the National Cancer Institute through CureSearch® for Children's Cancer. Side effects of treatment are better managed as a result of improvements in nursing and supportive care, recognition of the psychologic effects of cancer treatment, and continued follow-up to track trends in the late effects of cancer treatment. Young children are particularly prone to long-term sequelae of cancer therapy. Clinical trials are continually focusing on more effective, targeted therapies with fewer side effects.

SUMMARY REVIEW

Incidence and Types

1. Cancer in children is rare, but is still the leading cause of death from disease in this population.
2. Leukemias and brain tumors account for 61% of cancer in children from birth to 14 years of age, with neuroblastoma and soft tissue or bone sarcomas less common.
3. The most common cancers among the adolescent and young adult populations (15 to 39 years of age) are Hodgkin lymphoma, leukemia, germ cell tumors (particularly testicular), central nervous system (CNS) tumors, non-Hodgkin lymphoma, thyroid cancer, melanoma, sarcomas, and breast, cervical, liver, and colorectal cancers.

Etiology

1. It is most likely the interaction of many factors produces cancer in children, a concept referred to as multiple causation or multifactorial etiology.
2. Oncogenes and tumor-suppressor genes have been associated with childhood malignancies.
3. Chromosomal aberrations or single-gene defects including aneuploidy, amplifications, deletions, translocations, and fragility are associated with the development of childhood cancer.
4. Wilms tumor and retinoblastoma are pediatric malignancies that are linked in a familial manner.
5. Childhood exposure to ionizing radiation, drugs, or viruses has been associated with the risk of developing cancer.

Prognosis

1. More than 80% of children diagnosed with cancer are cured.
2. Mortality rates have declined significantly in the past 40 years largely because of advances in treatment and increased participation in clinical trials.
3. Young children are particularly prone to long-term sequelae of cancer therapy. It is imperative that more effective, targeted therapies with fewer side effects be found.

CHAPTER OUTLINE

The human nervous system is a remarkable structure that is responsible for the body's ability both to interact with the environment and to regulate activities involving our internal organs, muscles, and glands. The nervous system *drives* the other systems of the body. It is a network composed of complex structures that transmit electrical and chemical signals between the body's many organs and tissues and the brain.

OVERVIEW AND ORGANIZATION OF THE NERVOUS SYSTEM

Although the nervous system functions as a unified whole, structures and functions of the nervous system have been divided to facilitate comprehension. Structurally, the nervous system is divided into the central nervous system and

the peripheral nervous system. The **central nervous system (CNS)** consists of the brain and spinal cord, enclosed within the protective cranial vault and vertebrae, respectively. The **peripheral nervous system (PNS)** is composed of the **cranial nerves,** which project from the brain and pass through foramina (openings) in the skull, and the **spinal nerves,** which project from the spinal cord and pass through intervertebral foramina of the vertebrae. Peripheral nerve pathways are differentiated into **afferent pathways (ascending pathways)** that carry sensory impulses toward the CNS and **efferent pathways (descending pathways)** that innervate **effector organs,** such as skeletal, cardiac, and smooth muscle, as well as glands, by transmitting motor impulses away from the CNS. Organs innervated by specific components of the nervous system are called *effector organs.* Cranial nerves are viewed most correctly as modified spinal nerves. Some cranial nerves function similarly to spinal nerves, whereas others have specialized sensory tasks, such as smell, taste, sight, and hearing.

Functionally, the PNS can be divided into the somatic nervous system and the autonomic nervous system. The **somatic nervous system** consists of motor and sensory pathways regulating voluntary motor control of skeletal muscle. The **autonomic nervous system (ANS)** also consists of motor and sensory components and is involved with regulation of the body's internal environment (viscera) through involuntary control of organ systems. The ANS is further divided into sympathetic and parasympathetic divisions. Today we understand that some aspects of the ANS can be controlled through mental practice with or without biofeedback techniques.

CELLS OF THE NERVOUS SYSTEM

The two basic types of cells that comprise nervous tissue are neurons and neuroglial cells. The neuron is the primary information/communication cell of the nervous system. Working in parallel systems, neurons can scan the environment, integrate many systems at higher cognitive levels, and initiate body responses to maintain homeostasis. The **neuroglial cells** are found in the CNS and PNS and can provide structural support and nutrition for neurons, remove debris, increase the speed of nerve impulses, and play a significant role, along with neurons, in processing and storing information (i.e., memory).[1]

Neurons

Neuronal structure varies considerably throughout the CNS. Neurons vary in size from micrometers to several meters long and have from one to many cell processes. Even the shapes and complexity of the processes can vary considerably. **Neurons** are specialized cells that share many of the same metabolic activities and constituents as other types of cells. The fuel source for the neuron is predominantly glucose; insulin, however, is not required for cellular glucose uptake in the CNS. Neurons contain many cellular constituents, namely, neurotubules, neurofilaments, neurofibrils, and Nissl substances. **Neurofilaments** and **neurofibrils** are composed of structural proteins and are responsible for structural support within the cell and movement of neuron processes, as seen in amoebae and white blood cells. **Microtubules** also are made of protein and are believed to be involved in the transport of cellular products. **Nissl substances** consist of endoplasmic reticulum and ribosomes and are involved in protein synthesis. The CNS is formed with more neurons than it needs, and those neurons that do not become involved in functional systems die. Some neurons continue to divide after birth. Olfactory neurons in the nose continue to divide throughout life.

A neuron (Figure 15-1) has three components: a cell body (soma) and the thin processes of the cell—the dendrites and axons. Most cell bodies are located within the CNS. Dense, packed cell bodies in the CNS are called **nuclei.** Cell bodies in the PNS are usually found in groups called **ganglia** or **plexuses.** The **dendrites** are extensions that carry nerve impulses *toward* the cell body. The **dendritic zone** is the receptive portion of a neuron that receives a stimulus and continues further conduction. **Axons** are long, conductive projections from the cell body that carry nerve impulses *away* from the cell body. The **axon hillock** is the cone-shaped, organelle-free area where the axon leaves the cell body. In large nerves, axons are bundled together as **fascicles.** The initial segment of the axon has the lowest threshold for stimulation, and as a result, action potentials begin there.

A typical neuron has only one axon, which may be covered with a segmented layer of lipid material called **myelin,** which acts as an insulating substance. This entire membrane is referred to as the **myelin sheath;** the thin membrane between the myelin sheath and the **endoneurium,** a delicate connective tissue around each axon in the PNS (see Figure 15-1, *C*), is the **neurilemma (Schwann sheath).** The neurilemma and the myelin sheath are interrupted at regular intervals by the **nodes of Ranvier.** Myelin acts as an insulator that allows ions to flow between segments rather than along the entire length of the membrane, resulting in increased velocity of neuronal conduction. This mechanism is referred to as **saltatory conduction.** If the Schwann cells are loosely wrapped around the axon, it is referred to as *unmyelinated,* and conduction velocity is not increased. Axons are capable of extensive branching, which occurs at the nodes of Ranvier. Two major principles of information processing in the nervous system are *divergence* and *convergence.* **Divergence** refers to the ability of these branching axons to influence many different neurons. **Convergence** is the term applied to branches of numerous neurons converging on and influencing one or a few neurons. Disorders of the myelin sheath (demyelinating diseases), such as multiple sclerosis and Guillain-Barré syndrome, demonstrate the important role myelin plays in nerve function (see Chapter 18). Besides depending on the myelin coating, conduction velocities also are influenced by the diameter of the axon. Larger axons transmit impulses at a faster rate.

Neurons are structurally classified on the basis of the number of processes (projections) extending from the cell body. There are four basic types of cell configuration: (1) unipolar, (2) pseudounipolar, (3) bipolar, and (4) multipolar (Figure 15-2). **Unipolar neurons** have one process that branches shortly after leaving the cell body. One example is found in the retina.

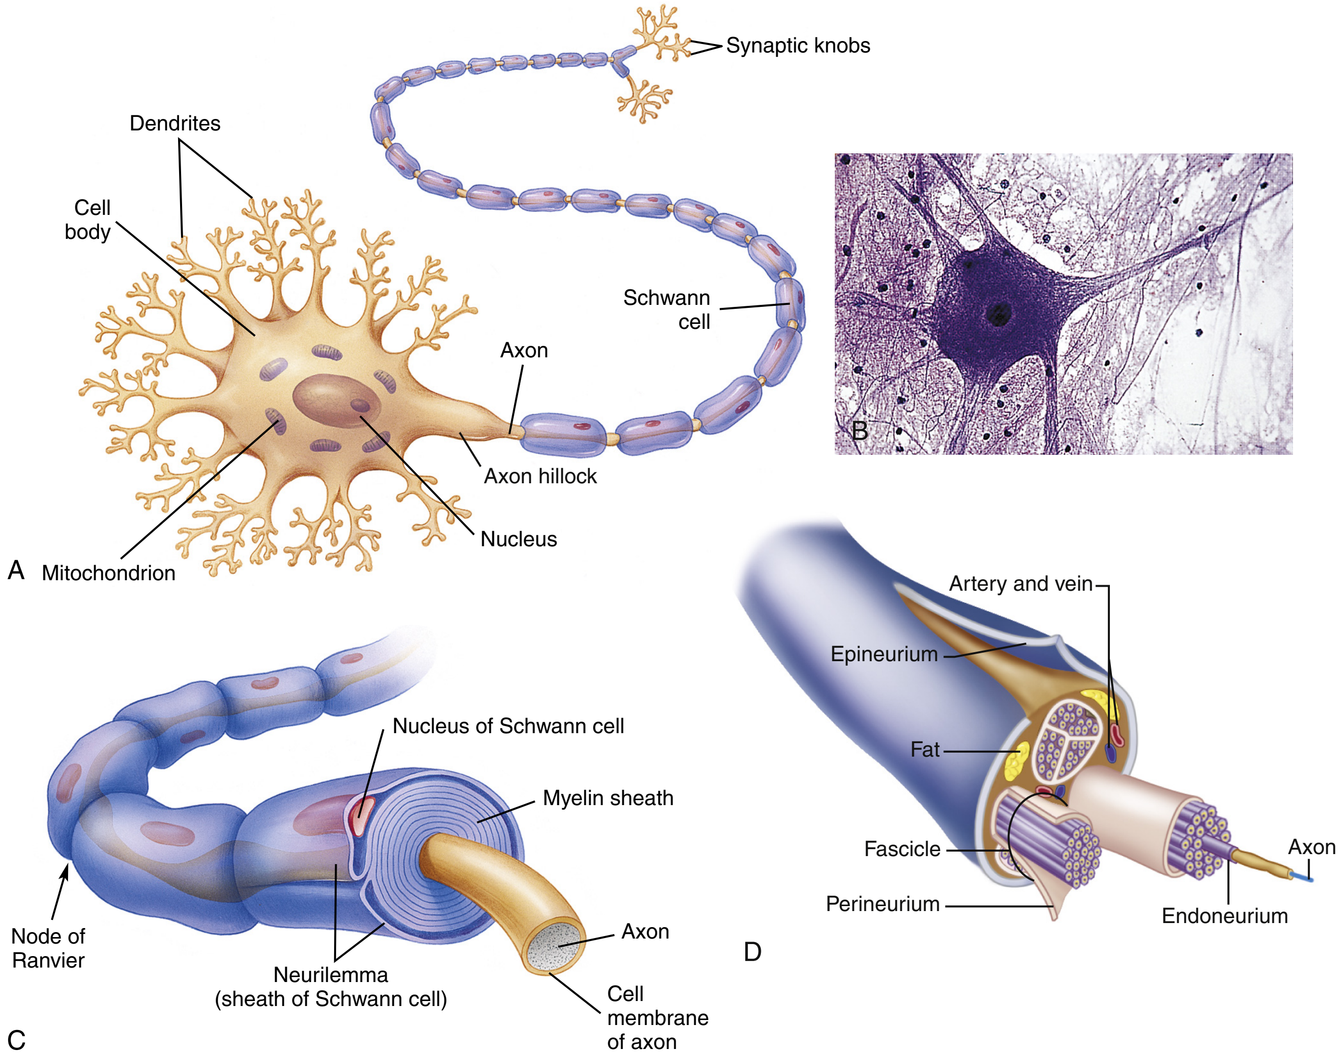

FIGURE 15-1 Structure of a Typical Neuron. **A,** Many dendrites carry nerve impulses to the cell body, and from the cell body the nerve impulses are conducted along a single, long axon. Long axons are encased at intervals by a myelin sheath. **B,** Photomicrograph of a neuron. **C,** A segment of myelinated fiber in cross section, showing myelin sheath composed of several layers of myelin, which insulate the axon. **D,** Axons bundled into fascicles. (**A** and **C** from Thibodeau GA, Patton KT: *Structure and function of the human body,* ed 12, St Louis, 2004, Mosby; **B,** copyright Edward Reschke; **D** from Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

Pseudounipolar neurons (some authors call them *unipolar*) have one process that has its dendritic portion extending away from the CNS and its axon portion projecting into the CNS (see Figure 15-2, *C*). The configuration is typical of sensory neurons in both cranial and spinal nerves. **Bipolar neurons** have two distinct processes arising from the cell body. This type of neuron connects to rod and cone cells of the retina. **Multipolar neurons** are the most common and have multiple dendrites and a single axon. A motor neuron is typically multipolar.

Functionally, there are three types of neurons (with their direction of transmission and typical configuration noted in parentheses): (1) sensory (afferent, mostly pseudounipolar), (2) associational (interneurons, multipolar), and (3) motor (efferent, multipolar). **Sensory neurons** carry impulses from peripheral sensory receptors to the CNS (Box 15-1). **Association neurons (interneurons)** transmit impulses from neuron to neuron, for example, from sensory to motor neurons, and are also involved in cognitive function. **Motor neurons** transmit impulses away from the CNS to an effector organ. In skeletal muscle the end processes form a complex neuromuscular (myoneural) junction.

Neuroglia and Schwann Cells

Neuroglia comprise the general classification of cells that support the neurons of the CNS. They make up approximately half of the total brain and spinal cord volume and are 5 to 10 times more numerous than neurons. Different types of neuroglia serve different functions. **Astrocytes,** for example, fill the spaces between neurons and surround blood vessels in the CNS (see What's New? Astrocytes). **Oligodendrocytes** function to deposit myelin within the CNS. Oligodendroglia are the CNS counterpart of the Schwann cells. **Ependymal cells** line the cerebrospinal fluid (CSF)–filled cavities of the CNS. **Microglia** remove debris (phagocytosis) in the CNS. Characteristics and

WHAT'S NEW?

Astrocytes

Neuroglial (glia) cells have been considered the *glue* that exists between or around neurons. Until recently, neurons have been considered the major players in the nervous system and glia just minor support cells. Astrocytes, the most abundant glial cells in the nervous system, were believed to be simple nutrient support "housekeeping" cells for neurons, and it was thought they helped form the blood-brain barrier. Recent reports on astrocytes portray a "partnership" with glial cells. Astrocytes (1) can be a source for new neurons; (2) build a structural framework around neurons, forming glia-vascular units to provide the specific blood flow (nutrients) that a neuron requires; (3) may regulate synaptic formation and maintenance, which helps consolidate memories; and (4) have a two-way interaction with neurons at synapses through the release of glial neurotransmitters that could facilitate either excitation or inhibition of neuron activity at the pre- and postsynaptic membranes. Alterations in astrocyte function play a significant role in brain malfunctions including hepatic encephalopathy, seizures, Alzheimer disease, and brain tumor invasiveness.

BOX 15-1 MAJOR TYPES OF SENSORY RECEPTORS

Nociceptors (pain)
Mechanoreceptors (touch, pressure, and mechanical deformation or encapsulated endings)
Photochemical (light on the retina)
Chemoreceptors (flavors, odors, oxygen levels, osmolarity of body fluids, and carbon dioxide levels in the blood)
Thermoreceptors (heat and cold)
Proprioception (sensing location of body parts)
Audition and balance (sound and positional movement)

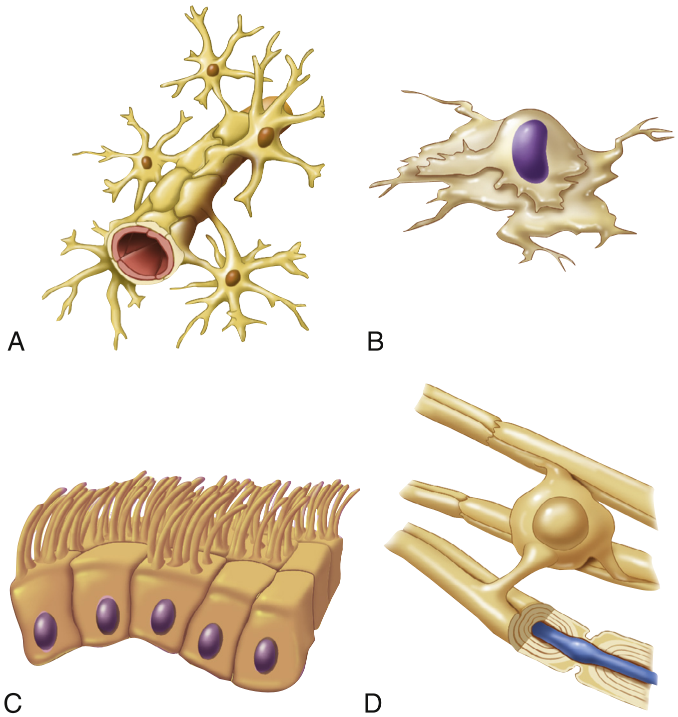

FIGURE 15-3 Types of Neuroglial Cells. **A,** Astrocyte attached to brain capillary; **B,** microglial cell; **C,** ependymal cells that form sheets to line fluid cavities in brain; **D,** oligodendrocyte wrapped around CNS nerve fiber forming myelin. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby.)

functions of neuroglia and Schwann cells are summarized in Figure 15-3 and Table 15-1.

The **Schwann cell,** or **neurolemmocyte,** is a glial cell that wraps around and covers axons in the peripheral nervous system. Schwann cells form and maintain the myelin sheath, and the nodes of Ranvier form the spaces on either side of the Schwann cell. If the myelin layer is tightly wrapped many times around the axon forming nodes of Ranvier, it increases conduction velocity and the neuron is referred to as *myelinated* (see Figure 15-1).

Nerve Injury and Regeneration

When an axon is severed, a typical sequence of events, known as **wallerian degeneration**, occurs. In the axon distal to the cut, the myelin sheath shrinks and disintegrates and this axon portion degenerates and disappears. The myelin sheaths re-form

TABLE 15-1 SUPPORT CELLS OF THE NERVOUS SYSTEM

CELL TYPE	PRIMARY FUNCTIONS
Astrocytes	Form specialized contacts between neuronal surfaces and blood vessels Provide rapid transport for nutrients and metabolites Believed to form an essential component of the blood-brain barrier Appear to be the scar-forming cells of the CNS, which may be the foci for seizures Appear to work with neurons in processing information and memory storage
Oligodendroglia (oligodendrocytes)	Formation of myelin sheath and neurilemma in the CNS
Schwann cells	Formation of myelin sheath and neurilemma in the PNS
Microglia	Responsible for clearing cellular debris (phagocytic properties)
Ependymal cells	Serve as a lining for ventricles and choroid plexuses involved in production of cerebrospinal fluid

CNS, Central nervous system; *PNS,* peripheral nervous system.

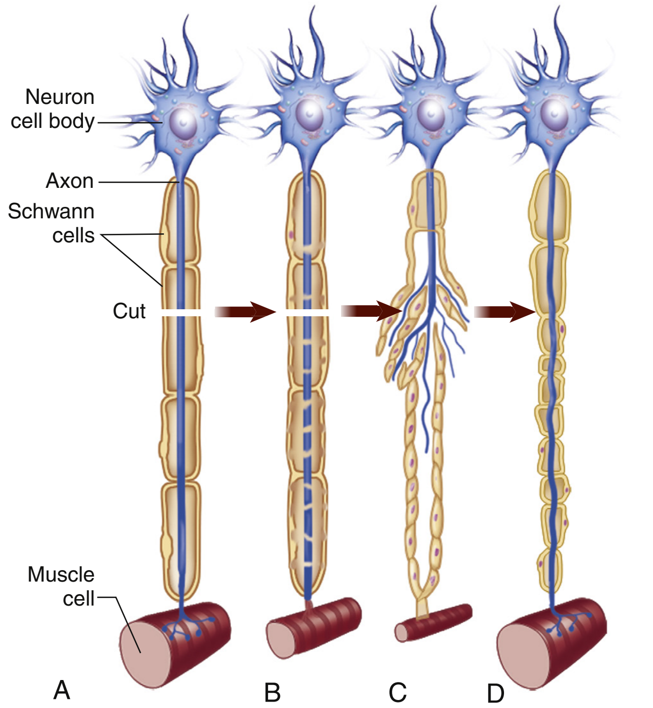

FIGURE 15-4 **Repair of a Peripheral Nerve Fiber.** When cut, a damaged motor axon can regrow to its distal connection only if the neurilemma remains intact (to form a guiding tunnel) and if scar tissue does not block its pathway. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

into Schwann cells that align in a column between the cut and the effector organ.

At the proximal end of the injured axon, similar changes occur, but only back as far as the next node of Ranvier. The cell body responds to trauma by swelling and then dispersing the Nissl substance (chromatolysis). During the repair process the cell increases metabolic activity, protein synthesis, and mitochondrial activity. Approximately 7 to 14 days after the injury, new terminal sprouts project from the proximal segment and may enter the remaining Schwann cell pathway. (Figure 15-4 contains a representation of these events.) This process, however, is limited to myelinated fibers and generally occurs only in the PNS. The regeneration of axonal constituents in the CNS is limited by increased scar formation and the different nature of myelin formation by the oligodendrocyte.

Nerve regeneration depends on many factors, such as location of the injury, the type of injury, the inflammatory responses, and the process of scarring. The closer the injury is to the cell body of the nerve, the greater the chances that the nerve cell will die and not regenerate. A crushing injury allows recovery more fully than does a cut injury. Crushed nerves sometimes recover fully, whereas cut nerves often form connective tissue scars that block or slow regenerating axonal branches.

NERVE IMPULSE

Neurons generate and conduct electrical and chemical impulses by selectively changing the electrical portion of their plasma membranes and influencing other nearby neurons by the release of chemicals (neurotransmitters). A neuron in its unexcited state maintains a resting membrane potential (see Chapter 1). When the membrane potential is raised sufficiently, an action potential is generated (see Figure 1-35), and the nerve impulse then flows to all parts of the neuron. The action potential response occurs only when the stimulus has sufficient strength; if it is too weak, the membrane remains unexcited. This property is sometimes termed the *all-or-none response.*

Synapses

Neurons are not physically continuous with one another. The region between adjacent neurons is called a **synapse.** Impulses are transmitted across the synapse by chemical (see Figures 15-5 and 15-14) and electrical conduction (Chapter 1); only chemical conduction is discussed here. The neurons that conduct a nerve impulse are named according to whether they relay impulses *toward* the synapse (**presynaptic neurons**) or *away* from the synapse (**postsynaptic neurons**). Four basic types of connections occur in regions of contact between the presynaptic and postsynaptic neurons. These are between axons (axo-axonic), from axon to cell body (axo-somatic), from axon to dendrite (axo-dendritic), and from dendrite to dendrite (dendro-dendritic).

Impulses are transmitted across the synapse by chemical conduction. The conducting substance is called a **neurotransmitter** and it is often formed in the neuron, transported to the **synaptic knobs (boutons)** of the presynaptic neuron's axon, and stored in synaptic vesicles within the knobs. Action potentials in the presynaptic neuron cause the synaptic vesicles to release their neurotransmitter(s) through the plasma membrane into the **synaptic cleft** (the space between the neurons), where they bind to specific neurotransmitter (protein) receptor sites on the plasma membrane of the postsynaptic neuron

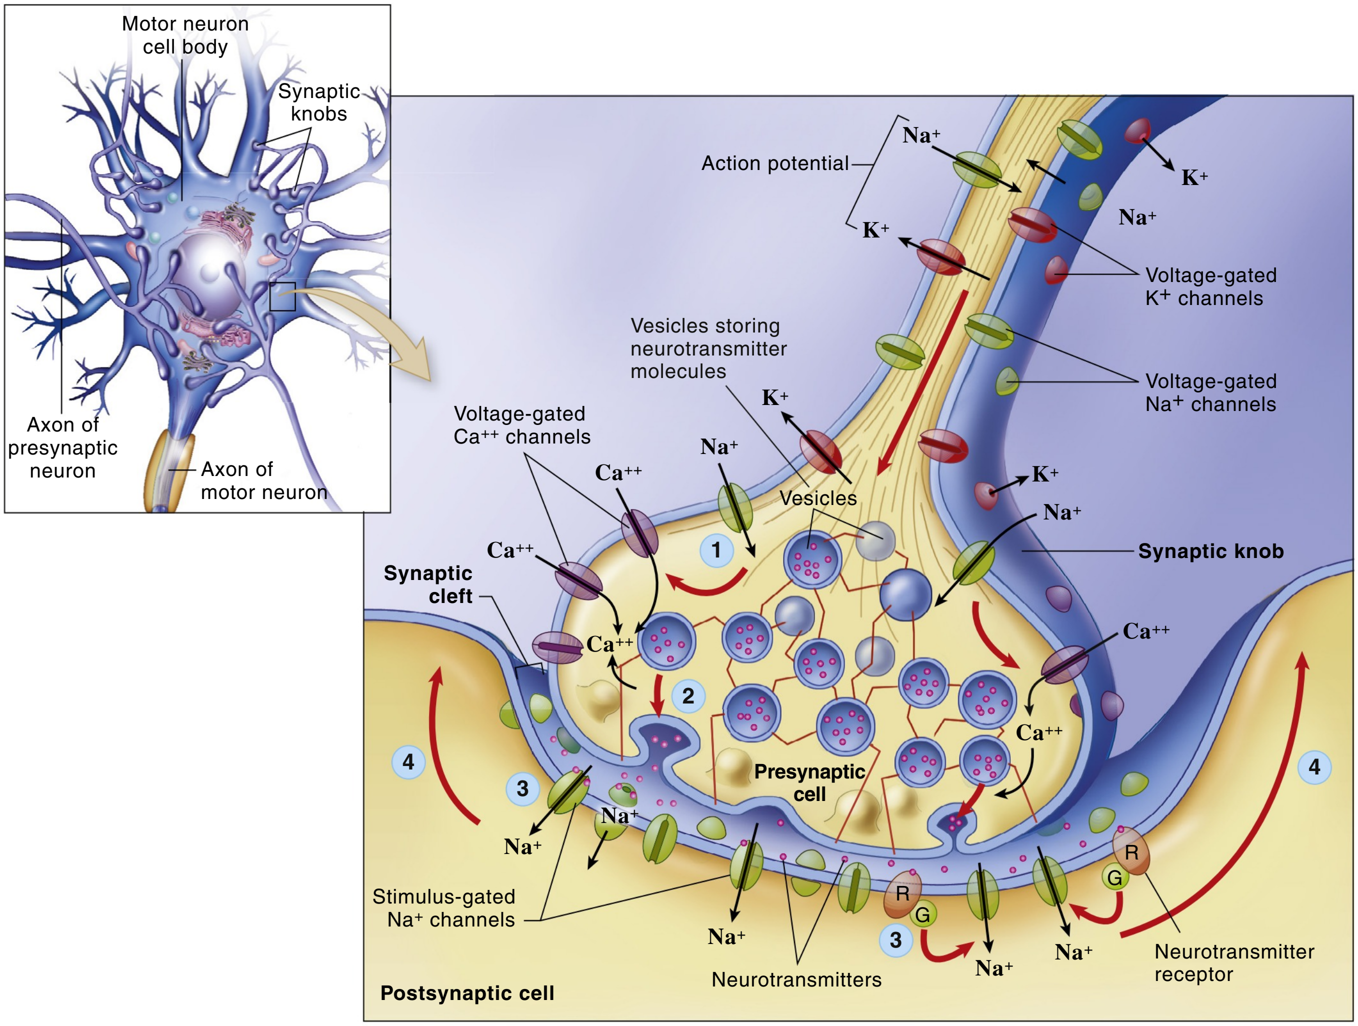

FIGURE 15-5 Neuronal Transmission and Synaptic Cleft. The electrical impulse travels along the axon of the first neuron to synapse at synaptic knobs. The chemical transmitter is secreted into the synaptic space to depolarize the membrane (dendrite or cell body) of the next neuron in the pathway. Details illustrate the synaptic knob (axon terminal) of a presynaptic neuron, the plasma membrane of a postsynaptic neuron, and a synaptic cleft. At step **(1)**—the arrival of an action potential at the synaptic knob—voltage-gated Ca^{++} channels open and allow extracellular Ca^{++} to diffuse into the presynaptic cell. At step **(2)** the Ca^{++} triggers the rapid exocytosis of neurotransmitter molecules from vesicles in the knob. At step **(3)** neurotransmitter diffuses into the synaptic cleft and binds to receptor molecules in the plasma membrane of the postsynaptic neuron. The postsynaptic receptors directly or indirectly trigger the opening of stimulus-gated ion channels, initiating a local potential in the postsynaptic neuron. At step **(4)** the local potential may move toward the axon, where an action potential may begin. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

(see Figure 15-5). Neurons can synthesize more than one neurotransmitter, and postsynaptic membranes can contain more than one type of transmitter-specific receptor.

Neurotransmitters

A neurotransmitter is defined as a chemical that "must be synthesized in the neuron, become localized in the presynaptic terminal (synaptic bouton), be released into the synaptic cleft, bind to a receptor site (binding site) on the postsynaptic membrane of another neuron or effector where it affects ion channels, and last, be removed by a specific mechanism from its site of action." More than 46 neurotransmitters, including norepinephrine, acetylcholine, dopamine, histamine, gamma-aminobutyric acid (GABA), and serotonin, have been identified.[2,3] Many of these transmitters have more than one function. For example, norepinephrine in the brain probably helps regulate mood, functions in dream sleep, and maintains arousal. Several neurotransmitters are amino acids, including GABA, glutamic acid, and aspartic acid. Small chains of amino acids, such as enkephalins and endorphins, also function as neurotransmitters. They (neuropeptides) are involved in the perception and integration of pain, as well as in emotional experiences. Neurotransmitter and neuromodulator substances are listed in Table 15-2.

Because the neurotransmitter is normally stored on one side of the synaptic cleft and the receptor sites are on the other side,

TABLE 15-2 SUBSTANCES THAT ARE NEUROTRANSMITTERS OR NEUROMODULATORS

SUBSTANCE	LOCATION	EFFECT	CLINICAL EXAMPLE
Acetylcholine	Many parts of the brain, spinal cord, neuromuscular junction of skeletal muscle, and many ANS synapses	Excitatory or inhibitory	Alzheimer disease (a type of dementia) is associated with a decrease in the number of acetylcholine-secreting neurons. Myasthenia gravis (weakness of skeletal muscles) results from a reduction in the number of acetylcholine receptors.
Monoamines			
Norepinephrine	Many areas of the brain and spinal cord; also in some ANS synapses	Excitatory or inhibitory	Cocaine and amphetamines* result in overstimulation of postsynaptic neurons.
Serotonin	Many areas of the brain and spinal cord	Generally inhibitory	Is involved with mood, anxiety, and sleep induction. Levels of serotonin are elevated in schizophrenia (delusions, hallucinations, withdrawal).
Dopamine	Some areas of the brain and ANS synapses	Generally excitatory	Parkinson disease (depression of voluntary motor control) results from destruction of dopamine-secreting neurons. Drugs used to increase dopamine production induce vomiting and schizophrenia.
Histamine	Posterior hypothalamus	Excitatory (H1 and H2 receptors) and inhibitory (H3 receptors)	There is no clear indication of histamine-associated pathologic conditions. Histamine is involved with arousal and attention and links to other brain transmitter systems.
Amino Acids			
Gamma-aminobutyric acid (GABA)	Most neurons of the CNS have GABA receptors	Majority of postsynaptic inhibition in the brain	Drugs that increase GABA function have been used to treat epilepsy by inhibiting excessive discharge of neurons.
Glycine	Spinal cord	Most postsynaptic inhibition in the spinal cord	Glycine receptors are inhibited by strychnine.
Glutamate and aspartate	Widespread in brain and spinal cord	Excitatory	Drugs that block glutamate or aspartate, such as riluzole, are used to treat amyotrophic lateral sclerosis. These drugs might prevent overexcitation from seizures and neural degeneration.
Neuropeptides			
Endorphins and enkephalins	Widely distributed in the CNS and PNS	Generally inhibitory	Morphine and heroin bind to endorphin and enkephalin receptors on presynaptic neurons and reduce pain by blocking the release of neurotransmitter.
Substance P	Spinal cord, brain, and sensory neurons associated with pain, GI tract	Generally excitatory	Substance P is a neurotransmitter involved in pain transmission pathways. Blocking release of substance P by morphine reduces pain.

*Increase the release and block the reuptake of norepinephrine.

chemical synapses operate in one direction. Therefore, action potentials are transmitted along a multineuronal pathway in one direction. The binding of the neurotransmitter at the receptor site changes the permeability of the postsynaptic neuron and, consequently, its membrane potential. Two possible scenarios can then follow: (1) the postsynaptic neuron may be excited (depolarized; **excitatory postsynaptic potentials** [**EPSPs**]), or (2) the postsynaptic neuron's plasma membrane may be inhibited (hyperpolarized; **inhibitory postsynaptic potentials** [**IPSPs**]). Cannabinoid transmitters are released from postsynaptic neurons that modulate neurotransmitter release from presynaptic neurons.[4,5] (Chapter 1 contains a review of electrical impulses and membrane potentials.)

Usually, a single EPSP cannot induce a neuron's action potential and the propagation of the nerve impulse. Whether an action potential occurs depends on the number and frequency of potentials the postsynaptic neuron receives—a concept known as **summation. Temporal summation** (time relationship) refers to the effects of successive, rapid impulses received from a single neuron on the same synapse. **Spatial summation** (spacing effect) is the combined effects of impulses from a number of neurons on a single synapse at the same time. **Facilitation** refers to the effect of EPSPs on the plasma membrane potential. The plasma membrane is facilitated when summation brings the membrane closer to the threshold potential and decreases the stimulus required to induce an action potential. The effect that a neurotransmitter has on the plasma membrane potential depends on the balance of these effects. The mechanisms of convergence, divergence, summation, and facilitation allow for the integrative processes of the nervous system.

Two points could be helpful in understanding the complexity of brain physiology. First, the aforementioned

neuromodulators appear to function to raise or lower the membrane potentials of neurons. These chemicals facilitate or inhibit the effect of neurotransmitters. Second, reciprocal synapses between dendrites—that is, one dendrite being able to depolarize or hyperpolarize the membrane potential of another dendrite through the use of neurotransmitters—demonstrate that the interactions between neurons are far more complicated than postulated by simple on-off models of brain function.

TABLE 15-3 DIVISIONS OF THE CENTRAL NERVOUS SYSTEM

PRIMARY VESICLES	SECONDARY VESICLES	ASSOCIATED STRUCTURES
Forebrain (prosencephalon)	Telencephalon	Cerebral hemispheres
		Cerebral cortex
		Rhinencephalon
		Basal ganglia

Midbrain (mesencephalon)	Mesencephalon	Corpora quadrigemina (tectum)
		Cerebral peduncles
		Tegmentum
		Red nucleus
		Substantia nigra
		Basis pedunculi
Hindbrain (rhombencephalon)	Metencephalon	Cerebellum
		Pons
	Myelencephalon	Medulla oblongata
Spinal cord	Spinal cord	Spinal cord

CENTRAL NERVOUS SYSTEM

Brain

The human brain enables individuals to reason, function intellectually, express personality and mood, and interact with the environment. The brain is a pinkish gray organ that weighs approximately 3 pounds and has the consistency of tofu or custard. It receives approximately 15% to 20% of the total cardiac output. The three major divisions of the brain, based on embryologic origin, are: (1) the forebrain, formed by the two cerebral hemispheres; (2) the midbrain, which includes the corpora quadrigemina, tegmentum, and cerebral peduncles; and (3) the hindbrain, which includes the cerebellum, pons, and medulla (Table 15-3). The midbrain, medulla oblongata, and pons make up the **brainstem,** which connects the hemispheres of the brain, cerebellum, and spinal cord. A collection of nuclei (nerve cell bodies) within the brainstem collectively constitute the **reticular formation** (Figure 15-6). The reticular formation is a large network of connected tissue nuclei that regulate vital reflexes, such as cardiovascular function and respiration. The reticular formation is essential for maintaining wakefulness and in conjunction with the cerebral cortex is referred to as the **reticular activating system.** Some nuclei within the reticular formation are involved in motor movements.[1]

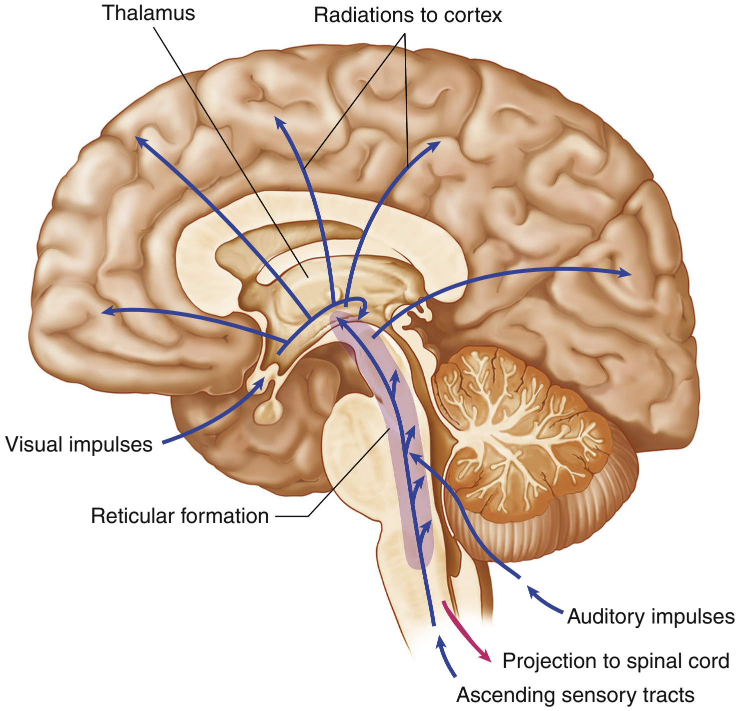

FIGURE 15-6 Reticular Activating System. System consists of nuclei in the brainstem reticular formation plus fibers (axons) that conduct to the nuclei from below and fibers that conduct from the nuclei to widespread areas of the cerebral cortex. Functioning of the reticular activating system is essential for consciousness. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

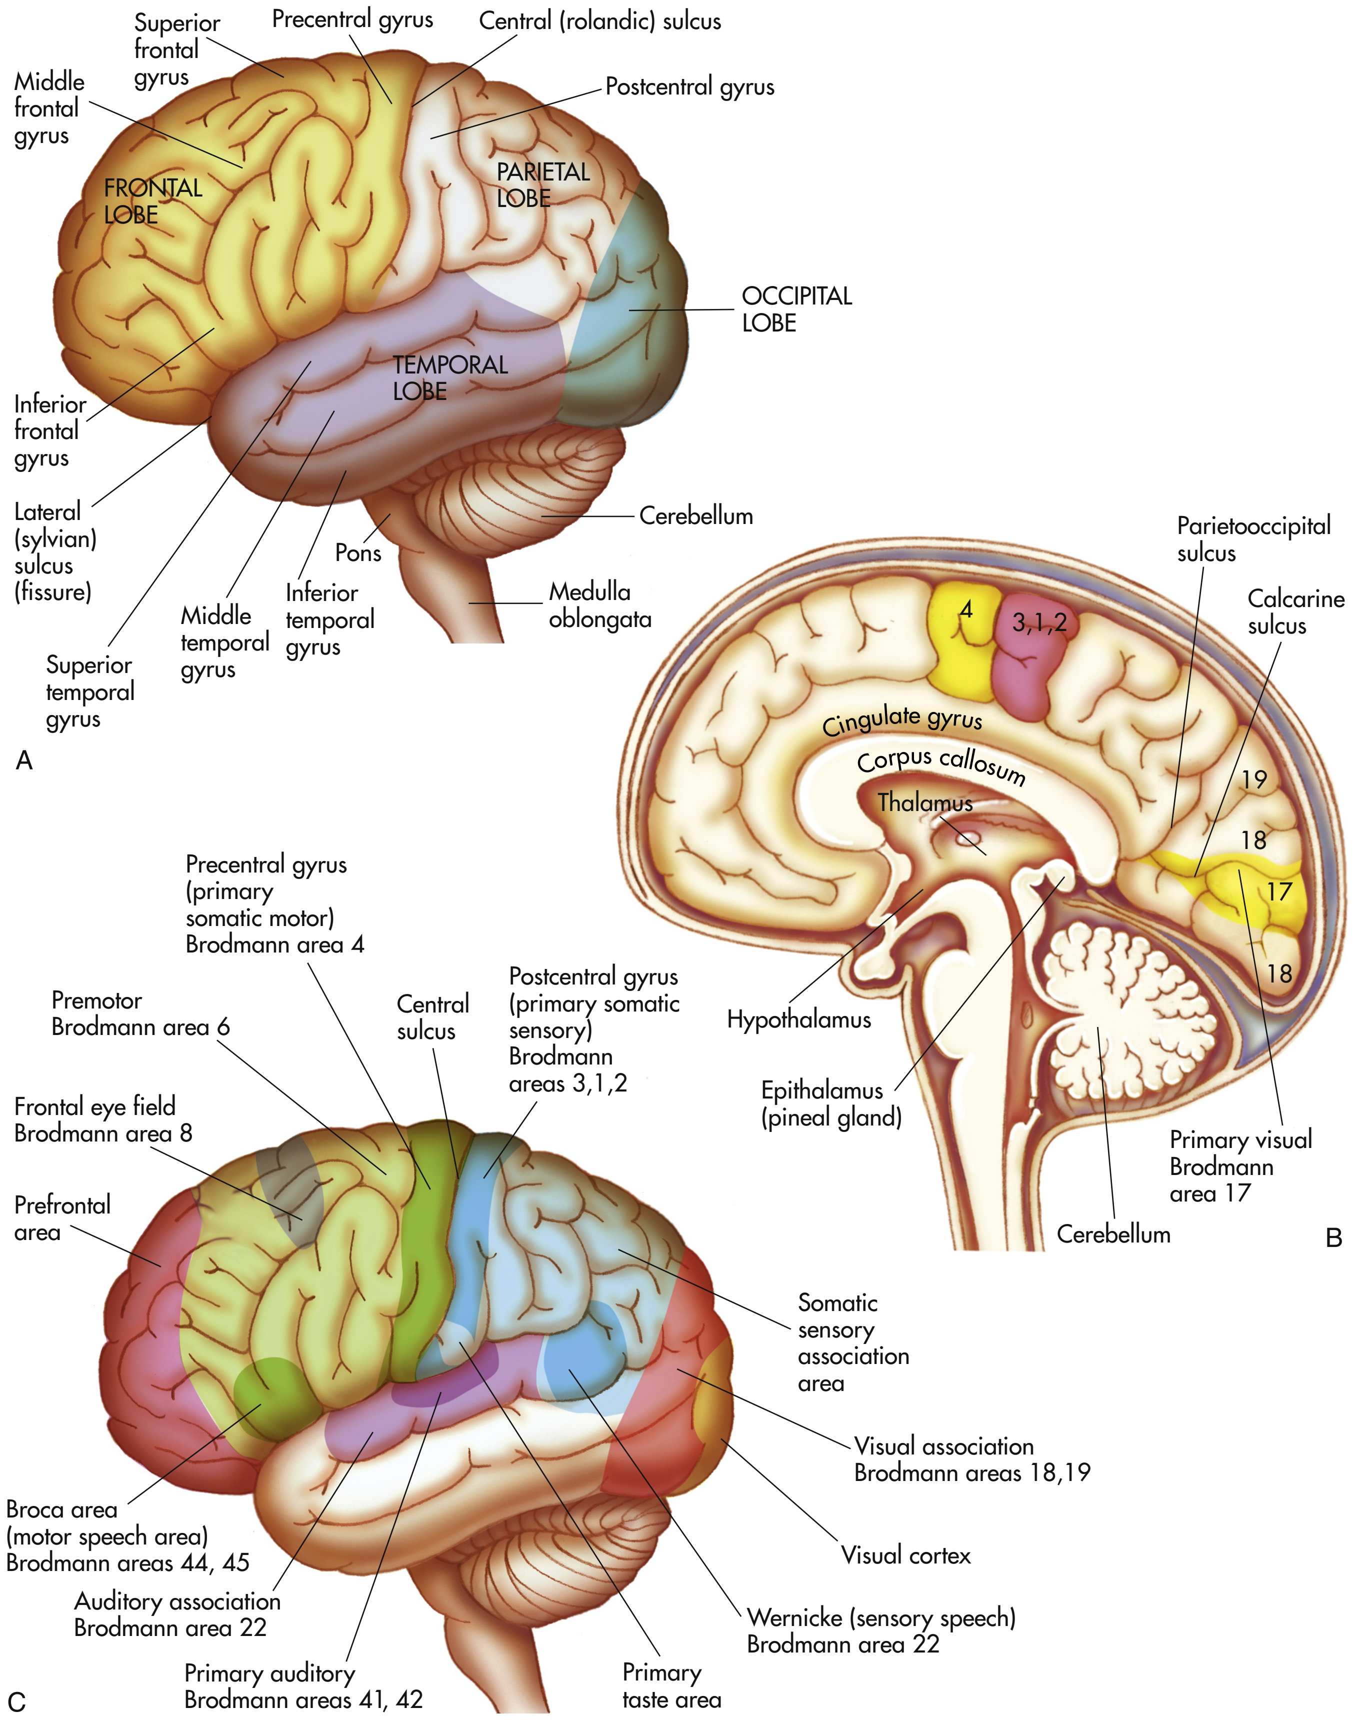

FIGURE 15-7 **Cerebral Hemispheres. A,** Left hemisphere of cerebrum *(lateral view).* **B,** Functional areas of the cerebral cortex *(midsagittal view).* **C,** Functional areas of the cerebral cortex *(lateral view).*

In general, many major divisions of the brain are associated with specific functions, such as the occipital lobe and vision, but attributing specific functions to definite regions of the brain is not entirely accurate. Many activities, such as motor movements and memory, may actually be performed in several regions. Understanding functional specificity is very useful to clinical personnel, especially when attempting to localize pathologic conditions in the nervous system. A neurologist often can localize the site of a tumor, stroke, or bullet wound in an individual just by performing a neurologic examination.

Many attempts have been made to ascribe function to various regions of the cerebral cortex. (Figure 15-7, *B* and *C*, illustrates these regions and identifies some functional areas.) Another basic CNS principle, **plasticity,** holds that the CNS is capable of change. For example, children with brain damage may experience "relocation" of some functional areas to other parts of the brain. This propensity for plasticity decreases with age, which explains why older individuals tend not to recover from brain injuries as well as younger individuals. This varying balance between specificity and plasticity makes understanding brain functions difficult.

Forebrain

Telencephalon. The **telencephalon** consists of the **cerebrum** (the largest portion of the brain), which includes the cerebral cortex and **basal ganglia.** The surface of the cerebrum is characterized by numerous convolutions called *gyri* (see Figure 15-7, *A*). The gyri greatly increase the cortical surface area. Grooves between adjacent gyri are called **sulci.** Deeper grooves are referred to as **fissures.** The **cerebral cortex** contains the cell bodies and dendrites of neurons, which often are referred to as **gray matter.** Gray matter is organized into columns perpendicular to the surface that receive, integrate, store, and transmit information. **White matter** lies beneath the cerebral cortex and is composed of myelinated nerve fibers, which send neuron "messages" throughout the nervous system and body.

The two cerebral hemispheres are separated by the longitudinal fissure. The surface of each hemisphere is divided into lobes that take their names from the region of the skull under which each of them lies. The posterior margin of the **frontal lobe** is the **central sulcus** (**fissure of Rolando,** central fissure); it borders inferiorly on the **lateral sulcus** (**sylvian fissure, lateral fissure**) (see Figure 15-7, *A*). The **prefrontal area** is responsible for goal-oriented behavior (i.e., ability to concentrate), short-term or recall memory, and elaboration of thought and inhibition on the limbic (emotional) areas of the CNS. The **premotor area** (Brodmann area 6) (see Figure 15-7, *C*) is involved in programming motor movements. This area also contains the neurons that contribute to the **basal ganglia system** (extrapyramidal system—efferent pathways outside the pyramids of the medulla oblongata). The frontal eye fields (the lower portion of Brodmann area 8), which are involved in controlling eye movements, are located in the middle frontal gyrus.

The **primary motor area** (Brodmann area 4) is located along the **precentral gyrus** forming the **primary voluntary motor area,** which has a somatotopic organization that often is referred to as a *homunculus* (little man) (Figure 15-8). Electrical

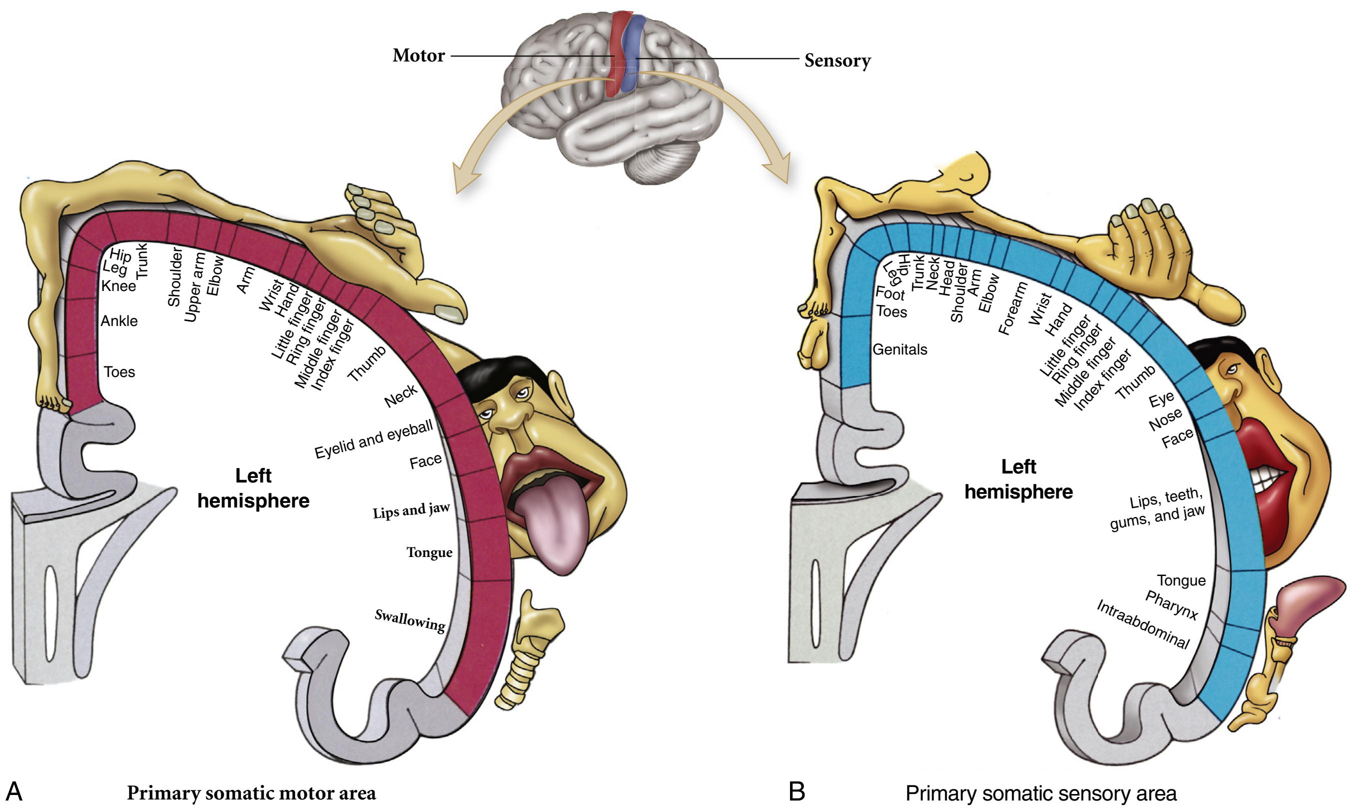

FIGURE 15-8 Primary Somatic Sensory **(A)** and Motor **(B)** Areas of the Cortex. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

stimulation of specific areas of this cortex causes specific muscles of the body to move. The medial part of the cortex in the **longitudinal fissure** (midline space between the two cerebral hemispheres) affects the lower limb and foot, whereas on the lateral surface, the superior third controls the torso and arm, the middle third the hand, and the lowest third the face and mouth/throat. The axons traveling from the cell bodies in and on either side of this gyrus project fibers (axons) that form the **corticospinal tracts** (pyramidal system) that descend down the spinal cord. Cerebral impulses control function on the opposite side of the body, a phenomenon called **contralateral control** (Figure 15-9, *A*). The **Broca speech area** (Brodmann areas 44, 45) is rostral to the inferior edge of the premotor area (Brodmann area 6) on the inferior frontal gyrus. It is usually on the left hemisphere and is responsible for the motor aspects of speech. Damage to this area, commonly as a result of a cerebrovascular accident (stroke), results in the inability to form, or difficulty in forming, words (expressive aphasia or dysphasia) (see Chapter 18).

The **parietal lobe** lies within the borders of the central, parietooccipital, and lateral sulci. This lobe contains the major area for somatic sensory input, located primarily along the **postcentral gyrus** (Brodmann areas 3, 1, 2), which is adjacent to the primary motor area. Communication between the motor and sensory areas (and among other regions in the cortex) is provided by **association fibers** (i.e., axons from association fibers). Much of this region is involved in sensory association (storage, analysis, and interpretation of stimuli). (Figure 15-8 shows the distribution of functions associated with both the primary motor area and the primary sensory area of the cerebral cortex.)

The **occipital lobe** lies caudal to the parietooccipital sulci and superior to the cerebellum. The primary visual cortex (Brodmann area 17) is located in this region and receives input from the retinas. Much of the remainder of this lobe is involved in visual association (Brodmann areas 18, 19). The **temporal lobe** lies inferior to the lateral sulcus and is composed of the superior, middle, and inferior temporal gyri. The primary auditory cortex (Brodmann area 41) and its related association area (Brodmann area 42) lie deep within the lateral sulcus on the superior temporal gyrus. The **Wernicke area** (posterior portion of Brodmann area 22) is located on the superior temporal gyrus. This area is responsible for reception and interpretation of speech, and dysfunction may result in receptive aphasia or dysphasia. The Wernicke area, along with adjacent portions of the parietal lobe, constitutes a *sensory speech area*. The temporal lobe also is involved as a major area for long-term memory and secondary functions, such as balance, taste, and smell.

Another cerebral area, the **insula,** lies hidden from view deep in the lateral sulcus. Lying directly beneath the longitudinal fissure is a massive white matter pathway called the **corpus callosum (commissural fibers).** The corpus callosum connects the two cerebral hemispheres and is essential in the coordination of activities between hemispheres, especially specific tasks that may be present in only one hemisphere (see Figures 15-7, *C*, and 15-15). As a last resort, part or all of the corpus callosum is cut to prevent the spread of epileptic loci (site of seizure activity) through the corpus callosum to the opposite cerebral hemisphere. Epileptic loci often are found in the temporal lobe (see Chapters 17 and 20). This procedure, evolved in the well-known split-brain studies, results initially in temporary aphasia and paralysis.

Inside the cerebrum are numerous tracts (white matter) and nuclei (gray matter). The major **cerebral nuclei** are called *basal ganglia* and include the corpus striatum and **amygdala.** The **corpus striatum** consists of the **lentiform nucleus** (lens shaped), the putamen and globus pallidus, and the ram's horn–shaped caudate nucleus. The **internal capsule** is a thick white-matter region in which afferent and efferent pathways, to and from the cerebral cortex, pass through the center of the cerebral hemispheres. The corpus striatum appears striped because of the rostral connections between its gray matter and the white matter of the internal capsule.

Functionally, the basal ganglia include, in addition to the corpus striatum, the subthalamic nucleus of the diencephalon and the substantia nigra of the mesencephalon. The basal ganglia plus their interconnections with the thalamus, premotor cortex, red nucleus, reticular formation, and spinal cord are part of the basal ganglia system (extrapyramidal system). The basal ganglia system is believed to exert a fine-tuning effect on motor movements. Parkinson disease and Huntington disease are conditions associated with defects of the basal ganglia (Box 15-2). They are characterized by various involuntary or exaggerated motor movements (see Chapter 17).

The **limbic system,** first described in 1878 by Broca, is composed of the **Papez circuit** (amygdala, parahippocampal gyrus, **hippocampus,** fornix, mamillary body of the hypothalamus, thalamus, and cingulate gyrus), septal area, habenula, nucleus accumbens, and other portions of the hypothalamus, and related autonomic nuclei. It is an extension or modification of the olfactory system (rhinencephalon). Its principal effects are believed to be involved with primitive behavioral responses, visceral reaction to emotion, feeding behaviors, biologic rhythms, and the sense of smell. Expression of affect (emotional and behavioral states) is mediated by extensive connections with the limbic system and prefrontal cortex. The limbic system has as one of its major functions the consolidation of memory through a reverberating circuit (see Chapter 17 and Figure 17-9).

Diencephalon. The **diencephalon,** surrounded by the cerebrum, is made up of four divisions: **epithalamus, thalamus, hypothalamus,** and **subthalamus** (see Table 15-3 and Figure 15-7, *B*). The epithalamus forms the roof of the third ventricle (a brain cavity) and composes the most superior portion of the diencephalon. It has connections between the limbic system and other parts of the brain. The pineal body (a component of the epithalamus) secretes melatonin, which maintains circadian rhythms and the sleep-wake cycle (see Chapters 16 and 21). The largest component of the diencephalon is the thalamus. It is approximately the size and volume of the thumb from the tip to the first joint. It borders and surrounds the third ventricle, and it is a major integrating center for afferent impulses to the cerebral cortex, except for olfaction. The perception of various sensations occurs at this level but requires cortical processing for interpretation. The thalamus also serves as a relay center for sensory aspects of motor information from the basal ganglia

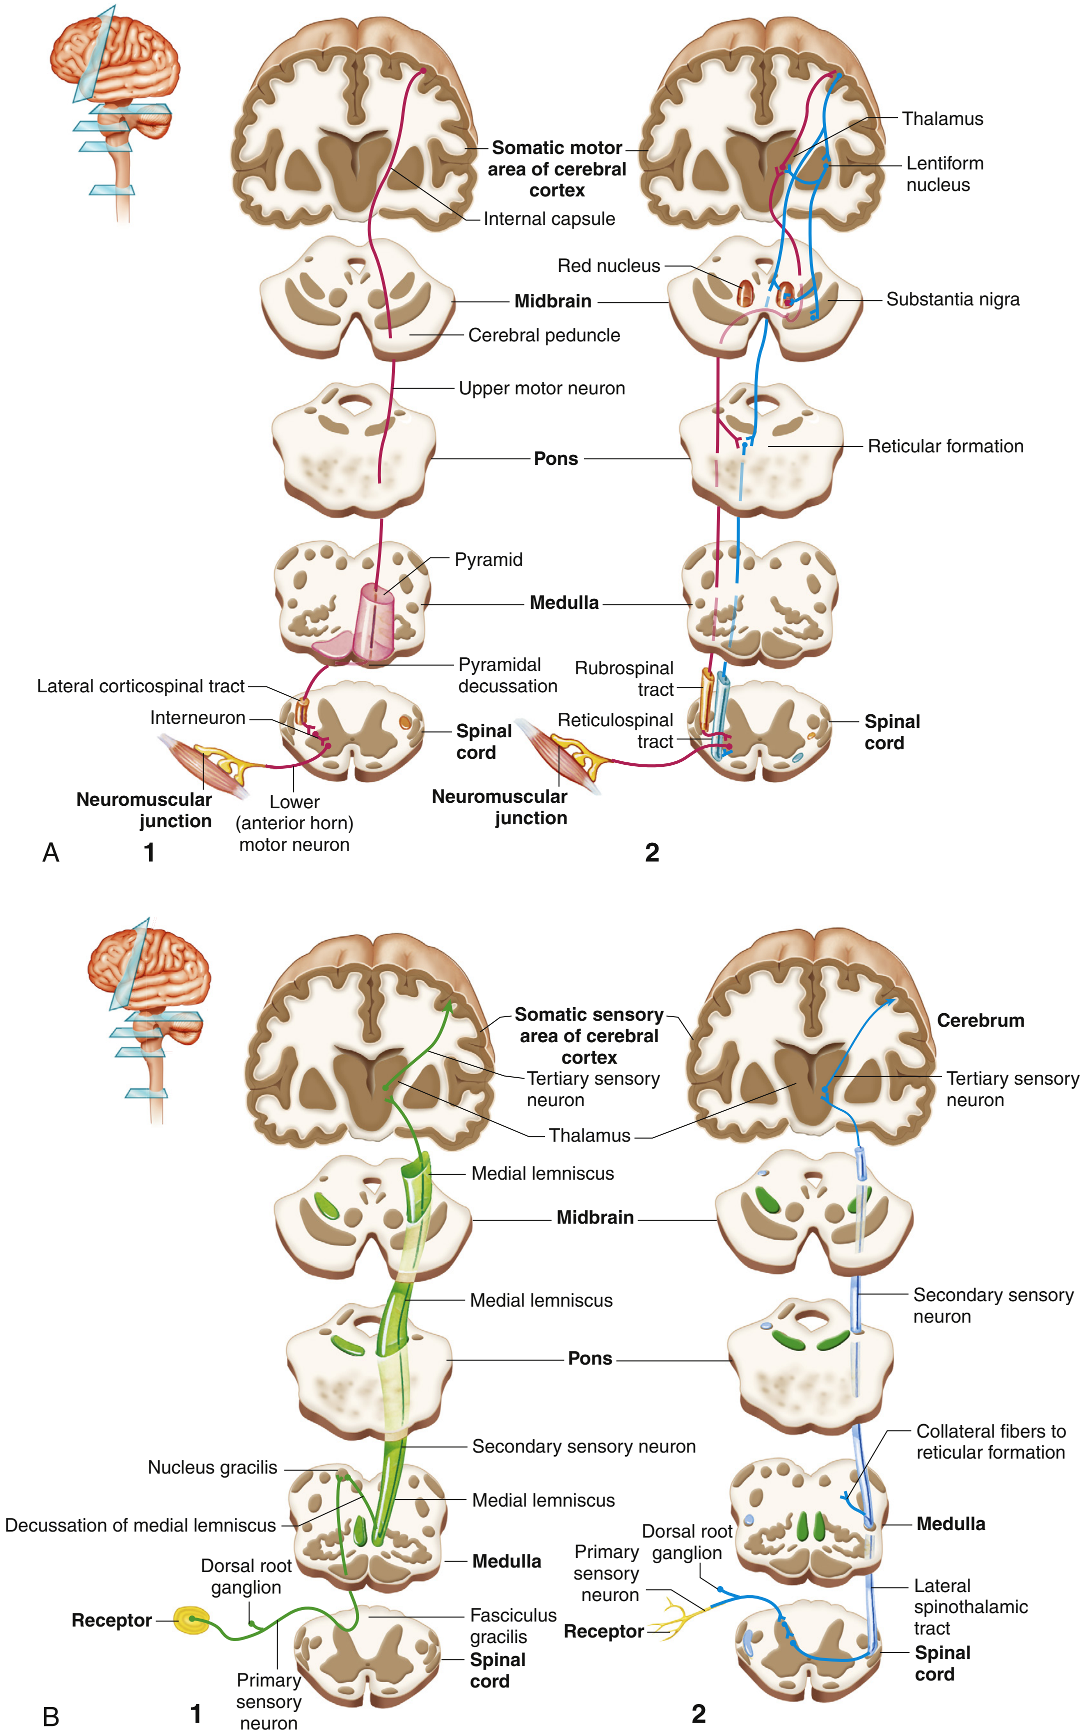

FIGURE 15-9 Examples of Somatic Motor and Sensory Pathways. **A,** Motor: **1,** the pyramidal pathway through the lateral corticospinal tract and **2,** the extrapyramidal pathways through the rubrospinal and reticulospinal tracts. Note that the pyramidal tracts decussate (cross over) to control the opposite side of the body. **B,** Sensory: **1,** pathways of the medial lemniscal system that conducts information about discriminating touch and kinesthesia and **2,** the spinothalamic pathway that conducts information about pain and temperature. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

BOX 15-2 INVASIVE TREATMENTS FOR PARKINSON DISEASE

Surgical treatment can provide gratifying relief from the disabling symptoms of Parkinson disease (PD) when pharmaceutical therapies are no longer effective or as an adjunct to pharmacotherapy. The forms of surgical intervention include deep brain stimulation (globus pallidus internus to improve motor symptoms and nucleus ventralis intermedius to improve tremor), ablation (thalamotomy, unilateral pallidotomy, and subthalamotomy), stem cell and fetal dopamine neuron replacement therapy, and gene therapy (mainly of the striatum to restore dopaminergic function). Deep brain stimulation with placement of brain electrodes is currently the surgical gold standard for treatment of PD because it results in symptom control with minimal tissue destruction. However, an ablation technique can be the preferable option for other individuals. Functional imaging during the procedures is contributing to the understanding of how these treatments affect neuronal activity. Stem cell grafts of dopamine neurons are being studied, but a number of problems still remain to be resolved, including poor cell survival of the grafted neurons and reinnervation into the host striatum. Gene therapy strategies include activation of dopamine-synthesizing enzyme genes in the subthalamic nucleus. Controlled trials are in progress and are showing some promise.

Data from Fasano A, Daniele A, Albanese A: *Lancet Neurol* 11(5):429–442, 2012; Freed CR, Zhou W, Breeze RE: *Neurotherapeutics* 8(4):549–561, 2011; Kahn E et al: *J Neurol Neurosurg Psychiatry* 83(2):164–170, 2012; Lindvall O, Björklund A: *Neurotherapeutics* 8(4):539–548, 2011; Obeso I et al: *Int Rev Psychiatry* 23(5):467–475, 2011; Politis M, Lindvall O: *BMC Med* 10:1, 2012; Schuepbach WM et al: *N Engl J Med* 368(7):610–616. 2013.

and cerebellum to appropriate cortical motor areas. Cerebral cortical information also projects to the thalamus, creating reverberating circuits.

The hypothalamus forms the base of the diencephalon. Hypothalamic function falls into two major areas: (1) maintenance of a constant internal environment and (2) implementation of behavioral patterns. Integrative centers control function of the ANS, regulation of body temperature, function of the endocrine system, and regulation of emotional expression. (Temperature regulation is discussed in Chapter 16.) The hypothalamus exerts its influence through the endocrine system, as well as through neural pathways (Box 15-3). (For endocrine functions of the hypothalamus and pituitary, see Chapter 21.)

BOX 15-3 FUNCTIONS OF THE HYPOTHALAMUS

Visceral and somatic responses
Affectual responses
Hormone synthesis
Sympathetic and parasympathetic activity
Temperature regulation
Feeding responses
Physical expression of emotions
Sexual behavior
Pleasure-punishment centers
Level of arousal or wakefulness

The subthalamus flanks the hypothalamus laterally. The subthalamus contains the **subthalamic nucleus,** which is part of the basal ganglia system (p. 456).

Midbrain

The **midbrain (mesencephalon)** (see Table 15-3) is composed of three structures: the **corpora quadrigemina,** or **tectum** (composed of the superior and inferior colliculi); the **tegmentum** (containing the red nucleus and substantia nigra); and the basis pedunculi. (The tegmentum and basis pedunculi are collectively termed the cerebral peduncles—see Figure 15-9, *A*.)

The **superior colliculi** are involved with voluntary and involuntary visual motor movements (e.g., the ability of the eyes to *track* moving objects in the visual field). The **inferior colliculi** accomplish similar motor activities but involve movements affecting the auditory system (e.g., positioning the head to improve hearing). The inferior colliculus is also a major relay center along the auditory pathway. The **red nucleus** is a major motor output center that is influenced by the cerebellum. The inferior-most portion of the basal ganglia is the **substantia nigra,** which synthesizes **dopamine,** a neurotransmitter and precursor of norepinephrine. Its dysfunction is associated with Parkinson disease (see Chapter 17) and drug addiction (see What's New? Nucleus Accumbens, Dopamine, and Drug Addiction). The **basis pedunculi** are made up of efferent fibers of the corticospinal, corticobulbar, and corticopontocerebellar tracts.

Other notable structures of this region are the nuclei and tracts of the third and fourth cranial nerves. The **cerebral aqueduct (aqueduct of Sylvius),** which carries cerebrospinal fluid (CSF), also traverses this structure. The obstruction of this aqueduct is often the cause of hydrocephalus.

Hindbrain

Metencephalon. The major structures of the **metencephalon** are the cerebellum and the pons. The **cerebellum** (see Figure 15-7, *A* and *B*) is composed of two cerebellar hemispheres covered with small convolutions called *folia*. Each hemisphere is divided by the primary fissure into two lobes (anterior and posterior) that are connected by a midline structure called the **vermis,** meaning worm.

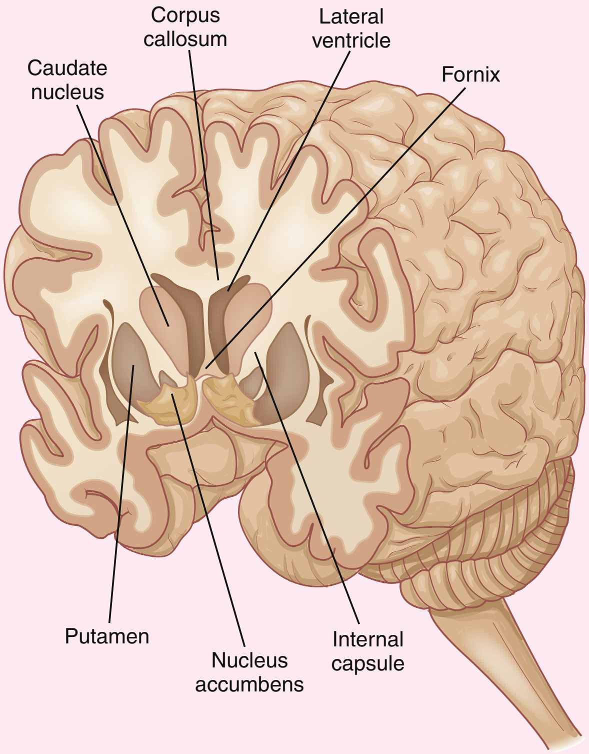
The cerebellum is responsible for conscious and unconscious muscle synergy and for maintaining balance and posture. This is accomplished through extensive neural connections from the spinal cord and medulla oblongata through the inferior cerebellar peduncle and with the midbrain and higher structures through the superior cerebellar peduncle. The two cerebellar hemispheres receive massive cerebral cortical input through the middle cerebellar pedunculi. These connections allow extensive sampling of visual, vestibular, and proprioceptive data from other regions of the CNS and periphery. Damage to the cerebellum is characterized by ipsilateral (same side) loss of equilibrium, balance, and motor coordination. The cerebellum has ipsilateral control of the body, in contrast to the cerebral cortex, which has contralateral (opposite side) control of the body.

The **pons** (bridge) is easily recognized by its bulging appearance below the midbrain and above the medulla oblongata. Primarily, it transmits information from the cerebellum to the brainstem nuclei and relays motor information from the

WHAT'S NEW?

Nucleus Accumbens, Dopamine, and Drug Addiction

A small nucleus (see accompanying figure) in the septal area of the frontal lobe has become a center of intense research. The nucleus accumbens is considered to be the principal site of action for addictive drugs and the anatomic basis of positive reinforcement and reward. The nucleus accumbens has input from the mesencephalon (ventral tegmental area) and many other neural areas. Mesencephalon neurons project dopamine to the nucleus accumbens and can affect its activity. Other neurotransmitters involved in this positive feedback system are gamma-aminobutyric acid (GABA), serotonin, and glutamate. Opiates can interfere with this system by allowing excessive amounts of dopamine to travel to the nucleus accumbens, contributing to drug craving and addiction. Research is in progress to discover pharmaceutical agents that target specific neurotransmitter receptors for the treatment of drug addiction.



Data from Gardner EL: *Adv Psychosom Med* 30:22–60, 2011; Lee BR, Dong Y: *Neuropharmacology* 61(7):1060–1069, 2011; Morales M, Pickel VM: *Ann N Y Acad Sci* 1248:71–88, 2012; Hikida T et al: *Proc Natl Acad Sci U S A* 110(1):342–347, 2013.

cerebral cortex to the contralateral cerebellar hemisphere. The pons is an important center for the control of respiration (i.e., rate and relationship of inspiration to expiration). The nuclei of cranial nerves V through VIII are located in this structure.

Myelencephalon. The **medulla oblongata** comprises the **myelencephalon** and is the lowest portion of the brainstem. Reflex activities, such as heart rate, respiration, blood pressure, coughing, sneezing, swallowing, and vomiting, are controlled in this area. The nuclei of cranial nerves IX through XII (see Table 15-6 for discussion) are located in this region. The lowest portion of the reticular formation is found here as well.

A major portion of the descending motor pathways (i.e., corticospinal tracts) crosses to the contralateral side, or decussates, at the inferior medulla oblongata (see Figure 15-9, *A*). These pathways, together with other areas of decussation in the CNS, are the basis for the phenomenon of contralateral control.

Spinal Cord

The **spinal cord** is the portion of the CNS that lies within the vertebral canal and is surrounded and protected by the vertebral column. The spinal cord has many functions, which include being a long nerve tract that connects the brain and body, conducting somatic and autonomic reflexes, providing motor pattern control centers, and serving as a sensory and motor modulation center. It continues from the medulla oblongata and ends inferiorly at the level of the first or second lumbar vertebra in adults (Figure 15-10). The end of the spinal cord, the **conus medullaris,** is cone shaped (Figure 15-11). Spinal nerves continue from the end of the spinal cord and form a nerve bundle called the **cauda equina.** The thin filament anchor from the conus medullaris to the coccyx is the **filum terminale** (see Figure 15-10).

Grossly, the spinal cord is divided into sections (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal) that

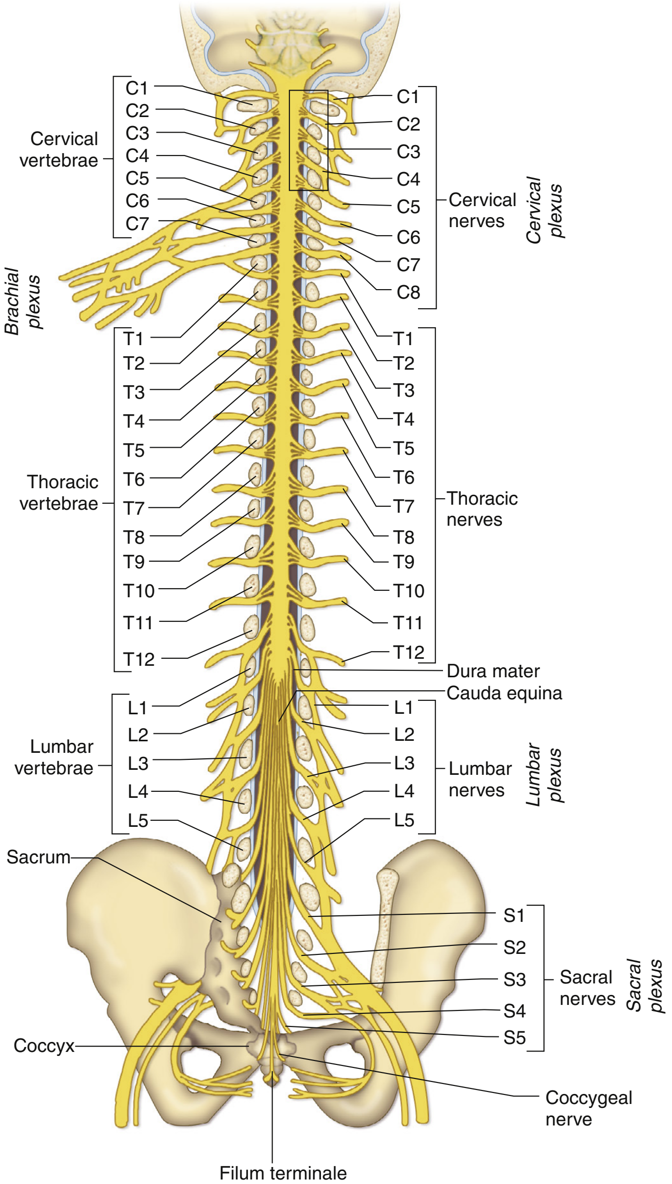


FIGURE 15-10 Spinal Cord Within Vertebral Canal and Exiting Spinal Nerves. Posterior view of brainstem and spinal cord in situ with spinal nerves and plexus. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

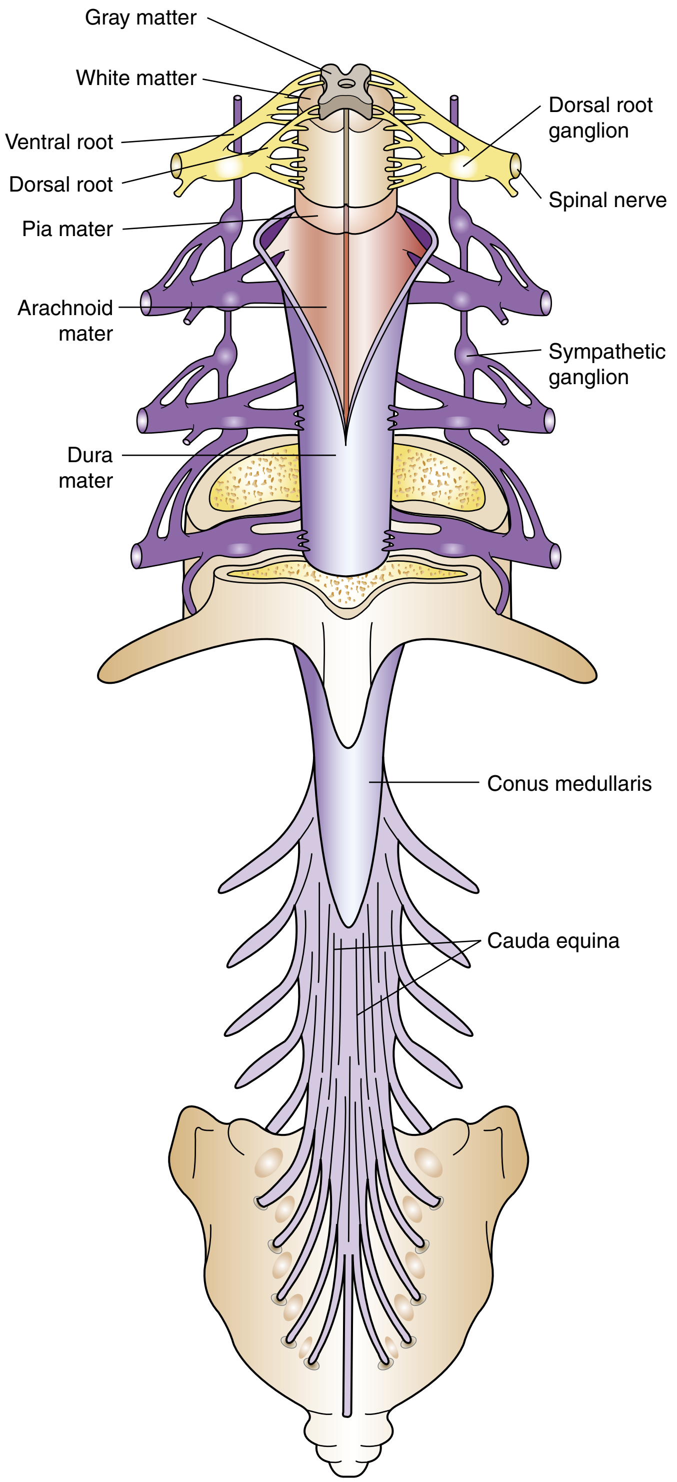

FIGURE 15-11 Spinal Nerves and Coverings of the Spinal Cord. Note how the dura mater extends to cover the spinal nerve roots and nerves. (Modified from Thibodeau GA, Patton KT: *Structure and function of the body,* ed 14, St Louis, 2012, Mosby.)

correspond to paired nerves (see Figure 15-10). A cross section of the spinal cord (see Figures 15-11 and 15-12) is characterized by a butterfly-shaped inner core of gray matter (containing nerve cell bodies). The **central canal** lies in the center of this region and extends through the spinal cord from its origin in the fourth ventricle. The gray matter of the spinal cord is divided into three regions with specific functional characteristics. These regions include the **posterior horn (dorsal horn),** which is composed primarily of interneurons and axons from sensory neurons whose cell bodies lie in the **sensory ganglion (dorsal root ganglion).** At the tip of the posterior horn is the **substantia gelatinosa,** a structure involved in pain transmission (see Chapter 16). The **intermediolateral gray horn (lateral horn)** contains cell bodies involved with the ANS. The **anterior horn (ventral horn)** contains the nerve cell bodies for efferent pathways leaving the spinal cord by way of spinal nerves. The terms *anterior* and *posterior* are preferred by many authors for describing human spinal cord anatomy, whereas *dorsal* and *ventral* are the common zoologic (veterinary) terms.

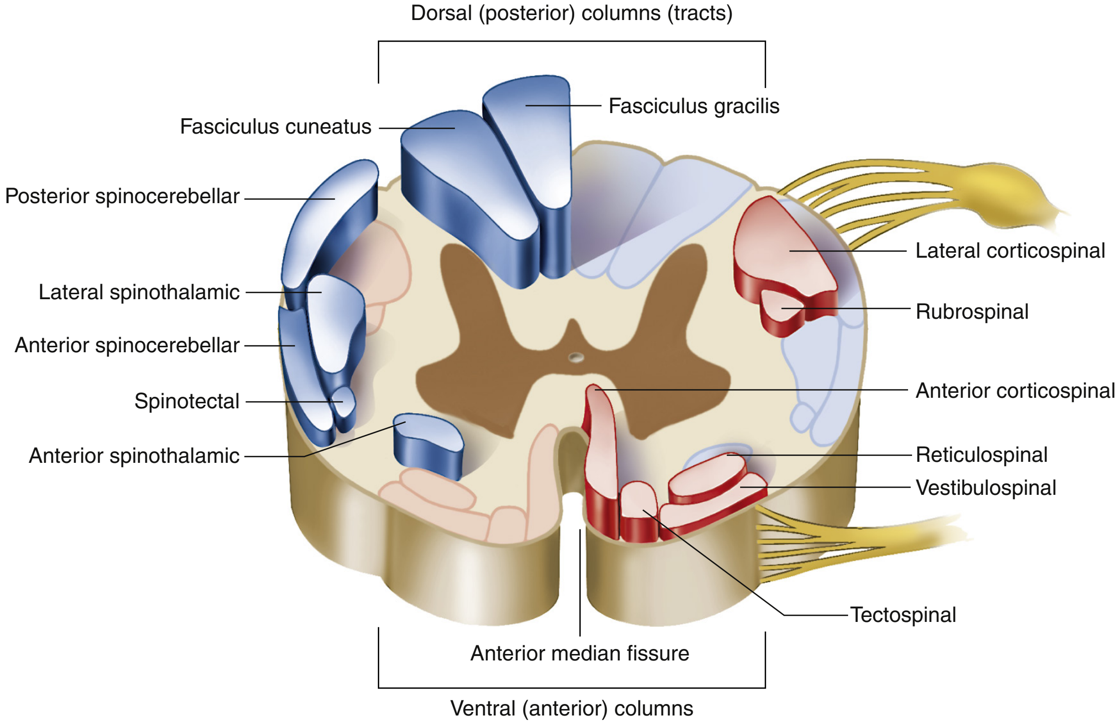

FIGURE 15-12 Major Tracts of the Spinal Cord. The major ascending (sensory) tracts, shown only on the left here, are highlighted in blue. The major descending (motor) tracts, shown only on the right, are highlighted in red. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

Surrounding the gray matter is white matter that forms ascending and descending pathways called **spinal tracts** and short ascending and descending integrative pathways. Spinal tracts are named to denote their beginning and ending points. For example, the **spinothalamic tract** carries nerve impulses from the spinal cord to the thalamus in the diencephalon. The white matter is subdivided into columns. These consist of the **anterior column (ventral column), lateral column,** and **posterior column (dorsal column),** that is, the fasciculus gracilis and fasciculus cuneatus. (Figure 15-12 identifies the location and principal activities of the major spinal tracts.)

Neural circuits in the spinal cord, when activated, display specific sets of motor responses. **Reflex arcs** form basic units that respond to stimuli and provide protective circuitry for motor output. Structures mandatory for a simple reflex arc (monosynaptic reflex) are a receptor, an **afferent (sensory) neuron,** an **efferent (motor) neuron,** and an effector muscle or gland. The afferent neuron is a pseudounipolar neuron, with its cell body in the sensory ganglion. A simple reflex arc contains only two neurons (e.g., knee jerk reflex). Most reflex arcs include one or more interneurons or association neurons between the afferent and efferent neurons (polysynaptic reflex). (Figure 15-13 illustrates a reflex arc.) The transmission time for polysynaptic reflexes is slower than that for monosynaptic reflexes because there are two or more synaptic delays. The afferent neuron of the reflex arc simultaneously sends sensory information to the effector organ and to higher CNS centers (see Figure 15-8, *B*; also see Figure 16-3). The motor effects from reflex arcs generally occur before perception of the event in the higher centers of the brain. Much of the regulation of the internal environment is mediated by polysynaptic ANS reflexes (e.g., cardiac muscle and smooth muscle contraction/relaxation and glandular responses).

Afferent pathways transmit information from peripheral receptors and the information ultimately terminates in the cerebral or cerebellar cortex, or both. Efferent pathways primarily relay information from the cerebrum to the brainstem or spinal cord (see Figure 15-9, *A*). **Upper motor neurons** (i.e., corticospinal and corticobulbar tracts) are the classification of motor pathways completely contained within the CNS (see Figure 17-31). Their primary roles include directing, influencing, and modifying reflex arcs, lower-level control centers, and motor (and some sensory) neurons. Generally, upper motor neurons form synapses with interneurons, which then form synapses with lower motor neurons before projecting into the periphery. **Lower motor neurons** (i.e., cranial and spinal efferent neurons) are responsible for direct influence on muscles. Their cell bodies lie in the gray matter of the spinal cord, but their processes extend into the PNS (see Figure 15-9, *A* and Figure 17-32). Destruction of upper motor neurons usually results in initial paralysis followed within days or weeks by partial recovery, whereas destruction of the lower motor neurons often leads to permanent paralysis, unless peripheral nerve damage is followed by nerve regeneration. (Injury to motor neurons is discussed in Chapter 18.)

Muscle activity (i.e., stimulation and contraction) is regulated by nerve impulses. Motor neurons innervate one or more muscle cells, forming **motor units** consisting of a neuron and the skeletal muscles it stimulates. The junction between the axon of the motor neuron and the plasma membrane of the muscle cell is called the **neuromuscular (myoneural) junction** (Figure 15-14). The skeletal muscle neuromuscular junction is

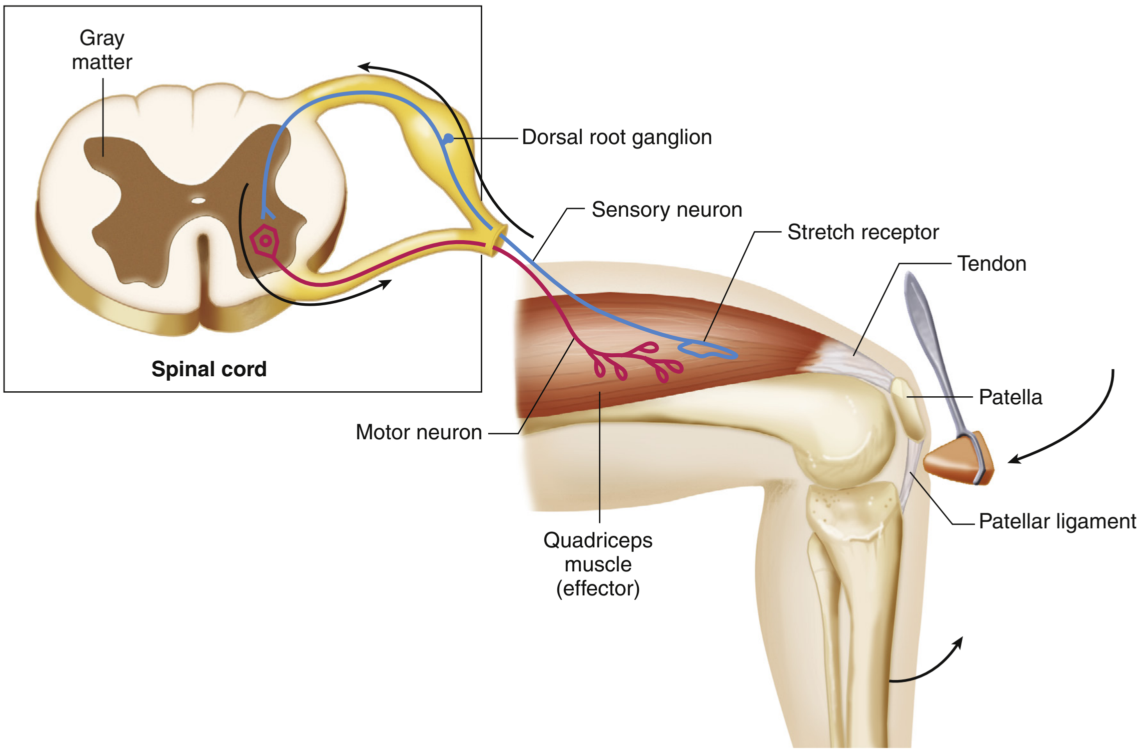

FIGURE 15-13 Cross Section of Spinal Cord Showing Simple Reflex Arc. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

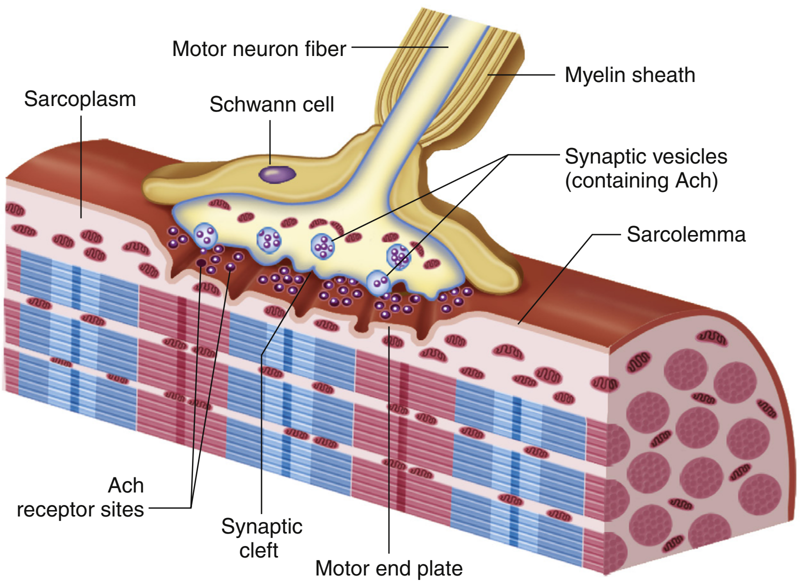

FIGURE 15-14 Neuromuscular Junction. This figure shows how the distal end of a motor neuron fiber forms a synapse, or "chemical junction," with an adjacent muscle fiber. Neurotransmitters (specifically, acetylcholine *[Ach]*) are released from the neuron's synaptic vesicles and diffuse across the synaptic cleft where they stimulate receptors in the motor end-plate region of the sarcolemma. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

more elaborate than the simpler smooth muscle neuromuscular junction.

Motor Pathways (Tracts)

The four clinically relevant motor pathways (tracts) are the **lateral corticospinal, corticobulbar** (upper motor neurons of cranial nerves), basal ganglia, and **vestibulospinal pathways.** The corticospinal (see Figure 15-9, *A*) and corticobulbar (see Figure 17-31) are essentially the same tract and consist of a two-neuron chain. The cell bodies originate in and around the precentral gyrus; pass through the corona radiata of the cerebrum, the internal capsule, and the middle three fifths of the basis pedunculus, pons, and pyramid; decussate (cross contralaterally) in the medulla oblongata; and form the lateral

corticospinal tract of the spinal cord (see Figure 15-12). The lateral corticospinal tract axons (upper motor neurons) leave the tract to go to specific interneurons or motor neurons in the anterior horn. The lateral corticospinal tract has the same somatotopic organization as the body. These spinal motor neurons project to specific motor units and are lower motor neurons. The corticobulbar (bulbar refers to brainstem) tract can be thought of as the part of the corticospinal tract that innervates the cranial motor nuclei for eye, face, tongue, throat, and neck movement. This tract innervates all the cranial motor nuclei bilaterally except for the facial (spinal), accessory, and hypoglossal nuclei, which receive primarily contralateral innervation. These tracts are involved in precise motor movements. The basal ganglia are part of a system that drives the reticular descending tracts. (Figure 15-12 shows only one of the two reticulospinal tracts.) These tracts modulate motor movement by inhibiting and exciting spinal activity. The vestibulospinal tract is an extrapyramidal tract and arises from the lateral vestibular nucleus in the pons and causes the extensor muscles of the body to rapidly contract, most dramatically witnessed when a person starts to fall backward.

Sensory Pathways

The three clinically important spinal afferent pathways are the posterior (dorsal) column, anterior spinothalamic, and lateral spinothalamic (see Figure 15-12; also see Figures 16-2 and 16-3). The **posterior (dorsal) column pathway** has a somatotopic organization (looks like your body) with the fasciculus gracilis and fasciculus cuneatus, respectively, carrying lower body and upper body fine touch, two-point discrimination, and proprioceptive information (i.e., **epicritic**). The posterior column is formed by a three-neuron chain. The first neuron of the chain is the primary afferent neuron. It is also the sensory neuron of the reflex arc. After entering the spinal cord it sends its axon ipsilaterally up the spinal cord in a specific part of the posterior column and synapses in one of three posterior column nuclei in the hindbrain. A basketball center has primary afferent neurons that run from the great toe up to the pons, which could be more than 6 feet long. The second-order neuron has its cell body in one of the three posterior column nuclei and sends its axon contralaterally and ascends to a specific nucleus of the thalamus and synapses. The third-order neuron, originating in the thalamus, continues the tract into the internal capsule, corona radiata, and postcentral gyrus (Brodmann areas 3, 1, 2) (see Figure 15-7, *C*). The **anterior** and **lateral spinothalamic tracts** are responsible for vague touch and for pain and temperature, respectively (see Figure 15-9, *B*). These modalities are referred to as **protopathic.**

Today the anterior and lateral spinothalamic tracts are combined by many neuroanatomists into the anterolateral system because these modalities are difficult to localize into finite tracts in the spinal cord. These tracts also form a three-neuron chain. However, the primary afferent neurons synapse in the posterior horn of the spinal cord, not just at the level they enter the intervertebral foramen but in a number of spinal segments above and below their point of entry. This is an example of divergence. The axons of the second-order neurons in the posterior horn cross to the contralateral side in the spinal cord in the lateral column, and ascend to the same thalamic nucleus as the posterior column pathway and continue on with the posterior column pathway to the postcentral gyrus.

Protective Structures

Cranium

The cranium is composed of eight bones. The cranial vault functions to enclose and protect the brain and its associated structures. The **galea aponeurotica,** which is a thick, fibrous band of tissue overlying the cranium between the frontal and occipital muscles, affords added protection to the bony structure of the skull. The subgaleal space has venous connections with the dural sinuses, and with increased intracranial pressure, blood can be shunted to this space, thus reducing pressure in the intracranial cavity. The subgaleal space is also a common site for placement of wound drains after intracranial surgery.

The floor of the cranial vault is irregular and contains many foramina (openings) that act as exit sites for cranial nerves, blood vessels, and the spinal cord. The cranial floor is divided into three fossae (depressions). The frontal lobes lie in the **anterior fossa;** the temporal lobes and base of the diencephalon lie in the **middle fossa (temporal fossa);** and the cerebellum lies in the **posterior fossa.** These terms are commonly used anatomic landmarks to describe the location of intracranial lesions.

Meninges

Surrounding the brain and spinal cord are three protective membranes: the dura mater, the arachnoid, and the pia mater. Collectively they are called the **meninges** (Figure 15-15). The **dura mater** (meaning literally "hard mother") is composed of two layers, with the venous sinuses formed between them. The outermost layer forms the **periosteum (endosteal layer)** of the skull, and the **inner dura,** or **meningeal layer,** is responsible for the formation of rigid, double-thickness membranous plates that serve to support and separate various brain structures.

One of these membranous plates (see Figure 15-15), the **falx cerebri,** dips between the two cerebral hemispheres along the longitudinal fissure. The falx cerebri is anchored anteriorly to the base of the brain at the crista galli of the ethmoid bone. The **tentorium cerebelli** is a membrane that separates the cerebellum below from the cerebral structures above. The tentorium may become involved during periods of increased intracranial pressure caused by an injury to the brain. An injury within the cranial cavity tends to shift intracranial contents, and as structures shift, they tend to be compressed against these rigid membranes, resulting in damage or destruction. A common example is tentorial herniation.

Below the dura mater lies the **arachnoid membrane,** characterized by its filmy, weblike structure. It loosely follows the contours of the cerebral structures but lies over the sulci.

The **subdural space** lies between the dura and arachnoid. Many small bridging veins that have little support traverse the subdural space. Their disruption results in a subdural hematoma (see Chapter 18 and Figures 18-5 and 18-6). The **subarachnoid space,** which contains CSF, lies between the arachnoid and the pia mater (see Figure 15-15). Damage to

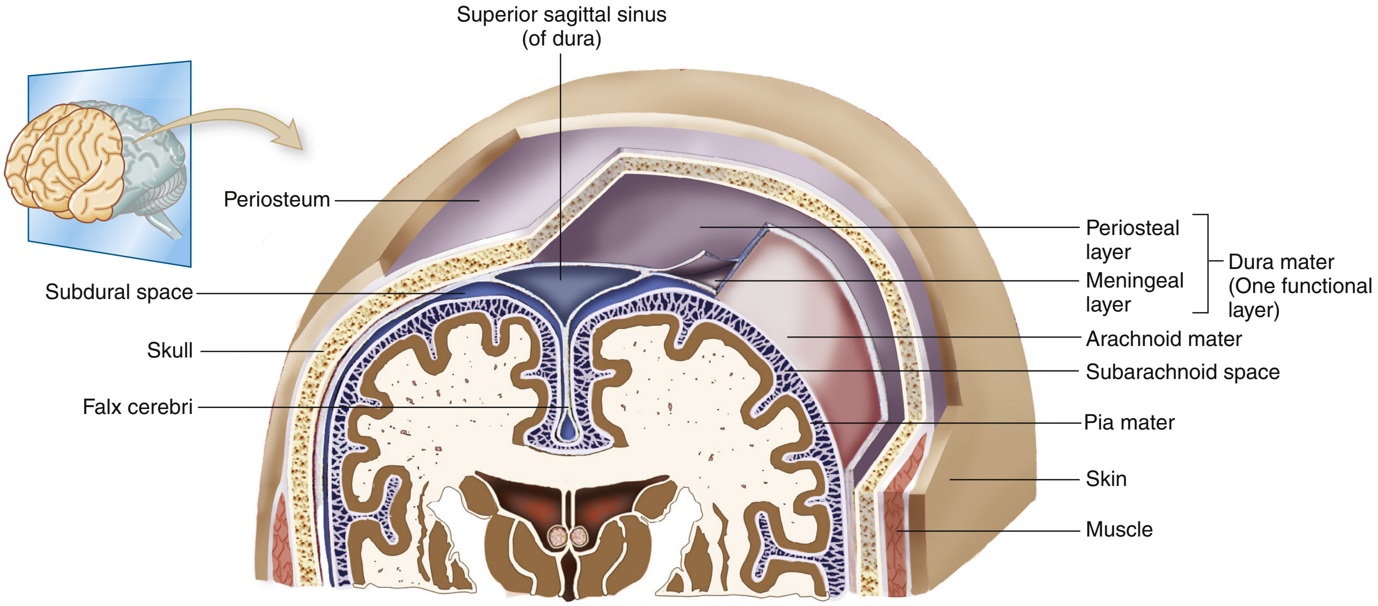

FIGURE 15-15 Coverings of the Brain. Frontal section of the superior portion of the head, as viewed from the front. The bony and the membranous coverings of the brain can be seen. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

intracranial vessels can lead to a condition called *subarachnoid hemorrhage,* which frequently results in signs of meningeal irritation, such as neck stiffness, positive Kernig sign, and low back pain.

Unlike the dura mater and arachnoid, the delicate **pia mater** (see Figure 15-15) closely adheres to the surface of the brain and spinal cord and even follows the sulci and fissures. It provides support for blood vessels serving brain tissue. The **choroid plexuses,** structures that produce cerebrospinal fluid (CSF), arise from the pia mater. The spinal cord is anchored to the vertebrae by extensions of the meninges called **denticulate ligaments.** The meninges continue beyond the end of the spinal cord to the lower portion of the sacrum. CSF, contained within the subarachnoid space, also circulates down to the large **lumbar cistern,** which extends from the second lumbar vertebra to the second sacral vertebra. Cisterns are expanded areas of the subarachnoid space. The **cerebellomedullary cistern (cisterna magna)** and the pontine cistern are two other important cisterns.

The meninges form potential and real spaces important to understanding functional and pathologic mechanisms. For example, between the dura mater and skull lies a potential space termed the **epidural space** (see Figure 15-15). In the spinal canal is a real epidural space filled with fatty tissue and a venous plexus. The arterial supply to the meninges consists of blood vessels that lie within grooves in the skull. As a result of trauma, the skull can be fractured and the blood vessels disrupted. The ruptured vessels can lead to an accumulation of blood within the epidural space, called an *epidural hematoma* (see Chapter 18 and Figure 18-4). Persons with alcoholism often fall and injure their head, resulting in an epidural hematoma. An inflammation of the meninges (meningitis) also can have life-threatening implications because of the relative proximity to the brain. (See Chapter 18.)

TABLE 15-4 COMPOSITION OF CEREBROSPINAL FLUID

CONSTITUENT	NORMAL VALUE
Na^+	148 mM
K^+	2.9 mM
Cl^-	125 mM
HCO_3^-	22.9 mM
Glucose (fasting)	50-75 mg/dl (60% of serum glucose)
pH	7.3
Protein	15-45 mg/dl
Albumin	80%
Gamma globulin	6-10%
Cells	
White (lymphocytes)	0-6/mm^3
Red (red blood cell [RBC])	0/mm^3

Cl^-, Chloride; *HCO_3^-,* bicarbonate; *K^+,* potassium; *Na^+,* sodium.

Cerebrospinal Fluid and the Ventricular System

Cerebrospinal fluid (CSF) is a clear, colorless fluid similar to blood plasma and interstitial fluid. The intracranial and spinal cord structures float in CSF and are thereby partially protected from jolts and blows. The buoyant properties of the CSF also prevent the brain from tugging on meninges, nerve roots, and blood vessels. (Constituents of CSF are listed in Table 15-4.) Between 125 and 150 ml of CSF, approximately the quantity of a small cup of coffee, is circulating within the **ventricles** (small cavities) and subarachnoid space at any given time. Approximately 600 ml of CSF is produced daily.

The choroid plexuses in the lateral, third, and fourth ventricles produce the major portion of CSF. (Ventricles are illustrated in Figures 15-15 and 15-16.) These plexuses are characterized by a rich network of blood vessels, supplied by the pia

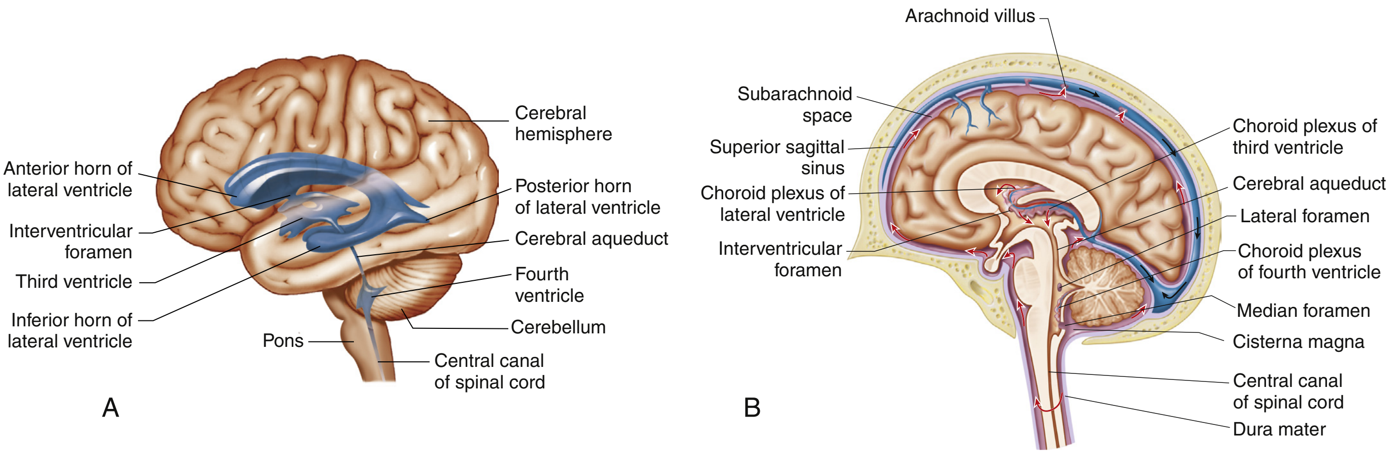

FIGURE 15-16 Flow of Cerebrospinal Fluid. **A,** Ventricles highlighted in blue within a translucent brain in a left lateral view. **B,** Flow of cerebrospinal fluid. The fluid is produced by filtration of blood by the choroid plexus of each ventricle, and from the ventricles flows to the subarachnoid space and then to the blood. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

mater, that lie in close contact with ventricular ependymal cells that secrete and absorb CSF.

The CSF exerts pressure within the brain and spinal cord. When a person is lying down, CSF pressure is approximately 120 to 180 mm of water pressure, or approximately 9 to 14 mmHg pressure. CSF flow is a result of a pressure gradient between the arterial system and the CSF-filled cavities. Beginning in the lateral ventricles, the CSF flows through the **interventricular foramen** (**foramen of Monro**) into the third ventricle and then passes through the cerebral aqueduct (aqueduct of Sylvius) into the fourth ventricle. From the fourth ventricle, the CSF may pass through either the paired **lateral apertures** (**foramina of Luschka**) into the pontine cisterns, located along the basal pons, or the midline **median aperture** (**foramen of Magendie**) into the cerebellomedullary cistern before communicating with the subarachnoid spaces of the brain and spinal cord. The CSF does not, however, accumulate. Instead, it is reabsorbed into the venous circulation through the arachnoid villi, primarily located superior to the falx cerebri in the **superior sagittal sinus.** The **arachnoid villi** protrude from the arachnoid space, through the dura mater, and lie within the blood flow of the venous sinuses. CSF is reabsorbed by means of a pressure gradient between the arachnoid villi and the cerebral venous sinuses. The villi function as one-way valves directing CSF outflow into the blood but preventing blood flow into the subarachnoid space. Thus CSF is derived from the blood, and after circulating throughout the CNS, it returns to the blood.

Samples of CSF are withdrawn for diagnostic purposes either (1) by inserting a needle between the third and fourth lumbar vertebrae into the lumbar cistern (subarachnoid space)—a procedure called **lumbar puncture**—or (2) by placing an intraventricular catheter. Spinal anesthesias (blocks) are administered in a manner similar to the lumbar puncture.

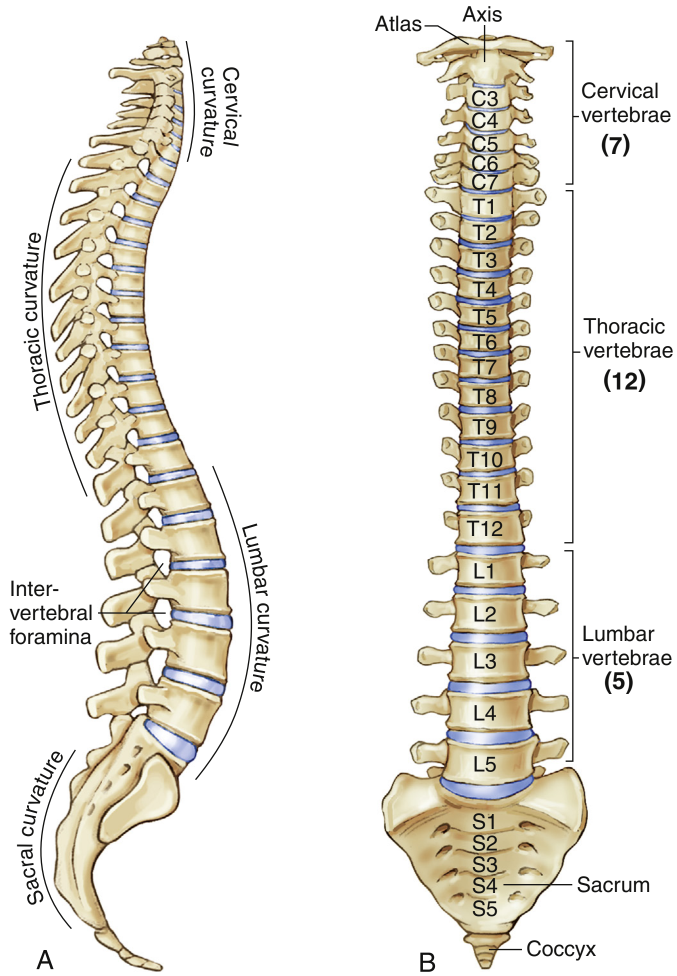

FIGURE 15-17 Vertebral Column. **A,** Right lateral view. **B,** Anterior view. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

Vertebral Column

The **vertebral column** (Figure 15-17) is composed of 33 vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 fused sacral, and 4 fused coccygeal. Between each interspace (except the fused sacral and

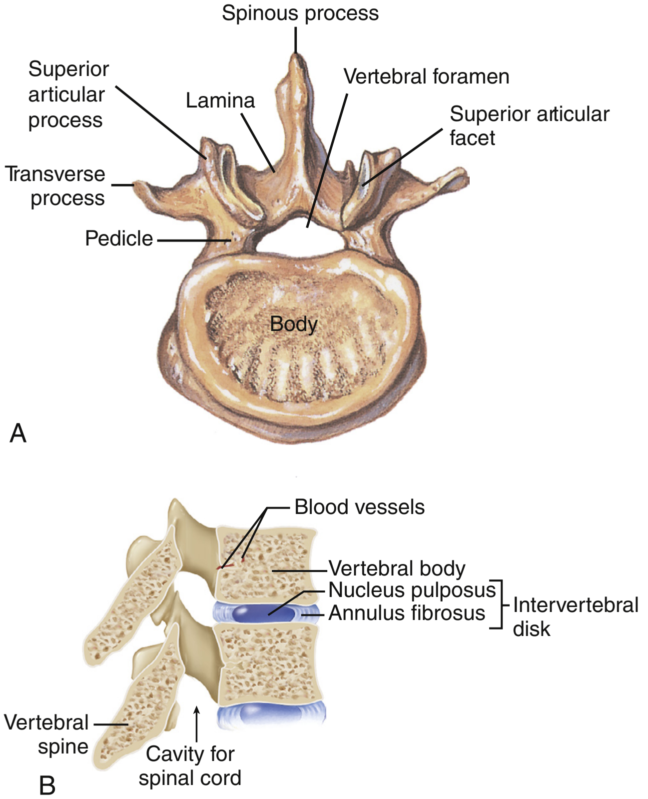

FIGURE 15-18 **A,** Lumbar Vertebra, Superior View. **B,** Intervertebral Disk. (**A** from Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 6, St Louis, 2007, Mosby; **B** from Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

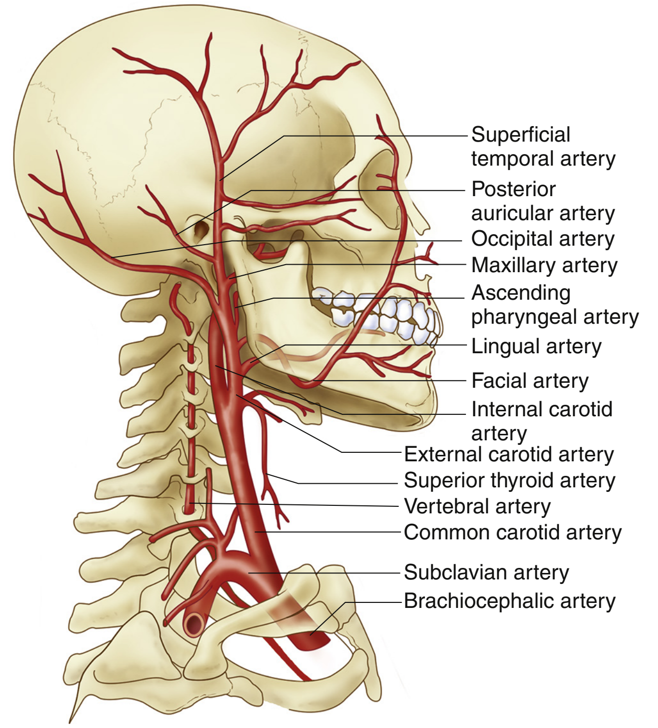

FIGURE 15-19 Major Arteries of the Head and Neck. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

coccygeal vertebrae) is an **intervertebral disk** (Figure 15-18). At the center of the intervertebral disk is the **nucleus pulposus,** a pulpy mass of elastic fibers. The intervertebral disk functions to absorb shocks, preventing damage to the vertebrae. The intervertebral disk is also a common source of back problems. If too much stress is applied to the vertebral column, the disk contents may rupture and protrude into the spinal canal, causing compression of the spinal cord or nerve roots. The disks also can degenerate.

Blood Supply

Blood Supply to the Brain

The brain receives approximately 20% of the cardiac output, or 800 to 1000 ml of blood flow per minute. Carbon dioxide serves as a primary regulator for blood flow within the CNS. It is a potent vasodilator in the CNS, and its effects ensure an adequate blood supply.

The brain derives its arterial supply from two systems: the **internal carotid arteries** and the **vertebral arteries** (Figure 15-19). The internal carotid arteries, anteriorly, supply a proportionately greater amount of blood flow. They originate from the common carotid arteries, enter the cranium through the base of the skull, and pass through the **cavernous sinus.** After giving off some small branches, they divide into the **anterior** and **middle cerebral arteries** (Figure 15-20). The vertebral arteries, posteriorly, originate as branches off the subclavian arteries, pass through the transverse foramina of the cervical vertebrae, and enter the cranium through the foramen magnum. They join at the junction of the pons and medulla oblongata to form the **basilar artery.** The basilar artery divides at the level of the midbrain to form paired **posterior cerebral arteries.** Three major paired arteries perfuse the cerebellum and brainstem and originate from the posterior arterial supply: the posterior inferior cerebellar artery, off the vertebral artery; and the anterior inferior cerebellar and superior cerebellar arteries, off the basilar artery. The basilar artery also gives rise to small pontine arteries. The large arteries on the surface of the brain and their branches are called **superficial arteries (conducting arteries).** The small branches that project into the brain are termed **projecting arteries (nutrient arteries).** Occluding any of these vessels can cause neurologic signs and symptoms that are often diagnostically unique.

The **arterial circle (circle of Willis)** (see Figure 15-20) is a structure credited with the ability to compensate for reduced blood flow from any one of the major contributors (collateral blood flow). The arterial circle is formed by the posterior cerebral arteries, posterior communicating arteries, internal carotid arteries, anterior cerebral arteries, and anterior communicating artery. The anterior cerebral, middle cerebral, and posterior cerebral arteries leave the arterial circle and extend to various brain structures. (Table 15-5 and Figure 15-21 illustrate structures served, functional relationships, and pathologic considerations related to occlusion of cerebral arteries.)

Cerebral venous drainage does not parallel (lie side by side) its arterial supply, whereas the venous drainage of the brainstem and cerebellum does parallel the arterial supply of the structures. The cerebral veins are classified as superficial veins and deep cerebral veins. The veins drain into venous plexuses and dural sinuses

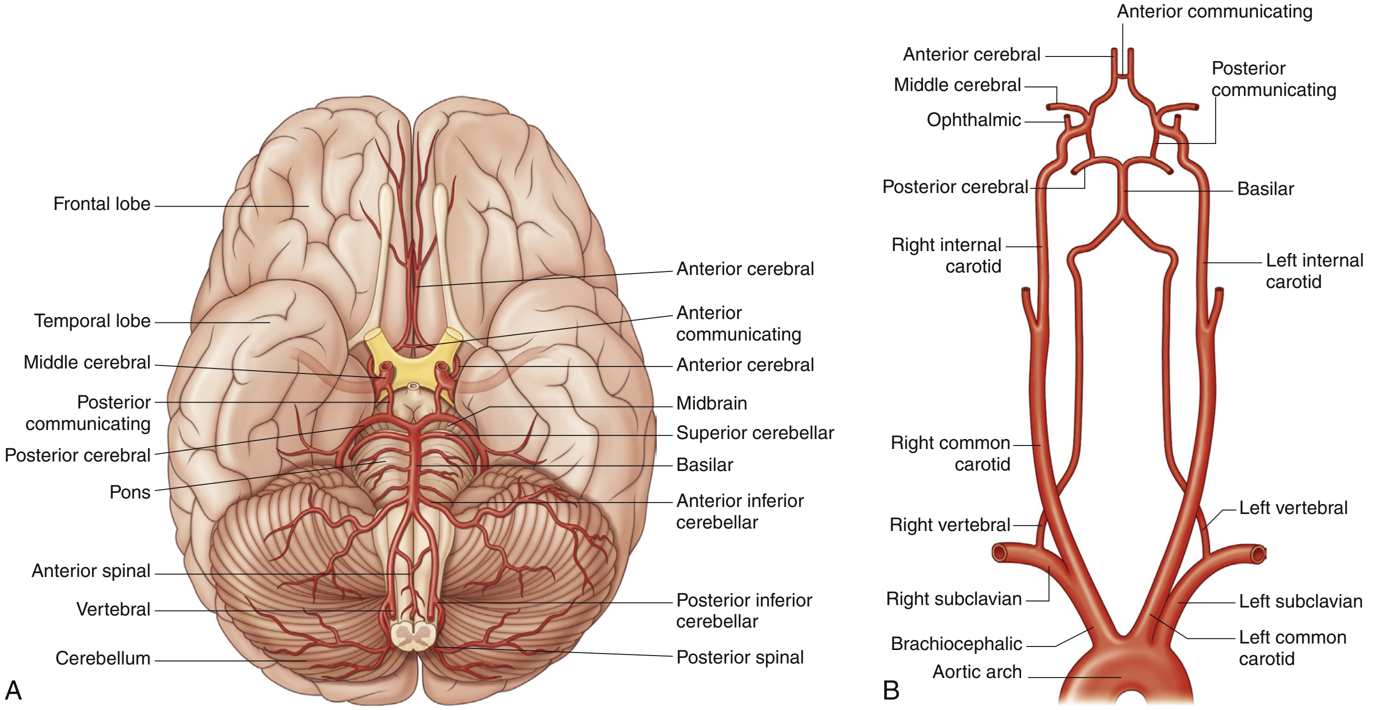

FIGURE 15-20 **Arteries at the Base of the Brain.** The arteries that compose the circle of Willis are the two anterior cerebral arteries, joined to each other by the anterior communicating two short segments of the internal carotids, off of which the posterior communicating arteries connect to the posterior cerebral arteries. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

TABLE 15-5 ARTERIAL SYSTEMS SUPPLYING THE BRAIN

ARTERIAL ORIGIN	STRUCTURES SERVED	CONDITIONS CAUSED BY OCCLUSION
Anterior cerebral artery	Basal ganglia; corpus callosum; medial surface of cerebral hemispheres; superior surface of frontal and parietal lobes	Hemiplegia on contralateral side of body, greater in lower than in upper extremities
Middle cerebral artery	Frontal lobe; parietal lobe; temporal lobe (primarily cortical surfaces)	Aphasia in dominant hemisphere and contralateral hemiplegia (see Chapter 17)
Posterior cerebral artery	Part of diencephalon and temporal lobe; occipital lobe	Visual loss; sensory loss; contralateral hemiplegia if cerebral peduncle affected

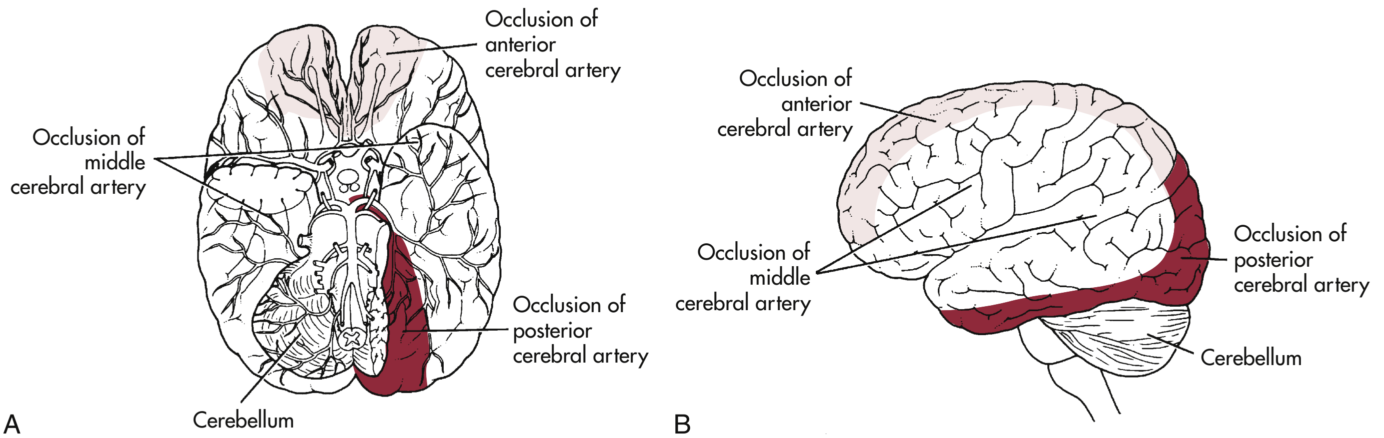

FIGURE 15-21 Areas of the Brain Affected by Occlusion of the Anterior, Middle, and Posterior Cerebral Artery Branches. **A,** Inferior view. **B,** Lateral view.

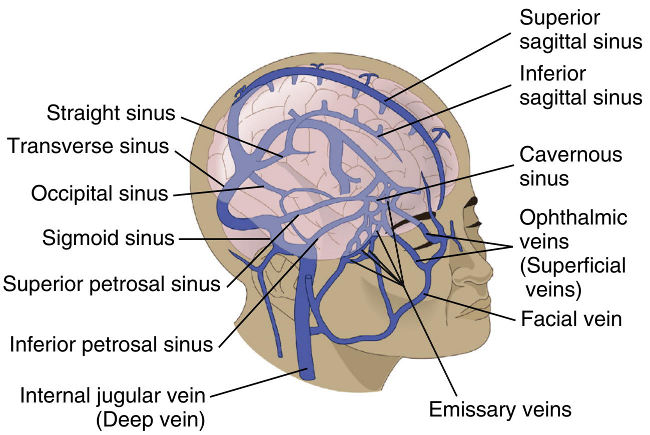

FIGURE 15-22 **Large Veins of the Head.** Deep veins and dural sinuses are projected on the skull. Note connections (emissary veins) between the superficial and deep veins. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

BOX 15-4 THE BLOOD-BRAIN BARRIER

The **blood-brain barrier (BBB)** is a term used to describe cellular structures that selectively inhibit certain substances in the blood from entering the interstitial spaces of the brain or cerebrospinal fluid (CSF). This term emphasizes the impermeability of the nervous system to large and potentially harmful molecules. Astrocytes wrap their foot processes around the epithelial cells of brain capillaries, contributing to the formation of the BBB. Tight junctions between capillary endothelial cells form a barrier that regulates the passage of ions (e.g., sodium and potassium) that could interfere with nerve transmission, prevent toxins from entering the brain, and promote transport of nutrients and removal of metabolites. Compromise of the BBB contributes to passage of molecules and immune cells into the brain causing disease. The BBB has substantial implications for drug therapy because certain types of antibiotics and chemotherapeutic drugs show a greater propensity than others for crossing the barrier. BBB permeability can be affected by hormones, neurotransmitters, and inflammatory mediators. Inhibiting these endogenous chemicals with drug therapy may reduce brain edema and slow the onset of degenerative brain diseases.

Data from Caraglia M et al: *Curr Cancer Drug Targets* 12(3):188–196, 2012; Cristante E et al: *Proc Natl Acad Sci U S A* 110(3):832–941, 2013; De Rosa G et al: *Curr Drug Metab* 13(1):61–69, 2012; Muldoon LL et al: *J Cereb Blood Flow Metab* 33(1):13–21, 2013; Rosenberg GA: *J Cereb Bood Flow Metab,* 2012 [Epub]; Van Sorge NM, Doran KS: *Future Microbiol* 7(3):383–394, 2012.

(formed between the dural layers) and eventually join the internal jugular veins at the base of the skull (Figure 15-22). Adequacy of venous outflow can have a significant effect on intracranial pressure. For example, in individuals with head injury, turning or letting the head fall to the side partially occludes venous return and can increase intracranial pressure because of decreased flow through the jugular veins.

The blood-brain barrier is discussed in Box 15-4.

Blood Supply to the Spinal Cord

The spinal cord derives its blood supply from branches off the vertebral arteries and from branches from various regions of the aorta (Figure 15-23). The **anterior spinal arteries** and the paired **posterior spinal arteries** branch off the vertebral artery at the base of the cranium and descend alongside the spinal cord. Arterial branches from vessels exterior to the spinal cord follow the spinal nerve through the intervertebral foramina, pass through the dura, and divide into the anterior and posterior radicular arteries.

The radicular arteries eventually reconnect to the spinal arteries. Branches from the radicular and spinal arteries form plexuses whose branches penetrate the spinal cord, supplying the deeper tissues. Venous drainage parallels the arterial supply closely and drains into venous sinuses located between the dura and periosteum of the vertebrae.

PERIPHERAL NERVOUS SYSTEM

The cranial and spinal nerves, including their branches and ganglia, constitute the PNS. A peripheral nerve (cranial or spinal) is composed of individual axons/dendrites, with most wrapped in a myelin sheath. These individual fibers are arranged in bundles called fascicles (see Figure 15-1 and Figure 15-24, *B*). The coverings provide structural support, a blood supply, and interstitial compartments necessary for the delivery of essential electrolytes to support nerve impulse conduction.

The 31 pairs of spinal nerves derive their names from the vertebral level from which they exit. There are eight cervical spinal nerves. The first cervical nerve exits above the first cervical vertebra, and the rest of the spinal nerves exit below their corresponding vertebrae. From the thoracic region (and inferiorly) nerves correspond to the vertebral level above their exit (see Figure 15-10).

Spinal nerves contain both sensory and motor neurons and are called **mixed nerves.** They arise as rootlets from the anterior and posterior horn cells of the spinal cord. These two spinal nerve roots converge in the region of the intervertebral foramen to form the spinal nerve (see Figure 15-11). Shortly after converging, the spinal nerve divides into anterior and posterior rami (branches). The anterior rami (except the thoracic) initially form plexuses (networks of nerve fibers), which then branch into the peripheral nerves. Instead of forming plexuses, the thoracic nerves pass through the intercostal spaces and innervate regions of the thorax.

The main spinal nerve plexuses innervate the skin and the underlying muscles of the limbs. The **brachial plexus,** for example, is formed by the last four cervical nerves (C5-C8) and the first thoracic nerve (T1). The brachial plexus innervates the nerves of the arm, wrist, and hand. The **lumbar plexus** (L2-L4) and **sacral plexus** (L5-S5) contain nerves that innervate the anterior and posterior portions of the lower body, respectively (see Figure 15-10).

The posterior rami of each spinal nerve, with their many processes, are distributed to a specific area in the body. Sensory signals thus arise from specific sites associated with a specific spinal cord segment. Specific areas of cutaneous (skin) innervation at these spinal cord segments are called **dermatomes.** The dermatomes of various spinal nerves are distributed in a fairly regular pattern, although adjacent regions between dermatomes can be innervated by more than one spinal nerve Figure 15-24, *D*.

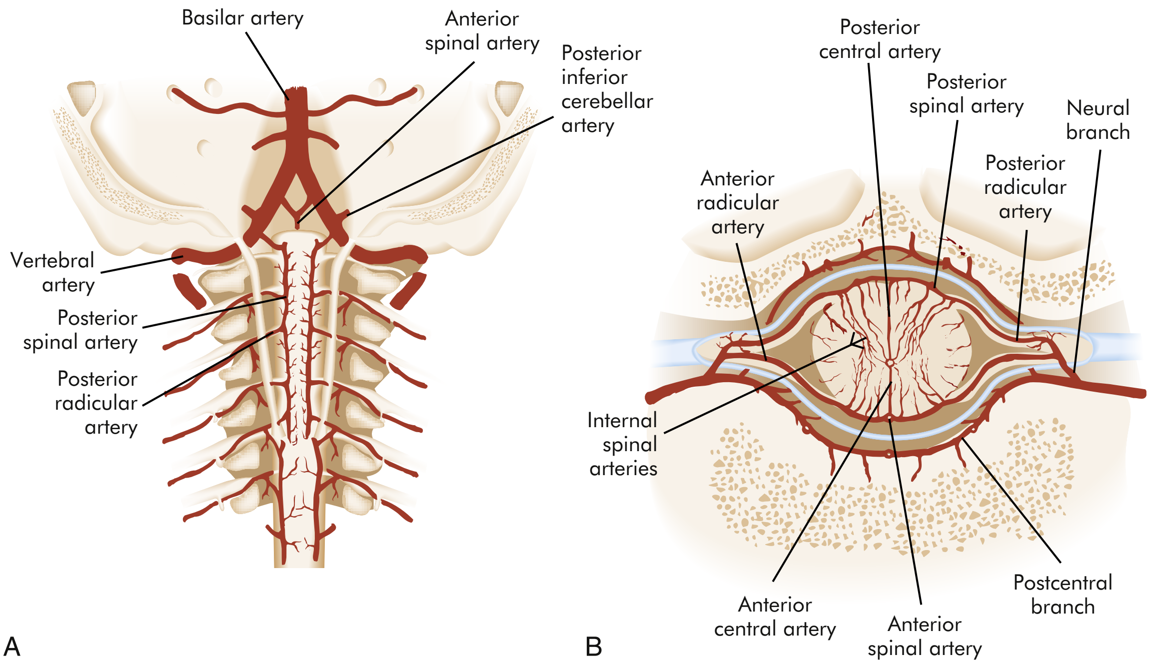

FIGURE 15-23 Arteries of the Spinal Cord. **A,** Arteries of cervical cord exposed *(posterior view)*. **B,** Arteries of spinal cord diagrammatically shown in horizontal section. (From Rudy EB, editor: *Advanced neurological and neurosurgical nursing,* St Louis, 1984, Mosby.)

Like spinal nerves, cranial nerves are categorized as peripheral nerves. Most of these are mixed nerves (like the spinal nerves), although some are purely sensory or motor. Cranial nerves arise from nuclei in the brain and brainstem. (Figure 15-24, *A,* illustrates their location, and Table 15-6 describes structural and functional characteristics.)

AUTONOMIC NERVOUS SYSTEM

Components of the ANS are located in both the CNS and the PNS; however, the ANS is considered part of the efferent division of the PNS, even though visceral afferent neurons are an important part of this system. Many neurons of the ANS travel in spinal nerves and in certain cranial nerves. The widespread activity of this system indicates that its components are distributed over the entire body. The peripheral autonomic nerves carry mainly efferent fibers. The motor component of the ANS is a two-neuron system consisting of **preganglionic neurons** (myelinated) and **postganglionic neurons** (unmyelinated). This arrangement contrasts with the somatic nervous system, in which a single motor neuron travels from the CNS to the innervated structure. Visceral afferent neurons have their cell bodies in some sensory and cranial ganglia and their fiber processes traveling in peripheral nerves. The CNS has autonomic areas in the intermediolateral horns of the spinal cord, cardiovascular and respiratory centers in the reticular formation, and both sympathetic and parasympathetic areas in the hypothalamus. CNS pathways interconnect all these areas.

The ANS coordinates and maintains a steady-state among visceral (internal) organs, such as regulation of cardiac muscle, smooth muscle, and the glands of the body. This system is considered an involuntary system because one generally cannot *will* these functions to happen. The ANS is separated structurally and functionally into two divisions: (1) the **sympathetic nervous system** (Figure 15-25) and (2) the **parasympathetic nervous system** (Figure 15-26).

Anatomy of the Sympathetic Nervous System

The sympathetic nervous system functions to mobilize energy stores in times of need (e.g., in the fight-or-flight response) (see Chapter 11 and Figure 11-2). The sympathetic division receives its innervation from cell bodies located from the first thoracic (T1) through the second lumbar (L2) regions of the spinal cord and is therefore called the **thoracolumbar division.** The preganglionic axons of the sympathetic division form synapses shortly after leaving the spinal cord in the **sympathetic ganglia.** These preganglionic axons travel several different ways: (1) directly synapsing with postganglionic neurons in the sympathetic chain ganglion at their level, (2) traveling up or down the sympathetic chain ganglion before forming synapses with a higher or lower postganglionic neuron (divergence), or (3) passing through the sympathetic chain ganglion postganglionic neurons within collateral ganglia (see Figure 15-25). Some preganglionic axons form pathways called **splanchnic nerves,** which lead to **collateral ganglia** surrounding the abdominal aorta. The collateral ganglia are named according to the branches of the aorta nearest them, namely, the **celiac, superior mesenteric,** and **inferior mesenteric.** These postganglionic neurons leave the collateral ganglia and innervate the viscera below the diaphragm.

Preganglionic sympathetic neurons that innervate the adrenal medulla also travel in the splanchnic nerves and do not synapse before reaching the gland. The secretory cells in the adrenal medulla are considered modified postganglionic neurons.

TABLE 15-6 THE CRANIAL NERVES

NUMBER AND NAME	ORIGIN AND COURSE	FUNCTION	HOW TESTED
I. Olfactory	Fibers arise from nasal olfactory epithelium and form synapses with olfactory bulbs that transmit impulses to temporal lobe	Purely sensory; carries impulses for sense of smell	Person is asked to sniff aromatic substances, such as oil of cloves and vanilla, and to identify them
II. Optic	Fibers arise from retina of eye to form optic nerve, which passes through sphenoid bone; two optic nerves then form optic chiasma (with partial crossover of fibers) and eventually end in occipital cortex	Purely sensory; carries impulses for vision	Vision and visual field tested with an eye chart and by testing point at which person first sees an object (finger) moving into visual field; inside of eye is viewed with ophthalmoscope to observe blood vessels of eye interior
III. Oculomotor	Fibers emerge from midbrain and exit from skull and extend to eye	Contains motor fibers to inferior oblique and to superior, inferior, and medial rectus extraocular muscles that direct eyeball; levator muscles of eyelid; smooth muscles of iris and ciliary body; and proprioception (sensory) to brain from extraocular muscles	Pupils examined for size, shape, and equality; pupillary reflex tested with a penlight (pupils should constrict when illuminated); ability to follow moving objects
IV. Trochlear	Fibers emerge from posterior midbrain and exit from skull to run to eye	Proprioceptor and motor fibers for superior oblique muscle of eye (extraocular muscle)	Tested in common with cranial nerve III relative to ability to follow moving objects
V. Trigeminal	Fibers emerge from pons and form three divisions that exit from skull and run to face and cranial dura mater	Both motor and sensory for face; conducts sensory impulses from mouth, nose, surface of eye, and dura mater; also contains motor fibers that stimulate chewing muscles	Sensations of pain, touch, and temperature tested with safety pin and hot and cold objects; corneal reflex tested with a wisp of cotton; motor branch tested by asking subject to clench teeth, open mouth against resistance, and move jaw from side to side
VI. Abducens	Fibers leave inferior pons and exit from skull and extend to eye	Contains motor fibers to lateral rectus muscle and proprioceptor fibers from same muscle to brain	Tested in common with cranial nerve III relative to ability to move each eye laterally
VII. Facial	Fibers leave pons and travel through temporal bone and extend to face	Mixed: (1) supplies motor fibers to muscles of facial expression and to lacrimal and salivary glands, and (2) carries sensory fibers from taste buds of anterior part of tongue	Anterior two thirds of tongue tested for ability to taste sweet (sugar), salty, sour (vinegar), and bitter (quinine) substances; symmetry of face checked; subject asked to close eyes, smile, whistle, and so on; tearing tested with ammonia fumes
VIII. Vestibulocochlear (acoustic)	Fibers run from inner ear (hearing and equilibrium receptors in temporal bone) to enter brainstem just below pons	Purely sensory; vestibular branch transmits impulses for sense of equilibrium; cochlear branch transmits impulses for sense of hearing	Hearing checked by air and bone conduction by use of a tuning fork; vestibular tests: Bárány and caloric tests
IX. Glossopharyngeal	Fibers emerge from midbrain and leave skull and extend to pharynx, salivary glands, and tongue	Mixed: (1) motor fibers serve pharynx (throat) and salivary glands, and (2) sensory fibers carry impulses from pharynx, posterior tongue (taste buds), and pressure receptors of carotid artery	Gag and swallow reflexes checked; subject asked to speak and cough; posterior one third of tongue may be tested for taste
X. Vagus	Fibers emerge from medulla, pass through skull, and descend through neck region into thorax and abdominal region	Fibers carry sensory and motor impulses for pharynx; a large part of this nerve is parasympathetic motor fibers, which supply smooth muscles of abdominal organs; receives sensory impulses from viscera	Same as for cranial nerve IX (IX and X are tested in common) because they both serve muscles of the throat
XI. Spinal accessory	Fibers arise from medulla and superior spinal cord and extend to muscles of neck and back	Provides sensory and motor fibers for sternocleidomastoid and trapezius muscles and muscles of soft palate, pharynx, and larynx	Sternocleidomastoid and trapezius muscles checked for strength by asking subject to rotate head and shrug shoulders against resistance
XII. Hypoglossal	Fibers arise from medulla and exit from skull and extend to tongue	Carries motor fibers to muscles of tongue and sensory impulses from tongue to brain	Subject asked to stick out tongue, and any position abnormalities are noted

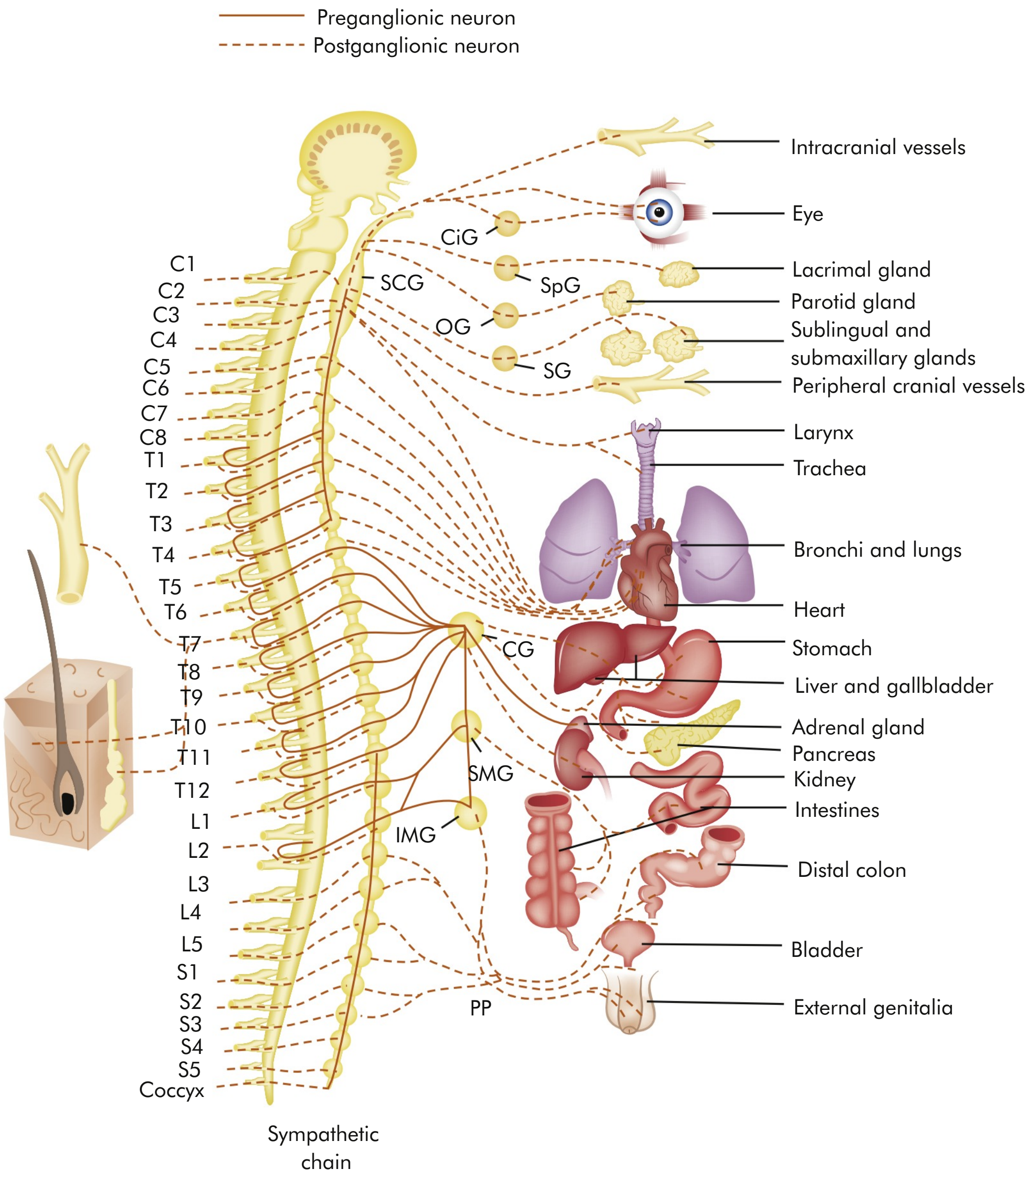

FIGURE 15-25 Sympathetic Division of the Autonomic Nervous System. *CG,* Celiac ganglion; *CiG,* ciliary ganglion; *IMG,* inferior mesenteric ganglion; *OG,* otic ganglion; *PP,* pelvic plexus; *SCG,* superior cervical ganglion; *SG,* submandibular ganglion; *SMG,* superior mesenteric ganglion; *SpG,* sphenopalatine ganglion. Because preganglionic sympathetic fibers are all myelinated, nerve conduction to the adrenal medulla is quick, and innervation causes the rapid release of epinephrine and norepinephrine. Epinephrine and norepinephrine are mediators of the fight-or-flight response (see Chapter 11).

Anatomy of the Parasympathetic Nervous System

The parasympathetic nervous system functions to conserve and restore energy. The nerve cell bodies of this division are located in the cranial nerve nuclei and in the sacral region of the spinal cord, and therefore constitute the **craniosacral division.** Unlike the sympathetic division, the preganglionic fibers in the parasympathetic division travel to ganglia close to the organs they innervate before forming synapses with the relatively short postganglionic neurons (see Figure 15-26). Parasympathetic nerves arising from nuclei in the brainstem travel to the viscera of the head, thorax, and abdomen within cranial nerves—including the oculomotor (III), facial (VII), glossopharyngeal (IX), and vagus (X) nerves.

Preganglionic parasympathetic nerves that originate from the sacral region of the spinal cord run either separately or together with some spinal nerves. The preganglionic axons join to form the **pelvic nerve,** which innervates the viscera of the pelvic cavity. These preganglionic axons synapse with postganglionic neurons in terminal ganglia located close to the organs they innervate.

Neurotransmitters and Neuroreceptors

Sympathetic preganglionic fibers and parasympathetic preganglionic and postganglionic fibers release **acetylcholine**—the

(From Rudy EB, editor: *Advanced neurological and neurosurgical nursing,* St Louis, 1984, Mosby.)

same neurotransmitter released by somatic efferent neurons (Figure 15-27). These fibers are characterized by **cholinergic transmission.** Most postganglionic sympathetic fibers release **norepinephrine** (adrenaline) and thus are considered to function by **adrenergic transmission.** A few postganglionic sympathetic fibers, such as those that innervate the sweat glands, release acetylcholine.

The action of catecholamines (epinephrine, norepinephrine, dopamine) varies with the type of neuroreceptor stimulated. It should be remembered that catecholamines also are released by the adrenal medulla gland that physiologically and biochemically resembles the sympathetic nervous system. Mainly two types of adrenergic receptors exist: α- and β-adrenergic receptors. Cells of the effector organs may have only one or both types of adrenergic receptors. The **α-adrenergic receptors** have been further subdivided according to the action produced: α_1-adrenergic activity is associated mostly with excitation or stimulation; α_2-adrenergic activity is associated with relaxation or inhibition. Most of the α-adrenergic receptors on effector organs belong to the α_1-adrenergic class. The **β-adrenergic receptors** are classified as β_1-adrenergic receptors (which facilitate increased heart rate and contractility and cause the release of renin from the kidney), β_2-adrenergic receptors (which facilitate all of the remaining effects attributed to β-adrenergic receptors), and β_3-adrenergic receptors (mediate lypolysis and thermogenesis and are up-regulated in cardiovascular disease).[6]

Norepinephrine stimulates all α-adrenergic and β_1-adrenergic receptors and β_3-adrenergic receptors, and only certain β_2-adrenergic receptors. The primary response from norepinephrine, however, is stimulation of the α_1-adrenergic receptors that cause vasoconstriction. Epinephrine strongly stimulates all four types of receptors and induces general vasodilation because of the predominance of β-adrenergic receptors in muscle vasculatures. (Table 15-7 summarizes the effects of neuroreceptors on their effector organs.)

Dopamine is a precursor of norepinephrine and epinephrine and is a brain neurotransmitter synthesized in the substantia

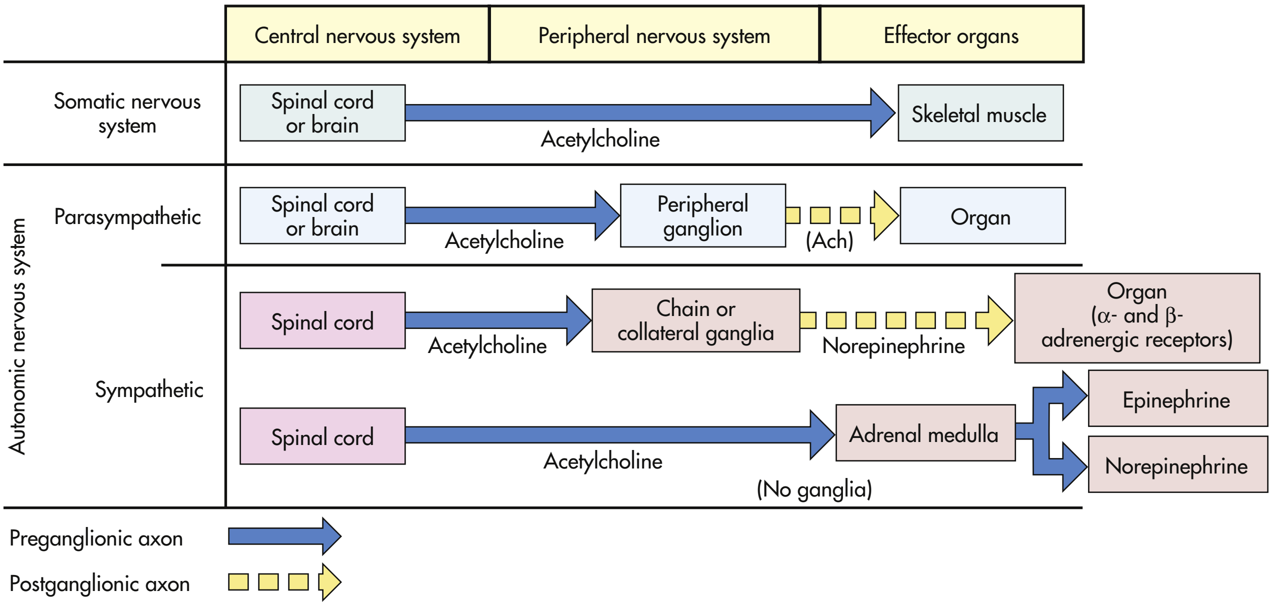

FIGURE 15-27 **Autonomic Nervous System and Type of Neurotransmitters Secreted by Preganglionic and Postganglionic Fibers.** Note that all preganglionic fibers are cholinergic (Ach). A somatic nerve is used for comparison.

TABLE 15-7 ACTIONS OF AUTONOMIC NERVOUS SYSTEM NEURORECEPTORS

EFFECTOR ORGAN OR TISSUE	ADRENERGIC RECEPTORS	ADRENERGIC EFFECTS	CHOLINERGIC EFFECTS (NICOTINE AND MUSCARINIC* RECEPTORS)
Eye			
Iris			
Radial muscle	α_1	Dilation	—

*Muscarinic receptors respond to circulating muscarinic antagonists.

nigra and the ventral tegmental areas of the brain There are five types of dopamine receptors distributed throughout the brain, D_1, D_2, D_3, D_4, and D_5. They have varying functions including pleasure, motivation, cognition, memory, learning, and fine motor control (see What's New? Nucleus Accumbens, Dopamine, and Drug Addiction, p. 460).

Many body organs are innervated by the sympathetic and parasympathetic nervous systems. The two divisions frequently cause opposite responses; for example, sympathetic stimulation of the gastrointestinal (GI) tract causes decreased peristalsis, whereas parasympathetic stimulation of the GI tract increases peristalsis. In general, sympathetic stimulation promotes responses that are concerned with the protection of the individual. For example, sympathetic activity increases blood glucose levels and temperature and raises blood pressure. In emergency situations a generalized and widespread discharge of the sympathetic system occurs. This is accomplished by an increased firing frequency of sympathetic fibers and by activation of sympathetic fibers normally silent and at rest (fibers to the sweat glands, pilomotor muscles, and the adrenal medulla, as well as vasodilator fibers to muscle). Regulation of vasomotor tone is considered the single most important function of the sympathetic nervous system. (Figure 15-28 illustrates some of the most important functions of the sympathetic nervous system; also see Figure 11-2.)

Increased parasympathetic activity promotes rest and tranquility and is characterized by reduced heart rate and enhanced visceral functions leading to digestion. Stimulation of the vagus nerve in the GI tract increases peristalsis and secretion, as well as relaxation of sphincters. Activation of parasympathetic fibers in the head, provided by cranial nerves III, VII, and IX, causes pupillary constriction, tear secretion, and increased salivary secretion. Stimulation of the sacral division of the parasympathetic system contracts the urinary bladder and facilitates the process of genital erection.

The parasympathetic system lacks the generalized and widespread response of the sympathetic system. Specific parasympathetic fibers are activated to regulate particular functions. Although the actions of the parasympathetic and sympathetic systems usually are antagonistic, there are exceptions. Changes in the shape of the lens (for near vision) require only oculomotor parasympathetic activity. Most of the blood vessels involved in the control of blood pressure are innervated by sympathetic nerves. Peripheral vascular resistance is increased and decreased by the relative activity of the sympathetic division without a counteracting parasympathetic component. To decrease blood pressure, therefore, it is more important to block or paralyze the continuous (tonic) discharge of the sympathetic system than to promote parasympathetic activity.

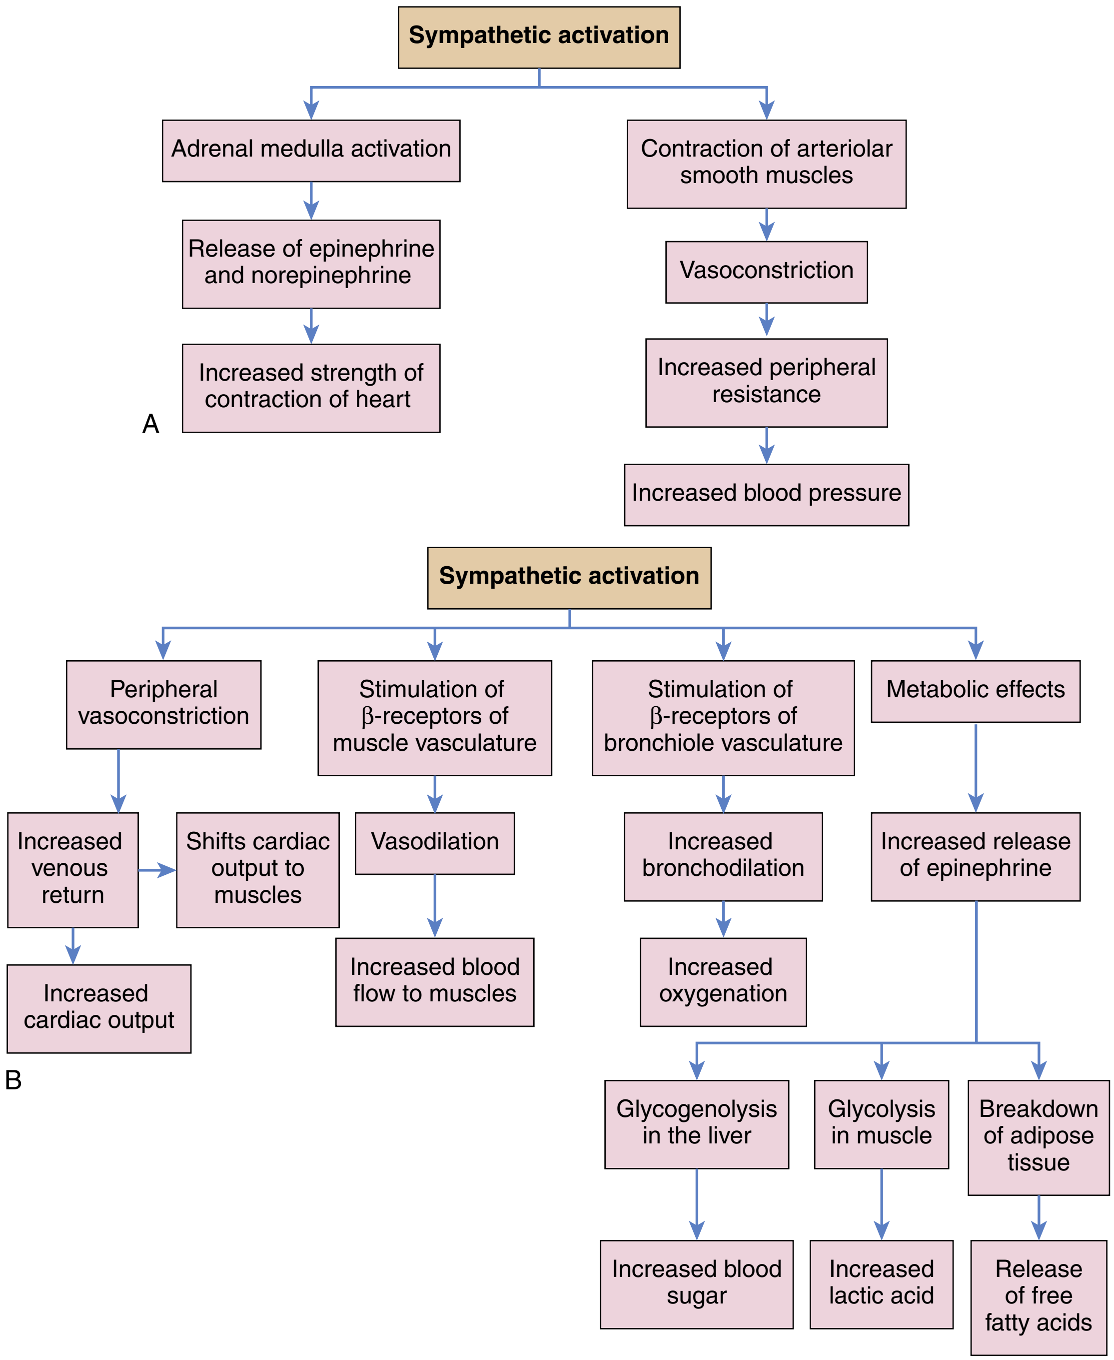

FIGURE 15-28 Some Important Functions of the Sympathetic Nervous System. **A,** Regulation of vasomotor tone. **B,** Regulation of strenuous muscular exercise (fight-or-flight response). (See also Chapter 11 and Figure 11-2 for more detail of the stress response.)

AGING AND THE NERVOUS SYSTEM

The CNS mechanisms involved in the aging process are extremely complex, and many questions concerning the neurologic effects of aging have yet to be answered. Some of the identified mechanisms associated with aging are pathologic, but the distinction between these mechanisms and those that are a part of the normal aging process remains somewhat ambiguous. Box 15-5 contains information on the structural, cellular, cerebrovascular, and functional changes that occur in the nervous system with aging.

TESTS OF NERVOUS SYSTEM FUNCTION

Skull and Spine Roentgenograms

Roentgenograms (x-ray films) of the skull or spine from multiple angles (views) are used primarily to localize bony defects, bone density, erosion, or calcified structures. The pineal gland

BOX 15-5 AGING AND THE NERVOUS SYSTEM

Structural Changes with Aging
Decreased brain weight and size, particularly frontal regions
Fibrosis and thickening of the meninges
Narrowing of gyri and widening of sulci
Increase in size of ventricles

Cellular Changes with Aging
Decrease in the number of neurons, not consistently related to changes in mental function
Decreased amount of myelin
Lipofuscin deposition (a pigment resulting from cellular autodigestion)
Decreased number of dendritic processes and synaptic connections
Formation of intracellular neurofibrillary tangles; significant accumulation in cortex associated with Alzheimer dementia
Imbalance in the amount and distribution of neurotransmitters

Cerebrovascular Changes with Aging
Arterial atherosclerosis (may cause infarcts and scars)
Increased permeability of the blood-brain barrier
Decreased vascular density

Functional Changes with Aging
Decreased tendon reflexes
Skeletal muscle atrophy
Progressive deficit in taste and smell
Decreased vibratory sense
Decrease in accommodation and color vision
Decrease in neuromuscular control with change in gait and posture
Sleep disturbances
Memory impairments
Cognitive alterations associated with chronic disease
Functional changes and nervous system aging have significant individual variation

Data from Brown WR, Thore CT: *Neuropathol Appl Neurobiol* 37(1):56–74, 2011; Crowley K: *Neuropsychol Rev* 21(1):41–53, 2011; Glorioso C, Sibille E: *Prog Neurobiol* 93(2):165–181, 2011; Hof PR, Mobbs C: *Neuroscience of aging,* Oxford, 2009, Academic Press; Jang YC, Van Remmen H: *Exp Gerontol* 46(2-3):193–198, 2011; Kumar A, Foster TC: Neurophysiology of old neurons and synapses. in older people becomes calcified and is useful as an internal brain landmark. X-ray films are probably the most commonly used radiologic studies.

Computed Tomography

Computed tomography (CT) creates two-dimensional reconstructions from multiple radiologic images (x-rays) using computer-assisted analysis. It is capable of demonstrating fine distinctions in shape, size, and densities of a variety of tissues based on differential absorption of x-rays. CT imaging is a noninvasive procedure used in evaluating cranial and spinal structures, as well as hemorrhages, tumors, and distortions in the brain caused by pressure differences. A variety of contrast media also are commonly used in conjunction with this procedure to aid in enhanced delineation of selected structures. **Spiral or helical CT** uses a multidetector scanner mounted on a rotating gantry to provide several axial images for imaging a large continuous anatomic area in a matter of seconds. **Helical CT angiography** uses contrast media for detection of aneurysms or ruptured aneurysms.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a commonly used testing modality. It uses a static magnetic field, instead of x-rays, to orient physiologic atomic particles. Disruption of this orientation by excitation of the particles using serial radiofrequency pulsations provides the image data. The specific tissue reaction is computer-analyzed to give an image of exquisite detail, similar to that provided by CT. The MRI also provides reconstruction of images in three views at right angles (i.e., axial, sagittal, coronal). MRI is reported to have none of the adverse effects associated with radiation examinations. **Magnetic resonance spectroscopy** can be completed at the same time as a standard MRI by analyzing the chemical composition of proton (hydrogen) or phosphorus-based molecules and is useful for evaluating the chemical composition and function of various regions of the brain. **Functional MRI (fMRI)** detects changes in blood oxygenation and flow and can be used to produce maps showing the parts of the brain that are functioning during a mental process.

Magnetic Resonance Angiography

A newer addition to MRI is **magnetic resonance angiography (MRA).** Special imaging techniques allow the visualization of blood vessels in great detail. MRA is likely to become indispensable, alone or in conjunction with cerebral angiography, in detecting and localizing pathologic lesions of the circulatory system of the brain.

Positron-Emission Tomography Scan

The **positron-emission tomography (PET) scan** uses CT imaging to detect the emission of positive electrons from trace amounts of radioactive substances injected into the bloodstream or administered as inhaled gases. With radioactive decay, radioactive substances emit a positron. As they are distributed in tissues, they display characteristic patterns that indicate physiologic and metabolic processes, for example, glucose and oxygen uptake, cerebral blood flow, neural and neurotransmitter function, and the effects of drugs. As a research tool, PET is being used to visualize the specific brain sites that are involved in the processing of information in the brain.

Brain Scan

The **brain scan** images radionuclide substances (technetium [^{99m}Tc]) that have been introduced into the bloodstream. For example, visualization of tissue uptake of the radioactive agent provides an indication of blood-brain barrier integrity (increased uptake of the agent indicates disruption). This scanning technique also can identify abnormalities in blood flow dynamics and cellular metabolic function. The brain scan is particularly helpful in detecting abnormal vascularity resulting from neoplasms, abscesses, and vascular lesions.

TABLE 15-8 CEREBROSPINAL FLUID ANALYSIS

PARAMETERS	NORMAL	ABNORMAL	POSSIBLE CAUSE
Pressure (initial readings)	120-180 mm H_2O (9-14 mmHg)	<60 mm H_2O	Faulty needle placement Dehydration Spinal block along subarachnoid space Block of foramen magnum
		>200 mm H_2O	Muscle tension Abdominal compression Brain tumor Subdural hematoma Brain abscess Brain cyst Cerebral edema (any cause) Hydrocephalus
Color (turbidity)	Clear, colorless	Cloudy	Increased cell count Increased microorganisms
		Yellow	Xanthochromic (caused by red blood cell [RBC] pigments) High protein content
		Smoky	Presence of RBCs
Red blood cells	None	Blood-tinged	Traumatic tap
		Grossly bloody	Traumatic tap Subarachnoid hemorrhage
White blood cells	0-6/mm^3	>10/mm^3 (cell counts range from <100/mm^3 to many thousands depending on causative factor; all are abnormal findings)	Occurs in many conditions: Bacterial infections of meninges Viral infections of meninges Neurosyphilis Tuberculous meningitis Metastatic neoplastic lesions Parasitic infections Acute demyelinating diseases Following introduction of air or blood into subarachnoid space
Protein*	15-45 mg/dl (1% of serum protein)	<10 mg/dl	Little clinical significance
		>60 mg/dl	Occurs in many conditions: Complete spinal block Guillain-Barré syndrome Carcinomatosis of meninges Tumors close to pial or ependymal surfaces or in cerebellopontine angle Acute and chronic meningitis Meningeal hemorrhage Demyelinating disorders Degenerative diseases
Glucose (CSF: Serum Ratio)	0.6: approximately 60% of blood glucose level - 50-55 mg/dl)	<0,4: <40 mg/dl >0,6: >60mg/dl	Acute bacterial meningitis Tuberculous meningitis Meningeal carcinomatosis Acute viral meningitis
		>100 mg/dl	Diabetes
Chloride	700-750 mg/dl 116-130 mEq/L	<625 mg/dl <110 mEq/L >800 mg/dl	Hypochloremia Tuberculous meningitis Not of neurologic significance; correlates with blood levels of chloride

Data from Rudy EB, editor: *Advanced neurological and neurosurgical nursing,* St Louis, 1984, Mosby; Marx JA editor in chief: *Rosen's emergency medicine,* Philadelphia, 2010, Saunders.
*__Note:__ If CSF contains blood, this will raise the protein level.

Isotope cisternography is another radionuclide imaging technique that uses brain scan imaging to detect CSF flow, CSF resorption, and integrity of CSF pathways. The radionuclide agent in this case is injected directly into the subarachnoid space. Under normal conditions the agent passes over the cortical surface and is resorbed through the arachnoid villi. Demonstration of the agent in the ventricular system after a specific period of time indicates CSF obstruction; that is, the CSF backflows from the subarachnoid space into the ventricles.

Cerebral Angiography

Angiography is a radiologic technique that demonstrates cerebrovascular blood flow. This technique commonly is performed by the introduction of a small catheter into the femoral artery. The catheter is then passed to the level of the cerebral circulation and through the aorta, and a contrast dye is injected. Serial x-ray films are then taken. These films demonstrate flow of the dye through the cerebral vasculature and provide information on patency, location, size, and flow pattern of the vessels. Another technique used in cerebral angiography is the retrograde (reverse flow) injection of the dye through catheterization of a brachial, axillary, subclavian, or femoral vein.

Myelography

A **myelogram** demonstrates intraspinal anatomy by the introduction of a radiographic dye into the lumbar subarachnoid space or the cerebellomedullary cistern (cisterna magna). The dye is allowed to flow in a cephalic direction, as in the case of a lumbar injection, or inferiorly in a cerebellomedullary cistern puncture. X-ray films are then obtained. The distribution of the dye delineates spinal cord and nerve root structure and integrity.

Echoencephalography (Ultrasound)

Echoencephalography, or **ultrasound,** is a safe, noninvasive procedure using sound waves that are deflected at differing rates, depending on the density of the tissue. Information is processed and displayed on an oscilloscope screen. It is useful primarily in the detection of structural characteristics of intracranial space–occupying mass lesions and the determination of ventricular dimensions, especially in newborns.

Electroencephalography

The **electroencephalograph (EEG)** is a recording of electrical impulses, arising from the cortical surface of the brain, which is detected by scalp electrodes. The recording of brain wave patterns is analyzed for alterations or localization (or both) of specific electrical activity. This test is especially useful in detecting and localizing foci that initiate seizure activity. It is also an important technique in determining, from a person's brain activity, whether the person is legally "brain dead."

Evoked Potentials

Evoked potentials (EPs) are a method of detecting electrical brain activity that results from a stimulus—primarily auditory, visual, or peripheral sensory. Electrical activity is computer formatted to display changes in trends. The primary uses of EPs include perioperative detection of sensory pathway integrity and disease- or drug-related sensory dysfunction.

Cerebrospinal Fluid Analysis

CSF generally is obtained from the lumbar or cisternal subarachnoid space by means of a hollow needle that allows passive flow. The lumbar puncture is performed most often at the L3-L4 interspace (below the level of the spinal cord at L1-L2). Cisternal puncture is performed by the insertion of a needle into the cerebellomedullary cistern using an approach from the back of the neck in the region of the foramen magnum. CSF pressure is commonly measured during these procedures. The CSF can be analyzed also for gross characteristics and constituents (color, blood cells, electrolytes, and protein) and cultured for microorganisms (Table 15-8).

SUMMARY REVIEW

Overview and Organization of the Nervous System

1. The divisions of the nervous system have been categorized as either structural (CNS and PNS) or functional (somatic nervous system and ANS).
2. The CNS is contained within the brain and spinal cord.
3. The PNS is composed of cranial and spinal nerves that carry impulses toward the CNS (afferent) and away from the CNS (efferent) to target organs or skeletal muscle.

Cells of the Nervous System

1. The neuron and neuroglial cells make up nervous tissue. The neuron is specialized to transmit and receive electrical and chemical impulses, and the neuroglial cell provides supportive functions. The neuron is further divided into unipolar, pseudounipolar, bipolar, and multipolar categories, according to structure and particular mechanics of impulse transmission.
2. The neuron is composed of a cell body, one or more dendrites, and an axon. A myelin sheath around selected axons forms an insulation that allows quicker nerve impulse conduction, referred to as *saltatory conduction.*
3. Neurons have four basic types of cell configuration: (a) unipolar, (b) pseudounipolar, (c) bipolar, and (d) multipolar. The three function types of neurons are sensory, associational, and motor.
4. Neuroglial cells ("nerve glue") support the CNS and comprise approximately half of the total brain and spinal cord volume.
5. Nerve injury triggers a sequence of events known as *wallerian degeneration.* The degree of nerve regeneration that occurs depends on many factors.

Nerve Impulse

1. The region between adjacent neurons is the synapse, and the region between the neuron and muscle is the myoneural junction.

SUMMARY REVIEW—cont'd

2. Neurotransmitters are responsible for chemical conduction across the synapse and myoneural junction. The nerve impulse is predominantly regulated by a balance of IPSPs and EPSPs, temporal and spatial summation, and convergence and divergence.

Central Nervous System

1. The brain is contained within the cranial vault and is divided into three distinct regions: (a) forebrain, (b) midbrain, and (c) hindbrain.
2. The forebrain comprises the two cerebral hemispheres and allows conscious perception of internal and external stimuli, thought and memory processes, and voluntary control of skeletal muscles. The deep portion of the forebrain is termed the *diencephalon* and processes incoming sensory data. The center for voluntary control of skeletal muscle movements is located along the precentral gyrus in the frontal lobe, whereas the center for perception is along the postcentral gyrus in the parietal lobe. The Broca area (rostral to the postcentral gyrus) and the Wernicke area (superoposterior temporal lobe) are major speech centers.
3. The midbrain is primarily a relay center for some motor and sensory tracts, as well as a center for auditory and visual reflexes.
4. The hindbrain allows sampling and comparison of sensory data from the periphery and motor impulses from the cerebral hemispheres for the purpose of coordination and refinement of skeletal muscle movement.
5. The spinal cord contains the majority of nerve fibers connecting the brain with the periphery. Reflex arcs are completed in the spinal cord and influenced by the higher centers in the brain.
6. The four clinically relevant motor pathways are the lateral corticospinal, corticobulbar, basal ganglia, and vestibulospinal.
7. The three clinically important afferent pathways are the posterior column, anterior spinothalamic, and lateral spinothalamic.
8. The CNS is protected by the scalp, bony cranium, meninges, vertebral column, and CSF. The CSF is formed from blood components in the choroid plexuses of the ventricles and is reabsorbed in the arachnoid villi (located in the dural venous sinuses) after circulating through the brain and spinal cord.
9. The paired carotid and vertebral arteries supply blood to the brain and connect to form the circle of Willis. The major branches projecting from the circle of Willis are the anterior, middle, and posterior cerebral arteries. Drainage of blood from the brain is accomplished through the venous sinuses and jugular veins.
10. Blood supply to the spinal cord originates from the vertebral arteries and branches arising from the aorta.

Peripheral Nervous System

1. The PNS functions to relay information from the CNS to muscle and effector organs through cranial and spinal nerve tracts arranged in fascicles (multiple fascicles bound together form the peripheral nerve).
2. The 31 pairs of spinal nerves contain sensory and motor neurons.

Autonomic Nervous System

1. The ANS is responsible for the maintenance of a steady-state in the internal environment. Two opposing systems constitute the ANS: (a) the sympathetic nervous system responds to stress by mobilizing energy stores and prepares the body to defend itself, and (b) the parasympathetic nervous system conserves energy and the body's resources.

Aging and the Nervous System

1. Major structural changes with aging include a decrease in number of neurons and a decrease in brain weight and size.
2. Decreased amounts of myelin, deposition of lipofuscin, and the presence of senile plaques, multiple neurofibrillary tangles, and Lewy bodies are common cellular changes with aging.
3. Cerebral atherosclerosis, decreased vascular density, and increased permeability of the blood-brain barrier occur with aging.
4. Functional changes with aging include diminished sensory functions, sleep disturbances, and memory impairments.

Tests of Nervous System Function

1. Tests of nervous system function include x-ray films, CT, MRI and MRA, PET, brain scan, cerebral angiography, myelography, echoencephalography, electroencephalography, EPs, and analysis of CSF.

CHAPTER OUTLINE

Alterations in sensory function may involve dysfunctions of the general or the special senses. Dysfunctions of the general senses include chronic pain and altered temperature regulation. Somatosensory alterations include tactile, proprioceptive, and vestibular dysfunction. Dysfunctions of the special senses include visual, auditory, olfactory, and gustatory (taste) dysfunction.

Pain is a unique sensory experience that, although universally described as unpleasant, is nonetheless essential to our survival. Pain provides protection by signaling the presence of disease or injury. Unlike pain, which need not be a part of everyday life, temperature is carefully monitored and regulated within clearly defined normal limits. Like pain, however, variations in temperature can signal disease. Fever is a common manifestation of dysfunction and is often the first symptom observed in an infectious or inflammatory condition.

Sleep is a normal, cyclic process that restores the body's energy and maintains normal functioning. Sleep is so essential to physiologic and psychologic function that sleep deprivation causes a wide range of clinical manifestations. Prolonged deprivation or disruption of sleep ultimately leads to serious dysfunction.

The special senses of vision, hearing, touch, smell, and taste are the means by which individuals perceive stimuli that are essential for interacting with the environment. Special sensory receptors are connected to specific areas of the brain through

the afferent pathways of the peripheral and central nervous system (CNS). Each of the special senses thus involves a connected system of organs and tissues that receives stimuli and sends sensory messages to areas of the CNS, where they are processed and guide behavior.

PAIN

Pain is one of the body's most important adaptive and protective mechanisms and all definitions suggest it is a complex phenomenon and cannot be characterized as only a response to injury. A widely accepted definition of pain is that drafted by the International Association for the Study of Pain (IASP) and accepted by the American Pain Society and the World Health Organization: "Pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage."[1] Waddell defines pain as "…a symptom, not a clinical sign, diagnosis or disease.…"[2] A clear understanding of the complexities of the pain experience—specifically one that encompasses an individual's emotions, cognition, motivation, prior history, and even issues of secondary gain—is needed to manage pain and to further understand the pain processes. "The inability to communicate verbally does not negate the possibility that an individual is experiencing pain and is in need of appropriate pain-relieving treatment. Pain is always subjective."[2]

Theories of Pain

The theories of pain include the specificity theory, pattern theory, gate control theory, and neuromatrix theory.

Specificity theory proposes that injury activates specific pain receptors and fibers that project to the brain. *Intensity of pain* is directly related to the amount of associated tissue injury (i.e., pricking one's finger with a needle would cause minimal pain, whereas cutting one's hand with a knife would produce more pain). The theory is useful when applied to specific injuries and the acute pain associated with them. It does not account for chronic pain or cognitive and emotional elements that contribute to more complex types of pain.[3]

Pattern theory describes the role of impulse intensity and the repatterning of the central nervous system (CNS). The pattern theory is limited because it does not account for all types of pain experiences.[4,5]

Gate control theory (GCT) integrates and builds upon features of the other theories to explain the complex multidimensional aspects of pain perception and pain modulation.[4] Pain transmission is modulated by a balance of impulses conducted to the spinal cord where cells in the substantia gelatinosa function as a "gate." The spinal gate regulates pain transmission to higher centers in the CNS. Large myelinated A-delta fibers and small unmyelinated C fibers respond to a broad range of painful stimuli (mechanical, thermal, and chemical). These fibers terminate on interneurons in the substantia gelatinosa (laminae in the dorsal horn of the spinal cord). **Nociceptive transmissions** on these fibers "open" the spinal gate and increase the perception of pain. Closure or partial closure of the spinal gates can occur from **non-nociceptive stimulation** (i.e., from touch sensors in the skin). These signals are carried on non-nociceptive larger A-beta fibers and decrease pain perception. This is why rubbing a painful area may alleviate some of the discomfort. Other efferent CNS pathways descend to the spinal cord and may close, partially close, or open the gate modulating the pain experience. The gate control theory, bolstered by progress in understanding neuronal pathways in the peripheral and central nervous systems, has greatly advanced our understanding of pain. As good as the GCT has been, however, there are observations about pain in paraplegics that "do not fit the theory."

Neuromatrix theory proposes that the brain produces patterns of nerve impulses drawn from various inputs, including genetic, psychologic, and cognitive experiences.[6] The qualities we normally feel from the body, including pain, also can be felt in the absence of inputs from the body (as noted with phantom limb pain). In other words, stimuli may trigger the patterns but do not produce them. Neuromatrix patterns are normally activated by sensory inputs from the periphery, but may originate independently in the brain with no external input.[7] The neuromatrix theory illustrates the plasticity (adaptable change in structure and function) of the brain. It does not supplant our understanding of the gate theory, and what we have learned about peripheral inflammation, spinal modulation, and midbrain descending control of pain. The neuromatrix theory expounds upon the gate control theory by explicating a body-self that provides a holistic, integrated, dynamic consideration of pain. However, there are many different kinds of pain and no single theory is adequate to explain the complex dynamics of the pain experience. Continuing research is advancing our understanding of the neural mechanisms of pain.[8,9]

Neuroanatomy of Pain

The integrated function of three portions of the nervous system is responsible for the sensation and perception of pain:

1. The afferent pathways, which begin in the peripheral nervous system (PNS), travel to the spinal gate in the dorsal horn and then ascend to higher centers in the central nervous system (CNS).
2. The interpretive centers located in the brainstem, midbrain, diencephalon, and cerebral cortex.
3. The efferent pathways that descend from the CNS to the dorsal horn of the spinal cord modulate pain.

The processing of potentially harmful (noxious) stimuli through a normally functioning nervous system is called **nociception.** Nociception involves four phases: transduction, transmission, perception and modulation.

Pain transduction begins when tissue is damaged by exposure to chemical, mechanical, or thermal noxious stimuli and is converted to electrophysiological activity. This causes activation of nociceptors,

Nociceptors

Nociceptors are free nerve endings in the afferent peripheral nervous system that selectively respond to different chemical, mechanical, and thermal stimuli. Nociceptors are located throughout the body (Table 16-1) but are not evenly distributed so the relative sensitivity to pain differs according to their location. The variable nature and distribution of nociceptors affects relative

sensitivity to pain in different areas of the body. For example, fingertips have more nociceptors than the skin of the back, and all skin has many more nociceptors than the internal organs. Unlike sensory neurons of the special senses of vision, gustation, and olfaction (discussed later), which are required to detect only one type of sensory stimulus (e.g., light for the sense of vision), primary nociceptive afferents have the remarkable ability to detect a wide range of stimuli. To do this, nociceptors are equipped with an array of transduction channels that can sense different forms of noxious stimulation and at different intensities. In addition to the previously well studied voltage-gated potassium, sodium, and calcium channels, there are multiple types of transmembrane receptors (called *transient receptor potential* [*TRP*] *channels*), which reside on "naked nerve endings" and respond to a variety of physical, chemical, and thermal stimuli.[10]

TABLE 16-1 STIMULI THAT ACTIVATE NOCICEPTORS (PAIN RECEPTORS)

LOCATION OF RECEPTOR	PROVOKING STIMULI
Skin	Pricking, cutting, crushing, burning, freezing
Gastrointestinal tract	Engorged or inflamed mucosa, distention or spasm of smooth muscle, traction on mesenteric attachment
Skeletal muscle	Ischemia, injuries of connective tissue sheaths, necrosis, hemorrhage, prolonged contraction, injection of irritating solutions
Bone	Periosteal injury, inflammation, fractures, tumors
Joints	Synovial membrane inflammation
Arteries	Piercing, inflammation
Head	Traction, inflammation, or displacement of arteries, meningeal structures, and sinuses; prolonged muscle contraction
Heart	Ischemia and inflammation

Nociceptors *(primary order neurons)* are categorized according to the stimulus to which they respond and by the properties of the axons associated with them. **A-delta (Aδ) fibers** are lightly myelinated, medium-sized fibers that are stimulated by severe mechanical deformation *(mechanonociceptors)* or by mechanical deformation and/or extremes of temperature *(mechanothermal nociceptors)*. Aδ fibers rapidly transmit sharp, well-localized "fast" pain sensations. These fibers are responsible for causing reflex withdrawal of the affected body part from the stimulus before a pain sensation is perceived. The smaller **unmyelinated C fibers** are polymodal and are stimulated by mechanical, thermal, and chemical nociceptors. The unmyelinated C fibers slowly transmit dull, aching, or burning sensations that are poorly localized and longer lasting. **A-beta (Aβ) fibers** are large myelinated fibers that transmit touch and vibration sensations. They do not normally transmit pain but play a role in pain modulation.[11]

Pain transmission is the conduction of pain impulses along the Aδ and C fibers into the dorsal horn of the spinal cord and to the brainstem, thalamus, and cortex (Figure 16-1).

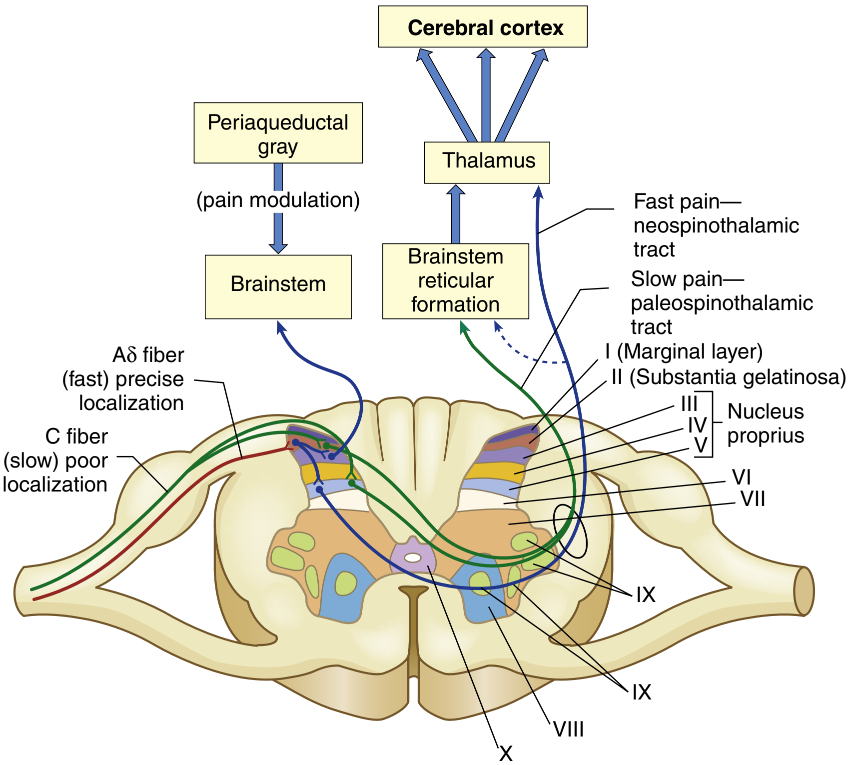

FIGURE 16-1 **Pain Fibers That Terminate Primarily in Laminae II and V of the Dorsal Horn.** The myelinated Aδ fibers (fast localized pain) synapse on a second set of neurons that carry the signal to the thalamus via the neospinothalamic tracts. The C fibers (slow pain) synapse on laminae II and V interneurons that connect with neurons in laminae II, IV, and V and carry the pain signal to the reticular formation and midbrain via the paleospinothalamic tract. The axons of the spinothalamic tracts cross over the spinal cord to ascend in the anterior and lateral spinal cord white matter.

Pathways of Nociception

The cell bodies of *primary-order neurons* or pain-transmitting neurons reside in the dorsal root ganglia just lateral to the spine along the sensory pathways that penetrate the posterior part of the cord. Once the axons of the Aδ and C fibers enter the cord they synapse with interneurons *(second-order neurons)* that may branch into ascending or descending collaterals for one or two cord segments in neuronal projections called the *dorsolateral tract*. Eventually all of the primary afferents terminate on interneurons in the *marginal layer* (laminae I) or *substantia gelatinosa* (laminae II) of the spinal cord (Figure 16-2).

Two classes of interneurons or second-order neurons are found in the dorsal horn: (1) *excitatory interneurons,* which relay nociceptive transmissions to projection cells, to other interneurons, or to motor cells concerned with local reflexes such as the pain withdrawal reflex; and (2) *inhibitory interneurons,* which modulate nociceptive transmission. The synaptic connections between cells of primary and second-order neurons located in the substantia gelatinosa and other spinal laminae function as a "pain gate." The "gate" in the spinal cord regulates the transmission of pain impulses that ascend to the brain for further processing and interpretation (see gate control theory, p. 485).

From the dorsal horn, nociception continues on the axons of projection neurons as they cross the midline of the cord and ascend to various areas of the brain. These ascending fibers are organized into tracts or funiculi that are found in the white matter of the spinal cord, and are named according to their location in the cord and to where they project—either to the higher cord and brainstem or to the diencephalon (thalamus and hypothalamus) and limbic structures. Most nociceptive information travels by means of ascending columns in the lateral spinothalamic tract (also called the anterolateral funiculus) (Figure 16-3).

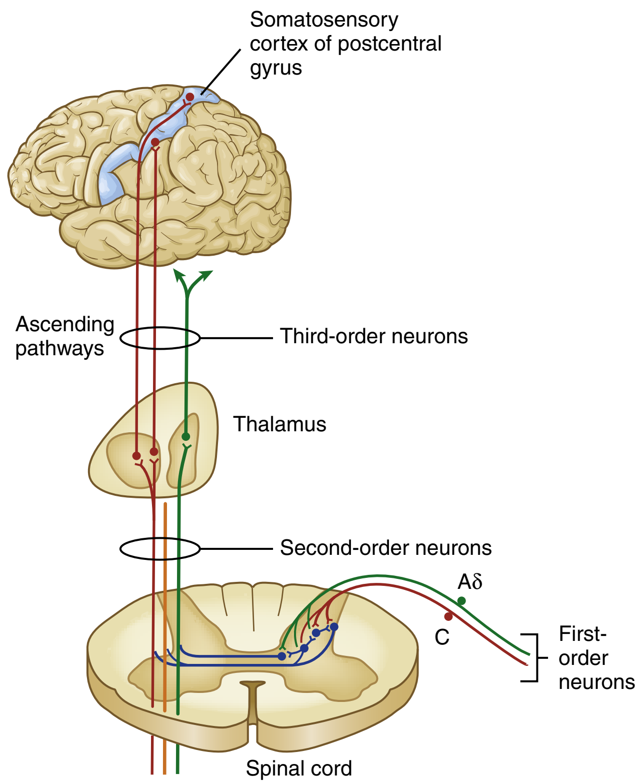

FIGURE 16-2 Nociception Pathways. Aδ and C fibers comprise the primary, first-order sensory afferents coming into the gate at the dorsal horn of the spinal cord. Second-order neurons cross the cord ("decussate") and ascend to the thalamus as part of the spinothalamic tract. Third-order afferents project to higher brain centers of the limbic system, the frontal cortex, and the primary sensory cortex of the postcentral gyrus of the parietal lobe.

Although the organization of all of the ascending tracts is complex, the principal target for nociceptive afferents is the thalamus (the major relay station of sensory information in general). Several other spinal cord projection systems convey nociceptive information directly or indirectly to the reticular formation of the brainstem and the periaqueductal gray (PAG) matter of the midbrain.

From the thalamus, brainstem, and midbrain, *third-order neurons* project to portions of the CNS and cortex involved in the processing and interpretation of pain and neuroendocrine responses (e.g., the response to fright or to surgical stress).[12] The extensive cortical networks that detect and react to pain are referred to as the "pain matrix."[13,14]

Pain perception is the conscious awareness of pain. Interpretation of pain is influenced by many factors including cultural preferences, male and female roles, and life experience, including past pain experiences and current expectations. Three systems interact to produce the perception of pain and individual responses to pain. The **sensory-discriminative system** is mediated by the somatosensory cortex and is responsible for identifying the presence, character, location, and intensity of pain. The **affective-motivational system** determines an individual's conditioned avoidance behaviors and emotional responses to pain. It is mediated through the reticular formation, limbic system, and brainstem with projections to the prefrontal cortex. The **cognitive-evaluative system** overlies the individual's learned behavior concerning the experience of pain and can modulate perception of pain. It is mediated through the cerebral cortex.

Pain Modulation

Pain modulation is the physiologic process of suppressing or facilitating pain. Pain modulation involves many different mechanisms that increase or decrease the transmission of pain signals throughout the nervous system. Depending on the mechanism, modulation can occur before, during, or after pain is perceived.[15]

Pathways of Modulation

Several mechanisms modulate pain both at the level of the spinal cord and in the brain (Figure 16-4). **Segmental inhibition of pain** occurs when Aβ fibers (which synapse in the dorsal horn along with their nociceptive Aδ and C fiber counterparts) close the pain gates through an inhibitory interneuron. These afferent Aβ fibers carry non-noxious low-threshold mechanical information gained by touch, vibration, and pressure. For example, hitting your thumb with a hammer and holding the thumb or putting it into your mouth provides distractive input that lessens the pain.

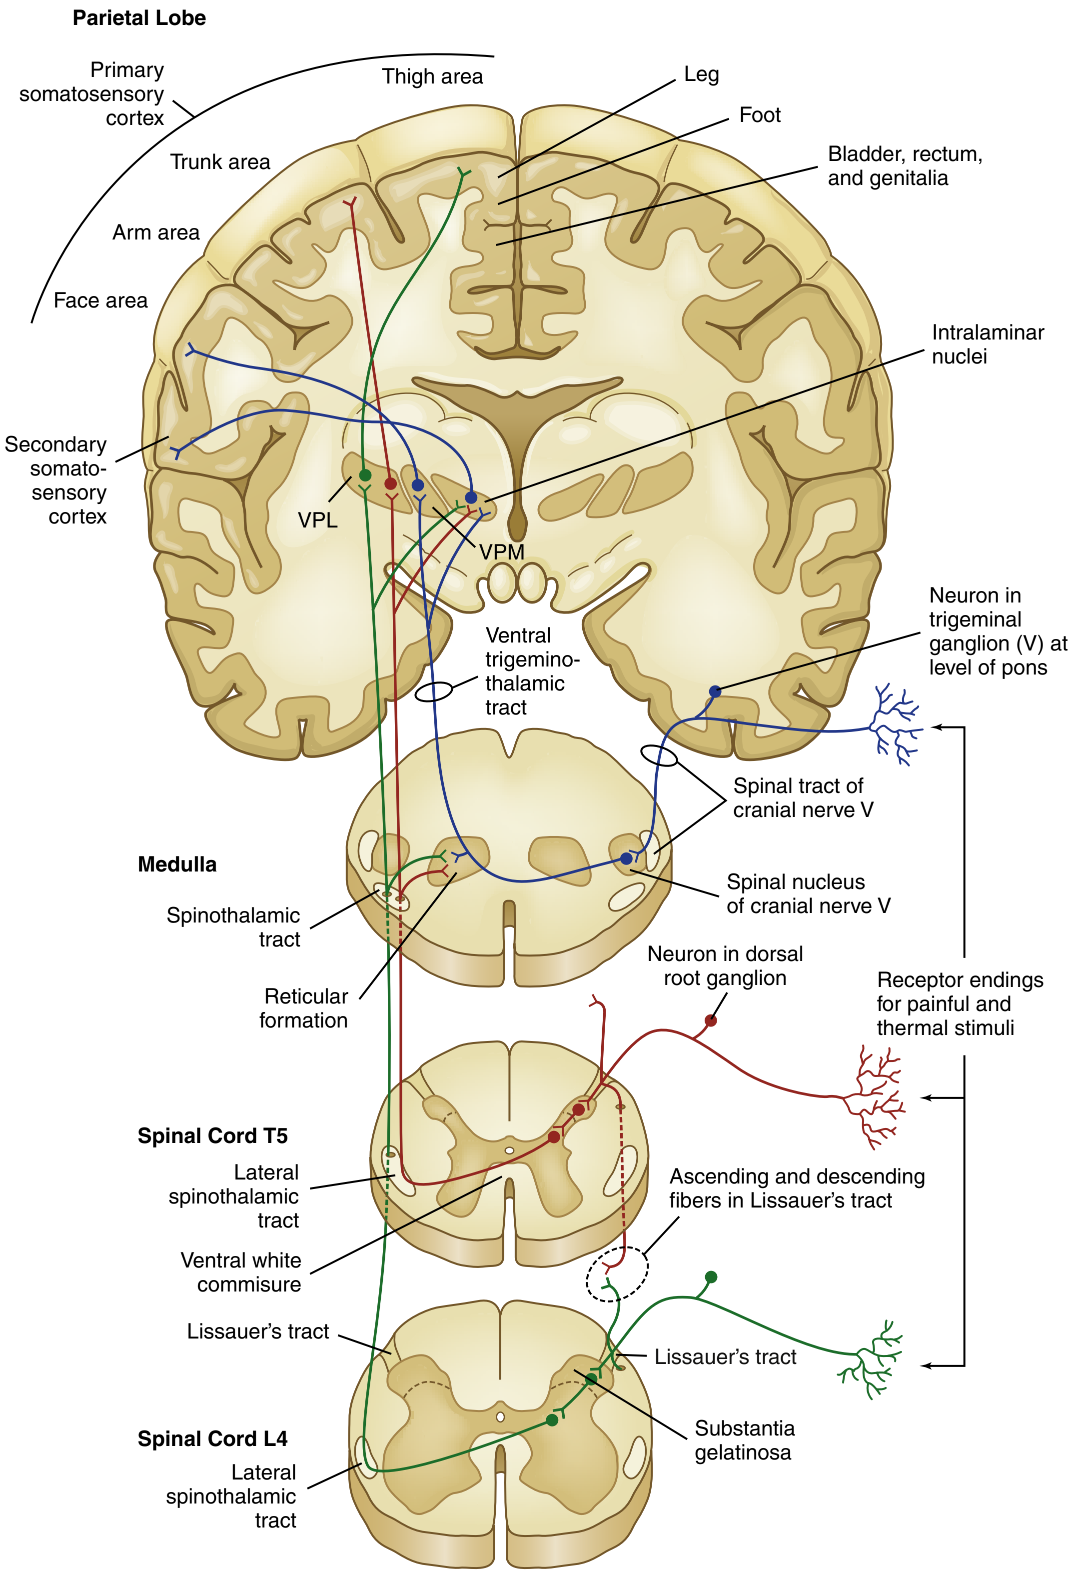

FIGURE 16-3 Central Nervous System Pathways That Mediate the Sensations of Pain and Temperature. *VPL,* Ventral posterior lateral thalamic nuclei; *VPM,* ventral posterior medial thalamic nuclei.

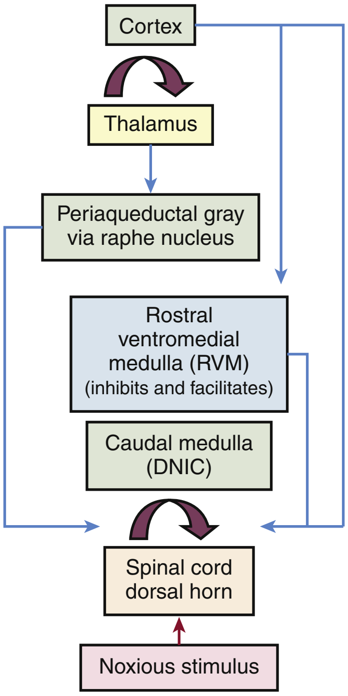

FIGURE 16-4 **Diagram Representing the Central Mechanisms of Pain Modulation.** A noxious peripheral stimulus activates both segmental and top-down (corticofugal and bulbospinal heterosegmental) modulatory mechanisms, which either accentuate or inhibit afferent pain transmission to the brain. The most important and widespread source of top-down (corticofugal) modulation arises from the cortex. Both thalamic and prethalamic nociceptive relays are under the influence of this top-down control. The dorsal horn of the spine is also under the influence of the caudal medulla through diffuse noxious inhibitory control (DNIC). (Modified from Villanueva L, Fields HL: *The pain system in normal and pathological states: a primer for clinicians,* Seattle, 2004, IASP Press.)

Descending modulation of pain arises from many brain areas. Powerful *heterosegmental control of nociception* probably originates from the cortex because almost all nociceptive relays within the CNS are under so-called top-down (corticofugal) modulation that often occurs even in the absence of painful stimuli.[16]

Diffuse noxious inhibitory controls (DNICs) are spinal-medullary-spinal pathways that are activated when peripheral pain stimulation remote from the pain site relieves pain (counter-irritation). It may be the basis for pain relief with acupuncture or deep massage. Several ascending and descending bulbospinal pathways (between the medulla and spinal cord) respond simultaneously to the noxious stimulus and participate in DNICs.[17]

Expectancy-related cortical activation can exert control over analgesic systems of the brainstem to attenuate or intensify pain. In other words, cognitive expectations (also known as the *placebo effect* or *nocebo [adverse] effect*) can cause real, measurable, often powerful physiologic effects that share some of the same descending corticofugal pathways as the pain modulation systems.[18,19]

The entire complex of modulatory pathways represents an integration of peripheral sensory axon terminals, spinal interneurons, and top-down control pathways that converge on the spinal dorsal horns. The result is to modify, dampen, or augment nociceptive transmission, depending on the many factors existing both within and without the organism.[20]

BOX 16-1 STIMULI THAT ACTIVATE NOCICEPTORS

Inflammatory Mediators (Excitatory)
Bradykinin
Leukotrienes
Prostaglandins
Serotonin
Substance P
Interleukins
Tumor necrosis factor-alpha
Nitric oxide
ATP
Neurokinins
Calcitonin gene–related peptide

Excitatory Transmitters
Glutamate (fast pain)
NMDA
AMPA
Tachykinins
Neurokinin A
Neurokinin B
Substance P
Other receptors
Calcitonin gene–related peptides
Somatostatins
Bombesins
Cholecystokinins

Inhibitory Transmitters
Gamma-aminobutyric acid (GABA)
Glycine
Descending pain modulators
Norepinephrine–α_2-receptors
Serotonin (5-hydroxytryptamine)
Opioids (μ, δ, κ receptors)
Endorphins, Enkephalins, Dynorphins — Released from PAG and NRM and other areas of the brain

AMPA, α-Amino-3-hydroxy-5-methyl-4-isoxazole-propionate; *ATP,* adenosine triphosphate; *NMDA, N*-methyl-D-aspartate; *NRM,* nucleus raphes magnus; *PAG,* periaqueductal gray.

Neurotransmitters of Pain Modulation

A wide variety of biogenic amines and other neurotransmitters act to modulate control over the transmission of pain impulses in the periphery, spinal cord, and brain. Pain neurotransmitters can be classified as inflammatory, pain excitatory, or pain inhibitory (Box 16-1). In the periphery, local injury and inflammation can result in direct or indirect excitation or inhibition of nociceptors.

Direct excitation occurs when nociceptors respond with a threshold depolarization initiated by the application of heat, radiation, toxic chemicals, or tissue trauma. *Indirect excitation* occurs when tissue injury results in inflammation and the release of inflammatory mediators including prostaglandins (PGE_2 and PGI_2), tumor necrosis factor-alpha (TNF-α), nitric oxide, bradykinins, histamine, and other cytokines (see Chapter 7). Activity within the nociceptors or damage to them causes them to release peptides and neurotransmitters, such as tachykinins (e.g., substance P and neurokinins), calcitonin gene–related peptide (CGRP), and adenosine triphosphate (ATP), which promote the spread of pain locally and further contribute to vasodilation, increased vascular permeability, and degranulation of even more mast cell cytokines. The resultant “inflammatory soup” serves to lower the threshold for nociceptive depolarization and increases the magnitude of the response to noxious stimulation, known as **hyperalgesia.** The consequence of some or all of these mechanisms is known as **peripheral sensitization.** Normally peripheral sensitization phenomena extinguish themselves as the tissue heals and inflammation subsides. However, when primary afferent function is altered in an enduring way by injury or disease, hyperalgesia may persist and cause chronic pain.

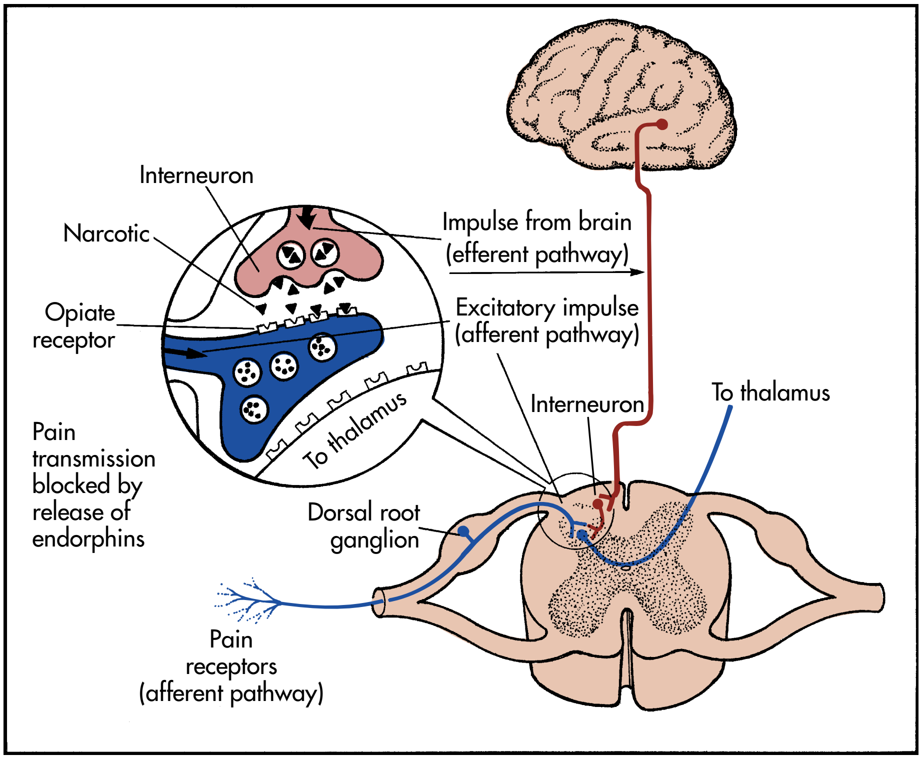

FIGURE 16-5 **Descending Pathway and Endorphin Response.** The biologic receptors of the enkephalins and endorphins are located close to known pain receptors in the periphery and ascending and descending pain pathways.

Excitatory Neurotransmitters. **Glutamate** is the most common excitatory neurotransmitter in the brain and spinal cord. Glutamate activates two different kinds of receptors: AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazole propionate) receptors, which are very fast, and NMDA (*N*-methyl-D-aspartate) receptors, which are implicated in memory and long-term potentiation of synapses. Both of these receptors lead to nerve membrane excitation and depolarization of the cell. Glutamate receptors mediate many spinal and central responses to painful stimulation.[21] High levels of glutamate and aspartate have been found in the periaqueductal gray (PAG) as well as at the synapses of first-order nociceptors with ascending spinothalamic tract neurons. Repeated stimulation of nociceptive afferents results in an activity-dependent increase in the excitability of neurons in the dorsal horn of the cord. Glutamate, which accumulates in the dorsal horn, results in the displacement of a magnesium ion that serves to inhibit the NMDA receptor. With the loss of the blocking magnesium ion, receptor "*wind-up*" or sensitization in the CNS to further nociception becomes evident. This is known as **central sensitization** (increased excitability of neurons). Although central sensitization is triggered in dorsal horn neurons by activity in peripheral nociceptors, innocuous activation of fibers carrying low-threshold mechanoreception (light touch) will activate second-order nociceptive neurons, giving rise to **allodynia** (the induction of pain by normally nonpainful stimuli) and hypersensitivity. Changes in microglia, astrocytes, gap junctions, membrane excitability, and gene transcription also contribute to central sensitization.[22] Thus both peripheral and central sensitization can lead to chronic pain syndromes.

Inhibitory Neurotransmitters. **Gamma-aminobutyric acid (GABA)** and **glycine** have major inhibitory effects in the spinal cord and brain.[23] For example, dorsal horn laminae interneurons are rich in GABA (GABA-A, GABA-B, etc.) and function to inhibit release of pain neurotransmitters. Loss of GABAnergic interneurons in the dorsal horn after nerve injury may cause loss of pain inhibition, resulting in chronic pain.[24] Glycine receptors inhibit pain and also have anti-inflammatory, cytoprotective, and immune modulating effects. Norepinephrine and 5-hydroxytryptamine (serotonin) contribute to pain modulation (inhibition) in the medulla and pons.

Endogenous opioids are a family of morphine-like neuropeptides that inhibit transmission of pain impulses in the spinal cord, brain, and periphery. Their receptors also play a role in various central nervous system, gastrointestinal system, immune system, and other organ system disorders.[25] There are four types of opioid neuropeptides: (1) *enkephalins,* (2) *endorphins,* (3) *dynorphins,* and (4) *endomorphins.* These substances are neurohormones that act as neurotransmitters by binding to one or more G-protein–coupled opioid receptors. Three distinct types of **opioid receptors** are found in the body: mu (μ) meaning morphine (with subtypes μ_1 and μ_2), kappa (κ) (with subtypes κ_1 and κ_2), and delta (δ). A fourth receptor is nociceptin-opioid peptide (NOP) receptor. Its ligand is **nociceptin** and it is homologous to dynorphin.

Each receptor type binds differently with the various types of opioids. Agonist activity at the opioid receptors by endogenous opioids inhibits the release of excitatory neurotransmitters such as substance P in the dorsal horn (blocking the transmission of the painful stimulus) or in other areas of the brain such as the PAG or the rostral ventromedial nuclei in the brainstem (Figure 16-5).

Opioids from the midbrain release adrenergic and serotonergic descending pathways from GABAnergic inhibition and decrease pain. Leukocytes release opioids and participate in peripheral pain control. Because leukocyte opioids do not cross the blood-brain barrier, they do not have central nervous system side effects such as respiratory depression, somnolence, or addiction.[26]

Perhaps the best known and the most prevalent of these natural opioids are the **enkephalins.** There are two types of enkephalins: *methionine-enkephalin* (Met-enkephalin) and *leucine-enkephalin* (Leu-enkephalin), and their ratio is 4:1, respectively. They were the first endogenous opioids extracted in research. Enkephalins, like the other endogenous opioids, can be identified immunohistochemically. They are found concentrated in the hypothalamus, the PAG matter, the nucleus raphe magnus of the medulla, and the dorsal horns of the spinal cord.

Endorphins were first discovered in the human PAG with β-endorphin being the best studied of the group. The synthesis and activity of β-endorphin are concentrated in the hypothalamus and the pituitary gland. β-Endorphin is purported to produce a greater sense of exhilaration, or "high," than all of the other endorphin types. It is a strong μ-receptor agonist and is generally believed to provide substantial natural pain relief.

Dynorphins (the most potent of these endogenous neurohormones) are found in the hypothalamus, the brainstem, the PAG–rostral ventromedial medulla (PAG-RVM) system, and the spinal cord. Dynorphins and nociceptin, which bind strongly to κ-receptors located in the dorsal horn of the spinal cord and in areas of the brain, generally serve to impede pain signals but can, in certain circumstances, incite pain through mechanisms of up-regulation.[27]

Endomorphins have potent analgesic, gastrointestinal (GI), and anti-inflammatory effects. Endomorphin-1 and endomorphin-2 are peptides isolated from the brain and the spinal cord and show the highest affinity and selectivity for the μ-opiate receptor.[28,29]

In addition to analgesic effects, endogenous opioids are involved in a variety of other functions throughout the body including modulation of stress and anxiety, feeding behavior, cough suppression, immune and inflammatory responses, and alcohol intake.[30] Endogenous opioids of one type or another are found to bind to almost all tissues in the body and thus affect numerous biologic functions.[25]

Pain Threshold and Pain Tolerance

Pain threshold is the point at which a stimulus is perceived as pain and it does not vary significantly among people or in the same person over time. Intense pain at one location, however, may cause an increase in the threshold in another location. For example, a person with severe pain in one knee is less likely to experience chronic back pain that is less intense. This phenomenon is called **perceptual dominance.** Because of perceptual dominance, pain at one site may mask other painful areas.[3,31]

Pain tolerance is the duration of time or the intensity of pain that an individual will endure before initiating overt pain responses and is generally decreased with repeated exposure to pain. Pain tolerance is influenced by the person's cultural perceptions, expectations, role behaviors, physical and mental health, gender, fatigue, anger, boredom, apprehension, and sleep deprivation. Tolerance may be increased by alcohol consumption, persistent use of pain medication, hypnosis, warmth, distracting activities, and strong beliefs or faith.[32]

BOX 16-2 CATEGORIES OF PAIN

- I. **Neurophysiologic pain**
  - A. Nociceptive pain
    - 1. Somatic
    - 2. Visceral
    - 3. Referred
  - B. Neuropathic (non-nociceptive)
    - 1. Central pain (lesion/dysfunction in brain or spinal cord)
    - 2. Peripheral pain (lesion/dysfunction in peripheral nervous system [PNS])
- II. **Neurogenic pain**
  - A. Neuralgia (pain in the distribution of a nerve)
  - B. Constant
    - 1. Sympathetically independent
    - 2. Sympathetically dependent
- III. **Temporal pain (time related)**
  - A. Acute pain
  - B. Chronic
- IV. **Regional pain**
  - A. Abdominal pain
  - B. Chest pain

Clinical Descriptions of Pain

Pain can be described in a variety of ways, including duration (acute vs. chronic), inferred neurophysiologic mechanisms (nociceptive vs. non-nociceptive [i.e., neuropathic]), etiology, and region affected. Because of the complex nature of pain, however, many terms overlap and more than one approach is often used. The broad categories of pain are summarized in Box 16-2. Some of the most common clinical pain presentations are summarized in the following sections.

Acute Pain

Acute pain is a protective mechanism that alerts the individual to a condition or experience that is immediately harmful to the body and mobilizes the individual to take prompt action to relieve it. Acute pain is transient, usually lasting seconds to days, and sometimes up to 3 months.[33] It begins suddenly and is

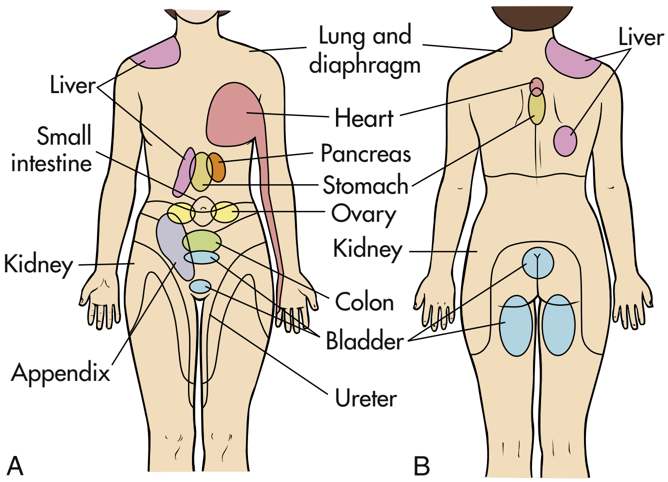

FIGURE 16-6 Sites of Referred Pain. **A,** Front. **B,** Back.

relieved after the chemical mediators that stimulate pain receptors are removed. Stimulation of the autonomic nervous system results in physical manifestations including increased heart rate, hypertension, diaphoresis, and dilated pupils. Anxiety related to the pain experience, including its cause, treatment, and prognosis, is common and there is expectation of limited duration.

Acute pain arises from cutaneous and deep somatic tissue, or from visceral organs and can be classified as (1) acute somatic, (2) acute visceral, and (3) referred.

Somatic pain is superficial, arising from connective tissue, muscle or bone, and skin. It is either sharp and well localized (especially fast pain carried by Aδ fibers) or dull, aching, throbbing, and poorly localized as seen in polymodal C fiber transmissions.

Visceral pain refers to pain in internal organs and the lining of body cavities with an aching, gnawing, throbbing, or intermittent cramping quality. It is transmitted by sympathetic afferents and is poorly localized because of the lesser number of nociceptors in the visceral structures. Visceral pain is associated with nausea and vomiting, hypotension, restlessness, and, in some cases, shock. It often radiates (spreads away from the actual site of the pain) or is referred.

Referred pain is pain that is felt in an area removed or distant from its point of origin—the area of referred pain is supplied by the same spinal segment as the actual site of pain. Impulses from many cutaneous and visceral neurons converge on the same ascending neuron, and the brain cannot distinguish between the two. Because the skin has more receptors, the painful sensation is experienced at the referred site instead of the site of origin. Referred pain can be acute or chronic. Figure 16-6 illustrates common areas of referred pain and their associated sites of origin.

Chronic Pain

Chronic pain is usually defined as lasting at least 3 months and lasting well beyond the expected healing time following the initial onset of tissue damage or injury. Chronic or persistent pain serves no purpose and is poorly understood. It often appears to be out of proportion to any observable tissue injury. It may be ongoing (e.g., low back pain) or intermittent (e.g., migraine headaches). Changes in the peripheral and central nervous systems that cause dysregulation of nociception and pain modulation processes (peripheral and central sensitization) are thought to lead to chronic pain.

The following mechanisms have been implicated in the initiation and entrenchment of chronic pain states[34,35]:

- Changes in sensitivity of neurons—lower threshold with peripheral and central sensitization
- Spontaneous impulses from regenerating peripheral nerves
- Alterations in the dorsal root ganglion in response to peripheral nerve injury and neurotransmitters—reorganization of nociceptive neurons (deafferentation pain)
- Loss of pain inhibition in the spinal cord
- Up-regulation of nociceptive chemokines and their receptors
- Structural and functional alterations in brain processing neural networks

Neuroimaging studies have demonstrated brain changes in individuals with chronic pain that may lead to cognitive deficits and decreased ability to cope with pain.[36,37] It is thought to be due, in part, to the stress of coping with continuous pain and may be reversible when pain is controlled.[38,39] Chronic pain often does not respond to usual therapy. Because it is not yet possible to predict when acute pain will develop into chronic pain, early and individualized prevention and treatment of acute pain is encouraged.[40,41]

Physiologic responses to intermittent chronic pain are similar to those associated with acute pain, whereas persistent pain allows for physiologic adaptation, producing normal heart rate and blood pressure. This leads many to mistakenly conclude that people with chronic pain are malingering because they do not appear to be in pain. As chronic pain progresses, certain behavioral and psychologic changes often emerge, including depression, difficulty eating and sleeping, preoccupation with the pain, and avoidance of pain-provoking stimuli.[42] The desire to relieve pain and the need to hide it become conflicting drives for those with chronic pain, who fear being labeled complainers.[43,44] Comparison of acute and chronic pain is summarized in Table16-2. Common chronic pain conditions are listed in Table 16-3.

Chronic Pain Syndromes. **Specific** (i.e., intervertebral disk degeneration) and **non–specific low back pain** (not attributable to a specific pathologic source) are global, common, chronic, and disabling pain conditions. The prevalence of non–specific low back pain is about 23% with 11% to 12% of those affected being disabled.[45,46] Prevalence estimates and definition of risk factors vary among studies depending on the definition of low back pain used. Acute back pain is relatively rare and many individuals of all ages have chronic recurrent back pain. Both cortical and spinal alterations in pain processing are associated with low back pain. Treatment is often ineffective and the personal and societal burden is great.[45,47,48]

Myofascial pain syndrome (MPS) is associated with injury to muscle, fascia, and tendons and includes myositis, fibrositis, myofibrositis, myalgia (see Chapter 44 for fibromyalgia),

TABLE 16-2 COMPARISON OF ACUTE AND CHRONIC PAIN

CHARACTERISTIC	ACUTE PAIN	CHRONIC PAIN
Experience	An event	A situation; state of existence
Source	External agent or internal disease usually known	Unknown; if known, treatment is prolonged or ineffective
Onset	Usually sudden	May be sudden or develop insidiously
Duration	Transient (up to 6 months)	Prolonged and persistent (months to years)
Pain identification	Painful and nonpainful areas generally well identified	Painful and nonpainful areas less easily differentiated: change in sensations becomes more difficult to evaluate
Clinical signs	Increased pulse rate, elevated blood pressure, increased respiratory rate, diaphoresis, dilated pupils	Response patterns vary; fewer overt signs (adaptation)
Significance	Significant (informs person something is wrong)	Person looks for significance
Pattern	Self-limiting or readily corrected	Continuous or intermittent; intensity may vary or remain constant
Course	Suffering usually decreases over time	Suffering usually increases over time
Actions	Leads to actions to relieve pain	Leads to actions to modify pain experience
Prognosis	Likelihood of eventual complete relief	Complete relief usually not possible

Data from Black RG: *Surg Clin North Am* 55(4):999, 1975.

TABLE 16-3 COMMON CHRONIC PAIN CONDITIONS

CONDITION	DESCRIPTION
Persistent low back pain	Most common chronic pain condition Results from poor muscle tone, inactivity, muscle strain, or sudden, vigorous exercise
Myofascial pain syndromes	Second most common chronic pain condition Pain results from muscle spasm, tenderness, and stiffness Examples include myositis, fibrositis, myofibrositis, myalgia, and muscle strain—conditions that involve injury to the muscle and fascia As disorder progresses, pain becomes increasingly generalized
Chronic postoperative pain	Chronic pain that can occur with disruption or cutting of sensory nerves
Cancer pain	Can be pain attributed to advance of disease, associated with treatment, or attributed to coexisting disease entities
Deafferentation pain	Painful condition resulting from damage to a peripheral nerve Common types include severe burning pain triggered by various stimuli, such as cold, light touch, or sound, and reflex sympathetic dystrophies (occur after peripheral nerve injury and are characterized by continuous, severe, burning pain associated with vasomotor changes and muscle wasting)
Hyperesthesias	Increased sensitivity and decreased pain threshold to tactile and painful stimuli Pain is diffuse, modified by fatigue and emotion, and mixed with other sensations May result from chronic irritations of central nervous system areas
Hemiagnosia	Loss of ability to identify source of pain on one side of the body Painful stimuli on that side produce discomfort, anxiety, moaning, agitation, and distress but no attempt to withdraw from the stimulus Associated with stroke
Phantom limb pain	Pain experienced in amputated limb after stump has completely healed; may be immediate or occur months later Influenced by emotions or sympathetic stimulation Trigger points—small hypersensitive regions in muscle or connective tissues that, when stimulated, produce pain in a specific area

and muscle strain. These conditions involve myofascial trigger points within a taut band of skeletal muscle. The pain may be the result of low-threshold mechanosensitive afferents projecting to sensitized dorsal horn neurons and the development of peripheral and central sensitization.[49] Neuroaxonal degeneration with alterations in neuromuscular transmission may occur. Compression of the trigger point causes referred pain, motor dysfunction, and autonomic responses. During the early stages of the disorder the pain is localized, but as the disorder progresses it becomes deep, aching, and more generalized. These, like many other chronic conditions, begin as a result of poor muscle tone, inactivity, muscle or tendon strain, or sudden vigorous exercise and can evolve into a chronic pain state.

Chronic postoperative pain occurs in some individuals and includes complex regional pain syndrome, phantom limb pain, chronic donor site pain, post-thoracotomy pain syndrome, postmastectomy pain syndrome, and joint arthroplasty pain. Plastic changes in the peripheral nervous system (PNS) and CNS contribute to allodynia and hypersensitivity. Multimodal approaches to analgesia are needed for pain management including adequate management of preoperative pain and postoperative management of acute pain.[41,50]

Cancer pain is often chronic and associated with neuropathies. The categories include[51]: (1) pain attributed to tumor growth and advance of the disease, (2) pain associated with treatment of the disease, and (3) pain attributed to coexisting entities (e.g., osteoarthritis) that are unrelated to the disease. Cancer and immune cells can release mediators that sensitize primary afferent nociceptors in the area of the tumor. Infection and inflammation, increasing pressure of a growing tumor on nerve endings, tissue destruction, distention of visceral surfaces, and obstruction of ducts and intestine also cause pain.[52] Alterations in the dorsal horn and other central pain processing pathways lead to central sensitization and chronic pain.[52] Therapeutic approaches to the management of cancer pain have advanced significantly in recent years, particularly in palliative care and hospice programs. Frequent assessment of pain, management of breakthrough pain, and implementation of individualized interdisciplinary therapeutic strategies (including pharmacotherapeutic, anesthetic, neurosurgical, psychologic, and rehabilitative techniques along with frequent evaluations) are essential to optimal cancer pain management.[53]

Neuropathic Pain

Neuropathic pain results from primary injury to the peripheral or central nervous system and is not the result of pain signaling from peripheral tissues or organs. Chronic neuropathic pain leads to long-term plastic changes along somatosensory pathways from the periphery to the cortex and abnormal processing of sensory information by the PNS and CNS. The pathogenesis of neuropathic pain syndromes includes both peripheral and central mechanisms of pain sensitization.[54]

Peripheral neuropathic pain is caused by peripheral nerve trauma, diabetic or alcohol abuse–induced neuropathy, carcinoma, nutritional deficiencies, and human immunodeficiency virus (HIV). When injured nerves become hyperexcitable, they generate ectopic discharges, resulting in spontaneous firing of some neurons with low thresholds for mechanical, chemical, or thermal stimuli. Pain sensation can occur in the absence of a stimulus and may be evoked by movement *(incident pain),* and hypersensitivity and/or allodynia may be present in the involved body part.

Central neuropathic pain is caused by a lesion or dysfunction in the CNS (brain or spinal cord). Alterations of the sensory pathways and impairment of descending inhibitory mechanisms contribute to the pain. Examples of central causes of neuropathic pain include brain or spinal cord trauma, tumors, vascular lesions, multiple sclerosis, Parkinson disease, postherpetic neuralgia (PHN), phantom limb pain, and reflex sympathetic dystrophy.

Neuropathic pain is often paroxysmal with hyperesthesia and paresthesias (tingling sensations of pins and needles), burning, shooting, or stabbing sensations. Neuropathic pain is often described as "gnawing" and miserable. No single diagnostic test for neuropathic pain (or for pain in general) is available, and differentiating some neuropathies from other chronic somatic pain syndromes can be difficult.[55,56]

Lesions resulting in loss of sensory input to the dorsal column of the spinal cord from a part of the body are called *deafferentation*. **Deafferentation pain syndromes** are neuropathies that result from lesions in the peripheral nervous system (i.e., complex regional pain syndrome type II, postherpetic neuralgia, phantom limb pain, tumor infiltration of nerve tissue; damage from radiation, chemotherapy, brachial plexus avulsion, or surgical sectioning of a nerve) or lesions in the central nervous system that interrupt the spinothalamic pathways at any level of the nervous system (i.e., thalamic lesions or stroke). Deafferentation pain syndromes are associated with hyperexcitability of the somatosensory thalamus and cortex.[57] Deafferentation pain, which is poorly controlled by many analgesics, is usually described as a constant, dull, viselike ache, accompanied by paroxysms of burning or electric shock–like sensations. There may be loss of temperature sensation. The pain may manifest over a large and diffuse area or be well-defined and circumscribed. It is usually irritating and constant, can be difficult to treat, and can cause considerable suffering.[58,59]

Hemiagnosia pain is a form of central pain associated with stroke that produces paralysis and hypersensitivity/allodynia on one half of the body. In this painful condition, often a concomitant loss of ability to identify the source of pain through normal sensory pathways occurs. The result is a confusing presentation in which even mild stimulation of the affected side of the body produces discomfort, anxiety, moaning, agitation, and distress, with a diminished ability to withdraw from the offending stimulus.

Phantom limb pain is pain that an individual feels in an amputated limb after the stump has completely healed. Nonpainful phantom limb sensations occur in almost all amputees, but the sensations usually fade with time. This is distinguished from the syndrome of phantom limb pain, a chronic pain occurring in 80% to 100% of amputees.[60,61] It is more likely to appear in individuals who experienced pain in the limb before amputation. Theories about the cause of phantom limb pain include regeneration or hyperactivity of injured or cut peripheral nerves, scar tissue or neuroma formation in the cut peripheral nerves, spinal cord deafferentation, and alterations in the thalamus and cortex. It has been proposed that CNS integration, including reorganization and plastic changes of the somatosensory cortex, results in the perception of pain from receptors associated with the amputated limb even though the limb itself is no longer present.[62] The absence of inhibitory effects of sensory input from the missing peripheral body part may cause increased autonomous activity of dorsal horn neurons with pain transmission. The cause is likely multifactorial, contributing to the difficulty of prevention or effective treatment.[63]

Sympathetically mediated pain (SMP) is another type of neuropathic pain that can occur after peripheral nerve or extremity injury. The diseases formerly called *reflex sympathetic dystrophy* and *causalgia,* both thought to arise from sympathetic nervous system imbalance, are now called **complex regional pain syndromes (CRPSs)** type I (associated with injury but no apparent nerve injury) and type II (evidence of nerve injury). CRPS develops 1 to 2 weeks after an extremity injury (e.g., a fracture without identifiable nerve injury) (type I) or an injury to the brachial plexus or the median, sciatic, or other peripheral nerves (type II). The exact pathophysiologic mechanism is

unclear. A combination of injury and the presence of inflammatory cytokines and neuropeptides may lead to peripheral nociceptive sensitization and physiologic change in pain transmission and autonomic and motor systems.[64] The severe, diffuse, burning, and persistent pain occurs in the extremity or area supplied by the injured nerve. Hypersensitivity and allodynia are common. Discoloration and changes in the texture of the skin may appear in the affected area. Vasomotor changes usually begin with vasodilation and are followed by vasoconstriction and cool, cyanotic, and edematous extremities. Swelling and stiffness of proximate joints may occur. Hair loss is usually noted and there are changes in skin color and temperature.[65]

In the evaluation and management of neuropathic pain, as well as all other chronic pain states, psychologic components (e.g., depression or anxiety), sleep disturbances, work-related issues of impairment and disability, treatment expectations, the availability of social support from family and friends (or lack thereof), and legal compensation should not be overlooked.[66]

PEDIATRICS AND PERCEPTION OF PAIN

Infants and children have the anatomic and functional ability to perceive pain. Pain pathways and cortical and subcortical centers for pain perception, as well as neurochemicals associated with pain transmission and modulation, are functional in preterm and newborn infants. The nociceptor system is functional in fetuses by 20 to 24 weeks of gestation although the cortical experience may be minimal.[67,68] Repetitive, painful experiences and prolonged exposure to analgesic drugs in infants, in children, and during the neonatal period may permanently alter synaptic and neuronal organization[69] and fetal pain may have an enduring effect on behavior and pain perception.[70,71]

Facial expression, crying, body movements, and lack of consolability are the most consistent expressions of pain in infants. The painful facial expression includes lowered brows drawn together; presence of a vertical bulge and furrows in the forehead between the brows; broadened nasal root; tightly closed, scourged eye fissures; and angular, tongue cupping, squarish mouth and chin quiver (Figure 16-7). Physiologic responses include increases in heart rate, blood pressure, and respiratory rate although these measures lack sensitivity and specificity. There may be flushing or pallor, sweating, and decreased oxygen saturation.[72] Toddlers also express pain with crying, facial expression, and body language (tensed body, guarding, and hands holding body). Older children, between ages 5 and 18 years, tend to have a lower pain threshold than do adults. Children, like adults, have highly individual responses to pain. Any behavioral and physiologic indicators of pain must be carefully and accurately assessed[73] and adequately treated for children of all ages.[74,75]

AGING AND PERCEPTION OF PAIN

Studies on pain perception in the older adult population have yielded conflicting evidence. Some studies show an increase in pain threshold with aging; others show no change.[76-78] The varied results are probably a function of independent variation in

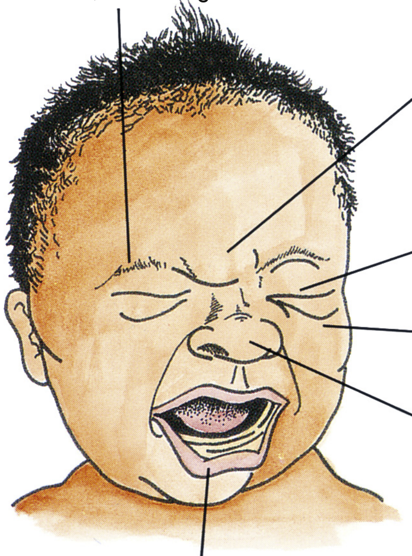

FIGURE 16-7 Painful Facial Expression of Infants. (From Hockenberry MJ: *Wong's nursing care of infants and children,* ed 7, St Louis, 2003, Mosby.)

the sensory-discriminative, motivational-affective, and cognitive-evaluative components of the pain experience. In general, studies confirm that an increase in the pain threshold occurs in some older adults. This change may be caused by peripheral neuropathies and changes in the thickness of the skin or cognitive impairment. (Neuropathies are discussed in Chapter 18.) A decrease in pain tolerance is also evident in some older adults, and women appear to be more sensitive to pain than are men[79,80] (see What's New? Pain and Gender). Pain in the older adult is also influenced by liver and renal function, including alterations in metabolism of drugs and metabolites and age-associated brain changes. Pain must be accurately assessed in relation to its effect on cognitive function, coexisting disease, drug interactions, other reactions to treatment, and an individual's ability to express pain and safety.[43] Poorly managed pain can result in depression, inactivity, and failure to maintain activities of daily living.[81]

TEMPERATURE REGULATION

In all homeothermic animals, temperature regulation is achieved through precise balancing of heat production, heat conservation, and heat loss. In humans, body temperature is maintained around 37° C (98.6° F) and rarely exceeds 41° C (105.8° F). The normal range is 36.2° to 37.7° C (97.2° to 99.9° F), but all parts of the body do not have the same temperature. The extremities, for example, are generally cooler than the trunk. The temperature at the core of the body (as measured by rectal temperature) is generally 0.5° C higher than the surface temperature (as measured by oral temperature) and has minimal fluctuations. The internal temperature varies normally in response to activity, environmental temperature, and daily

WHAT'S NEW?

Pain and Gender

Gender differences in the experience of pain and the response to analgesics have been studied in both animal and human research. Women report higher pain levels or have less tolerance for pain stimuli, such as heat, cold, pressure, and electrical stimulation. The differences may be related to mechanisms of excitatory and inhibitory control. Gender differences exist also in the prevalence of painful chronic diseases; for example, women are more affected by intestinal cystitis, fibromyalgia, and rheumatoid arthritis, and men are more affected by cluster headache. Pain symptoms differ for men and women for diseases such as coronary artery disease, irritable bowel syndrome, appendicitis, and cancer. Sex hormones are known to have an effect on the mechanisms and outcomes of opiate analgesia, and in rodents, morphine analgesia is more effective in males than in females. Pain sensitivities in women also vary across the phases of the menstrual cycle. Recent human and animal studies suggests that κ-opioid receptor analgesia is greater in women than in men and may reflect a difference in endogenous pain circuits mediated by different opiate receptor subtypes and influenced by effects of estrogen and progesterone. Gender differences with respect to pain also are influenced by role socialization, cognitive factors, and culture. Continuing research is needed to further understand gender differences in the operation of pain mechanisms and the development of more specific pain management strategies.

Data from Leresche L: *Clin Orthop Relat Res* 469(7):1871–1877, 2011; Mogil JS, Bailey AL: *Prog Brain Res* 186:141–157, 2010; Palmeira CC, Ashmawi HA, Posso Ide P: *Rev Bras Anestesiol* 61(6):814–828, 2011; Popescu A et al: *Pain* 150(2):309–318, 2010; Racine M et al: *Pain* 153(3):602–618, 2012; Racine M et al: *Pain* 153(3):619–635, 2012; Rasakham K, Liu-Chen LY: *Life Sci* 88(1-2):2–16, 2011.

fluctuation of **circadian rhythm** (the pattern of each 24-hour day). Oral temperatures generally fluctuate within 0.2° to 0.5° C during a 24-hour period. Women tend to have wider fluctuations that follow the menstrual cycle, with a sharp rise in temperature just before ovulation. In both genders the daily fluctuating temperature peaks around 6 PM and is at its lowest during sleep.[82] Maintenance of body temperature within the normal range is necessary for life.

Hypothalamic Control of Temperature

Temperature regulation **(thermoregulation)** is mediated by the hypothalamus. Peripheral thermoreceptors in the skin and abdominal organs (unmyelinated C fibers and thinly myelinated Aδ fibers) and central thermoreceptors in the spinal cord and other central locations provide the hypothalamus with information about skin and core temperatures. If these temperatures are low or high, the hypothalamus responds by triggering heat production, heat conservation, or heat loss mechanisms. The endocrine system also operates to control body temperature.[83]

Increased **heat production** is initiated by a series of hormonal mechanisms involving the hypothalamus and its connections with the endocrine system. The heat-producing mechanism begins with a hypothalamic hormone, thyroid-stimulating hormone–releasing hormone (TSH-RH). In turn, TSH-RH stimulates the anterior pituitary to release TSH, which acts on the thyroid gland, stimulating release of thyroxine (T_4), one of the thyroid hormones. This hormone then acts on the adrenal medulla, causing the release of epinephrine (a catecholamine and vasopressive hormone) into the bloodstream (see Chapter 21). Epinephrine causes vasoconstriction (improves thermal insulation), stimulates glycolysis, and increases metabolic rates, thus increasing heat production. Heat is distributed by the circulatory system.

The hypothalamus also triggers heat conservation. The mechanisms of heat conservation involve stimulating the sympathetic nervous system, which is responsible for stimulating the adrenal cortex, increasing skeletal muscle tone, initiating the shivering response, and producing vasoconstriction. The hypothalamus also functions in raising body temperatures by relaying information to the cerebral cortex. Awareness of cold provokes voluntary responses such as increasing body movement and wearing protective clothing.

The hypothalamus responds to warmer core and peripheral temperatures by reversing the same mechanisms. The TSH-RH pathway is shut down. The sympathetic pathway is prompted to produce cutaneous vasodilation, decreased muscle tone, and increased sweat production. Hypothalamic stimulation of the cerebral cortex provokes voluntary behavior to reduce heat production and promote heat loss.[84]

Mechanisms of heat production, heat loss, and heat conservation maintain body temperature within a narrow range of 98° F (36.6° C) and 100° F (37.7° C) when the ambient temperature is between 68° F (20° C) and 130° F (54.4° C).

Mechanisms of Heat Production

Chemical Reactions of Metabolism. The *chemical reactions* that occur during the ingestion and metabolism of food and those required to maintain the body at rest (basal metabolism) require energy and produce heat. These processes occur in the body core (primarily the liver) and are in part responsible for the maintenance of core temperature.

Skeletal Muscle Contraction. Skeletal muscles produce heat through two mechanisms: (1) gradual increase in muscle tone and (2) production of rapid muscle oscillations (*shivering*—which does not occur in neonates). Both increasing muscle tone and shivering are controlled by the posterior hypothalamus and occur in response to cold. As peripheral temperature drops, muscle tone increases and shivering begins. Shivering is a fairly effective method for increasing heat production because no work is performed and all the energy produced is retained as heat.[85]

Chemical Thermogenesis. Chemical thermogenesis, also called *nonshivering thermogenesis* or *adrenergic thermogenesis*, results from the release of epinephrine and norepinephrine. Epinephrine and norepinephrine produce a rapid, transient increase in heat production by raising the body's basal metabolic rate. Chemical thermogenesis seems to be different from hormone-triggered increases in the basal metabolic rate. Chemical thermogenesis produces a quick, brief rise in basal metabolic rate, whereas the hormone thyroxine triggers a slow, prolonged rise. Chemical thermogenesis occurs in brown adipose tissue. Brown adipose tissue is rich with mitochondria and blood vessels and is essential for nonshivering thermogenesis. White and brown adipocytes are found together in visceral and subcutaneous tissue. White adipocytes store energy and

brown adipocytes produce heat. Adipocytes demonstrate transdifferentiation and such plasticity allows direct conversion of one cell type into the other. With chronic cold exposure white-to-brown conversion increases thermogenesis, whereas excessive food consumption induces brown-to-white conversion to meet the need for energy storage.[86]

Mechanisms of Heat Loss

Heat loss is achieved through many mechanisms: (1) radiation, (2) conduction, (3) convection, (4) vasodilation, (5) decreased muscle tone, (6) evaporation, (7) increased pulmonary ventilation, (8) voluntary measures, and (9) adaptation to warmer climates.

Radiation. **Radiation** refers to heat loss through electromagnetic waves. These waves emanate from surfaces with temperatures higher than the surrounding air temperature. Thus if the temperature of the skin is higher than that of the air, the skin and therefore the body lose heat to the air.

Conduction. **Conduction** refers to heat loss by direct molecule-to-molecule transfer from one surface to another. Through conduction, the warmer surface loses heat to the cooler surface. Thus the skin loses heat through direct contact with cooler air, water, or another surface. In the same manner, the core of the body loses heat to the cooler body surface.

Convection. **Convection** is the transfer of heat through currents of gases or liquids. It greatly aids heat loss through conduction by exchanging warmer air at the surface of the body with cooler air in the surrounding space. Convection occurs passively as warmer air at the surface of the body rises away from the body and is replaced by cooler air, but the process may be aided by fans or wind. (The combined effect of conduction and convection by wind is conventionally measured as the *windchill factor*.)

Vasodilation. Peripheral vasodilation increases heat loss by diverting core-warmed blood to the surface of the body. As the core-warmed blood passes through the periphery, heat is transferred by conduction to the skin surface and from the skin to the surrounding environment. Because heat loss through conduction depends on the surrounding temperature, it is minimal to nonexistent if the surrounding air or water is warmer than the body surface.

Vasodilation occurs in response to autonomic stimulation under the control of the hypothalamus. It is useful in instances of moderate temperature elevation. As core temperature increases, vasodilation increases until maximal dilation is achieved. At that point the body must use additional heat loss mechanisms.

Decreased Muscle Tone. To decrease heat production, muscle tone may be moderately reduced and voluntary muscle activity curtailed. These mechanisms explain in part the "washed-out" feeling associated with high temperatures and warm weather. Decreased muscle tone and reduced activity have a limited effect on decreasing heat production, however, because muscle tone and heat production cannot be reduced below basal body requirements.

Evaporation. Evaporation of body water from the surface of the skin and the linings of the mucous membranes is a major source of heat reduction. Insensible water loss (in the absence of perceptible sweating) accounts for a loss of about 600 ml of water per day. Heat is lost as surface fluid is converted to gas, so that heat loss by evaporation is increased if more fluids are available at the body surface. To speed this process, fluids are actively secreted through the sweat glands. As much as 2.2 L of fluid per hour may be lost by sweating. Electrolytes are lost with the water. Therefore, loss of large volumes through sweating may result in decreased plasma volume, decreased blood pressure, weakness, and fainting. (Alterations in fluid balance are discussed in Chapter 3.)

Like other heat reduction mechanisms, stimulation of sweating occurs in response to sympathetic neural activity and depends on a favorable temperature difference between the body and the environment. In addition, heat loss through evaporation is affected by the relative humidity of the air. If the humidity is low, sweat evaporates quickly, but if the humidity is high, sweat does not evaporate and instead remains on the skin or drips off.

Increased Pulmonary Ventilation. Exchanging air with the environment through the normal pulmonary ventilation provides some heat loss, although it is minimal in humans. As air is inhaled, the air draws heat from the upper respiratory tract. The air is further warmed in the alveoli by blood in the microcirculation. This warmed air then is exhaled into the environment. This normal process occurs faster at higher body temperatures through an increase in ventilatory rates. Thus hyperventilation is associated with hyperthermia. (Normal pulmonary function is discussed in Chapter 34.)

Voluntary Mechanisms. In response to high body temperatures, people physically "stretch out," thereby increasing the body surface area available for heat loss. They also "slow down" or "take it easy," thereby decreasing skeletal muscle work, and they "dress for warm weather" with light-colored, loose-fitting garments to reflect heat and promote convection, conduction, and evaporation.

Adaptation to Warmer Climates. The body of an individual who moves from a cooler to a much warmer climate undergoes a period of adjustment, a process that takes several days to weeks. At first the individual experiences feelings of lassitude, weakness, and faintness with even moderate activity. Body temperatures rise with any work. Within several days, however, the individual experiences an earlier onset of sweating, the volume of sweat is increased, and the sodium content is lowered. Heart rate is decreased and stroke volume increased so that cardiac output remains unchanged. Extracellular fluid volume increases, as does plasma volume. These physiologic adaptations result in improved warm weather functioning and decreased symptoms of heat intolerance. People's work output, endurance, and coordination increase, and their subjective feelings of discomfort decrease.[87]

Mechanisms of Heat Conservation

The body conserves heat and protects core temperature through two important mechanisms: (1) involuntary vasoconstriction mediated by the sympathetic nervous system and (2) voluntary mechanisms.[88] To preserve core temperature, the skin and periphery are used as an insulating cover.[87]

Vasoconstriction. By constricting peripheral blood vessels, centrally warmed blood is shunted away from the periphery (where radiation, conduction, and convection would allow heat loss) to the core of the body, where heat can be retained. This mechanism takes advantage of the insulating layers of the skin and subcutaneous fat to protect core temperature.

Voluntary Mechanisms. In response to lower body temperatures, individuals typically "bundle up," "keep moving," or "curl up in a ball." Bundling up involves dressing with several layers of clothes that allow air to be trapped between the skin and the clothing, thus providing an additional layer of insulation. Keeping moving, stamping feet, clapping hands, jogging, and other types of physical activity increase skeletal muscle activity and thus promote heat production. Curling up in a ball decreases the amount of skin surface available for heat loss through radiation, convection, and conduction.

PEDIATRICS AND TEMPERATURE REGULATION

Infants and older adults require special attention to maintenance of body temperature. Term infants produce sufficient body heat, primarily through the metabolism of brown fat, but they are unable to efficiently conserve heat because of the infant's small body size, greater ratio of body surface area to body weight with heat loss through conduction and convection, and inability to shiver. Infants have a thin layer of subcutaneous fat and thus are not as well insulated as adults.[89] Therefore, it is important to keep infants warm with hats, clothing, and blankets. Children also have a greater ratio of body surface area to body weight, lower sweating rate, higher peripheral blood flow in the heat, and a greater extent of vasoconstriction in the cold than adults. They can acclimatize to changes in environmental temperatures, but do so at a lower rate than that seen in adults.[90]

AGING AND TEMPERATURE REGULATION

Older adults have poor responses to environmental temperature extremes as a result of slowed blood circulation, structural and functional changes in the skin, an overall decrease in heat-producing activities, and the presence of disease (i.e., congestive heart failure, chronic lung disease, diabetes mellitus, or peripheral vascular disease). Cold stress in older adults also decreases coronary perfusion.[91] Other factors affecting thermal regulation in the older adult population include decreased shivering response (delayed onset and decreased effectiveness), slowed metabolic rate, sedentary lifestyle, decreased vasoconstrictor and vasodilator responses, diminished or absent sweating, desynchronization of circadian rhythm, undernutrition, and decreased perception of heat and cold.[92-94]

Pathogenesis of Fever

Fever (febrile response or pyrexia) is a temporary resetting of the hypothalamic thermostat to a higher level in response to endogenous or exogenous pyrogens.[95] The pathophysiologic mechanism of fever begins with the introduction of **exogenous pyrogens** or endotoxins produced by pathogens (Figure 16-8). The most frequently encountered exogenous pyrogens are the lipopolysaccharide complex in the cell wall of gram-positive bacteria and viruses. **Endogenous pyrogens,** including prostaglandin E_2 (PGE_2), interleukin-1 (IL-1), IL-6, tumor necrosis factor-alpha (TNF-α), and interferon-γ, are produced by phagocytic cells as they destroy microorganisms within the host. The endogenous pyrogens act on the preoptic nucleus of the hypothalamus. An integrated behavioral, endocrine, and autonomic nervous system response is then initiated. Centers in the hypothalamus and brainstem signal an increase in heat production and heat conservation to raise body temperature to the new set point. Peripheral vasoconstriction occurs with shunting of blood from the skin to the body core. Epinephrine release increases metabolic rate, and muscle tone increases. Decreased release of vasopressin reduces the volume of body fluid to be heated. Shivering also may occur. The individual dresses more warmly, decreases body surface area by curling up, and may go to bed in an effort to get warm. Body temperature is maintained at the new level until the fever "breaks."

During fever, arginine vasopressin (AVP), α-melanocyte-stimulating hormone (α-MSH), and corticotropin-releasing factor are released from the brain, and systemic anti-inflammatory cytokines (i.e., IL-1 receptor agonist and IL-10) can act as **endogenous cryogens** or **antipyretics** to help diminish and control the febrile response.[95] This antipyretic effect constitutes a negative-feedback loop (see Figure 16-8). The antipyretic effect may help explain fluctuations in the febrile response. When the fever breaks, the set point is returned to normal. The hypothalamus responds by signaling a decrease in heat production and an increase in heat reduction mechanisms. The result is decreased muscle tone, peripheral vasodilation, flushed skin, and sweating. The individual feels very warm, replaces warm clothing with cooler clothes, throws off the covers, and stretches out. Once the body has returned to a normal temperature, the individual feels more comfortable and the hypothalamus adjusts thermoregulatory mechanisms to maintain the new temperature.

Benefits of Fever

Moderate fever aids responses to infectious processes through several mechanisms.[96] A raised body temperature kills many microorganisms and has adverse effects on the growth and replication of others. Higher body temperatures decrease serum levels of iron, zinc, and copper, all of which are needed for bacterial replication. The body switches from burning glucose to a metabolism based on lipolysis and proteolysis, thereby depriving bacteria of a food source. Anorexia and somnolence reduce the demand for muscle glucose.[97,98] Increased temperature also causes lysosomal breakdown and autodestruction of cells, thus preventing viral replication in infected cells. Acute-phase proteins produced by the liver during inflammation bind cations necessary for bacterial reproduction. Heat increases lymphocytic transformation and motility of polymorphonuclear neutrophils, thus facilitating the immune response. Phagocytosis is enhanced, and production of antiviral interferon may be augmented.[99]

Because fever is a beneficial response to infection, suppressing fever with antipyrogenic medications should be reviewed

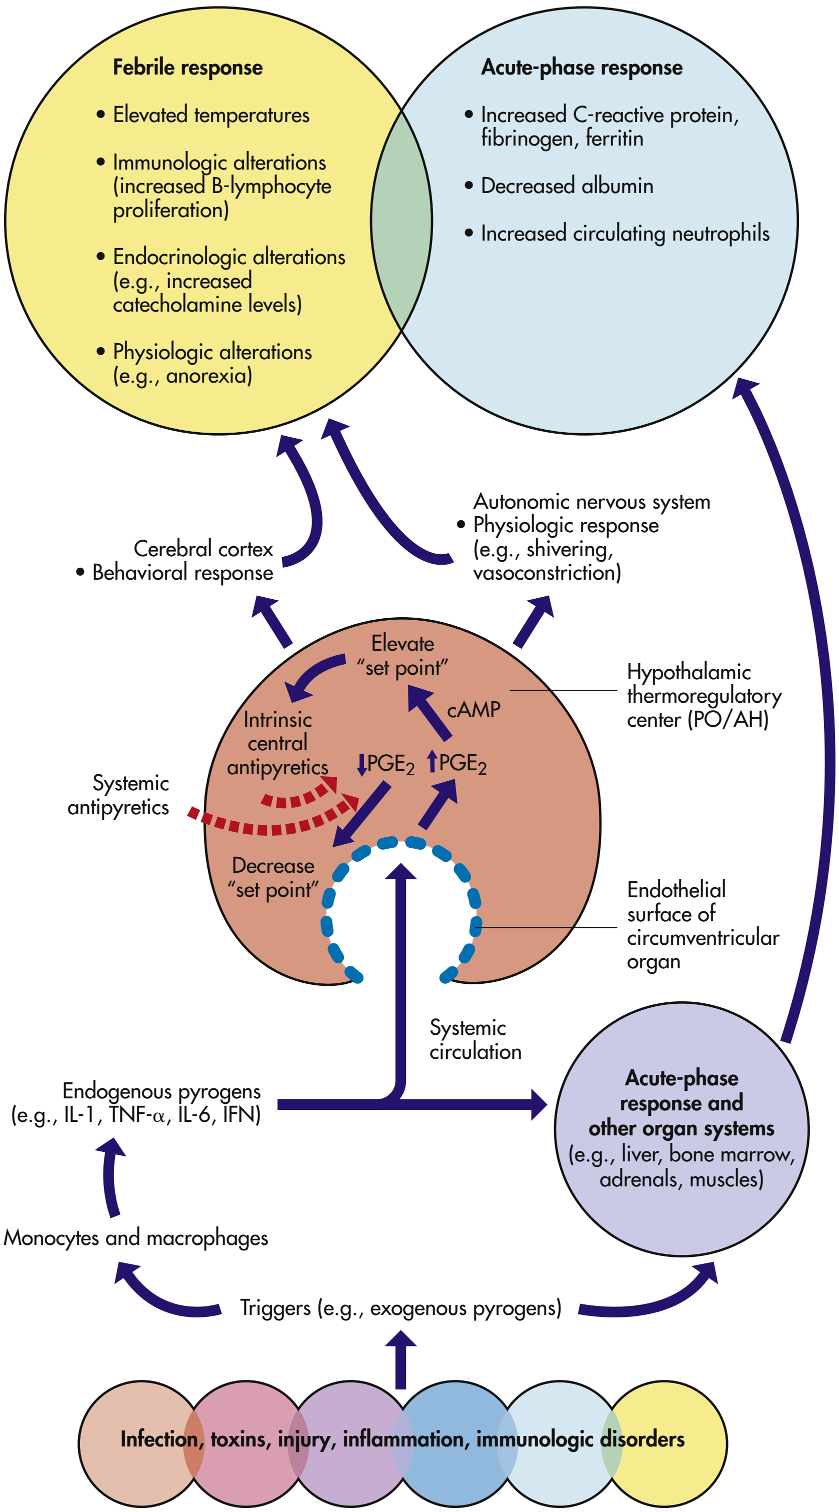

FIGURE 16-8 Pathogenesis of Fever and Acute-Phase Response. Certain disease states, through the elaboration of exogenous pyrogens, stimulate monocytes and macrophages to produce endogenous pyrogens such as IL-1, IL-6, TNF-α, and interferon-γ. These pyrogenic cytokines act at the endothelial surface of the circumventricular organ of the preoptic area of the anterior hypothalamus *(PO/AH)* to induce the production of PGE_2, which elevates the body's thermal set point. Physiologic and behavioral responses may be invoked to raise body temperature to a new set point. This febrile response must be considered in the context of an overlapping acute-phase response as a global nonspecific response to the original insult. Intrinsic central antipyretics and systemic antipyretics exert their effects by decreasing levels of PGE_2, thus decreasing the "set point" and lowering body temperature. The red dotted line represents a negative feedback response. *cAMP,* Cyclic adenosine monophosphate; *IFN,* interferon; *IL-1, IL-6,* interleukin-1, interleukin-6; *PGE_2,* prostaglandin E_2; *TNF-α,* tumor necrosis factor-alpha. (Modified from Armstrong D, Cohen J: *Infectious diseases,* ed 2, St Louis, 2004, Mosby.)

carefully.[100] Such treatment should be used only if the fever is high enough to produce serious side effects such as nerve damage or convulsion.

Infection and fever responses in older adults and in children may vary from those in the adult. Older individuals may have decreased or no fever response to infection. The absence of fever responses to infection and therefore the beneficial aspects of fever production may explain the increase in morbidity and mortality rates seen in very old individuals.[101] In contrast, children develop higher temperatures than do adults for relatively minor infections. Febrile seizures may occur with temperatures greater than 39° C (102.2° F), although most children do not develop febrile seizures until temperatures are much higher. Febrile seizures are more predominant in boys before age 5 years, and genetic factors contribute to susceptibility.[102] Febrile seizures are generally brief and self-limiting, lasting less than 5 minutes in 40% of children and less than 20 minutes in 75% of children. Although in most instances there appear to be no long-term effects on the child, a small percentage of children (1% to 2%) may develop epilepsy.[103] Prolonged febrile seizures are associated with the development of temporal lobe epilepsy in children and are probably associated with functional changes in neurons and neural networks.[104,105]

Fever of unknown origin (FUO) is a fever with a body temperature greater than 38.3° C (101° F) that remains undiagnosed after 3 days of hospital investigation or two or more outpatient visits. The clinical categories of FUO include classic, nosocomial, neutropenic, and HIV associated.[106]

Disorders of Temperature Regulation

Internal body temperature is maintained within a narrow range. Alterations in the regulation of heat production or heat loss can be life-threatening.

Hyperthermia

Hyperthermia is elevation of the body temperature without an increase in the hypothalamic set point. Hyperthermia can produce nerve damage, coagulation of cell proteins, and death. At 41° C (105.8° F), nerve damage produces convulsions in the adult. At 43° C (109.4° F), death results. Hyperthermia is not mediated by pyrogens, and may be associated with brain injury or applied therapeutically.

Therapeutic hyperthermia is a form of local, regional, or whole-body induced hyperthermia used to destroy pathologic microorganisms or tumor cells by facilitating the host's natural immune process or tumor blood flow.[107]

Accidental hyperthermia includes: (1) heat cramps, (2) heat exhaustion, (3) heat stroke, and (4) malignant hyperthermia.[108]

Heat Cramps. **Heat cramps** are severe spasmodic cramps in the abdomen and extremities that follow prolonged sweating and associated sodium loss. Heat cramps usually appear in individuals who are not accustomed to heat or in those who are performing strenuous work in very warm climates. Fever, rapid pulse rate, and increased blood pressure often accompany the cramps. Treatment involves administration of dilute salt solutions through oral or parenteral routes.

Heat Exhaustion. **Heat exhaustion,** or collapse, is a result of prolonged high core or environmental temperatures. These high temperatures cause the appropriate hypothalamic response of profound vasodilation and profuse sweating. Over a prolonged period the hypothalamic responses produce dehydration, decreased plasma volumes, hypotension, decreased cardiac output, and tachycardia. The individual feels weak, dizzy, nauseated, and faint. The symptoms of heat exhaustion cause the individual to stop work, lie down, and rest. Ceasing activity decreases muscle work, causing decreased heat production. Lying down redistributes vascular volume. The individual should be encouraged to drink warm fluids to replace fluid lost through sweating.

Heat Stroke. **Heat stroke** is a potentially lethal result of a breakdown in control of an overstressed thermoregulatory center.[109] The brain cannot tolerate temperatures greater than 40.5° C (104.9° F). When core temperature reaches or exceeds 40.5° C (104.9° F), the brain may be preferentially cooled by maximal blood flow through the veins of the head and face, specifically the forehead. Sweat production on the face is maintained even during dehydration. Evaporation of the sweat cools the blood in the veins of the face and forehead; the blood then is returned to the endocranial venous network and sinus cavernosus, cooling the blood in the cerebral arterial vessels that lie in proximity. Fanning the face enhances this mechanism. In this way the brain can be maintained temporarily at 40° C (104° F), even when core temperatures are higher. In instances of very high core temperatures (40° to 43° C [104° to 109.4° F]), the cardiovascular and thermoregulatory centers may cease to function appropriately. Sweating ceases, and the skin becomes dry and flushed. The individual may be irritable, confused, stuporous, or comatose. Visual disturbances may occur.

As heat loss through the evaporation of sweat ceases, core temperatures increase rapidly. High core temperatures and vascular collapse produce cerebral edema, degeneration of the CNS, swollen dendrites, renal tubular necrosis, and multiple organ failure. Death results unless immediate, effective treatment is initiated. Individuals who recover from heat stroke may have permanent damage to the thermoregulatory center and thus may have difficulty tolerating environmental temperature changes. A systemic inflammatory response syndrome (SIRS) that ensues following heat-induced tissue injury may cause the long term sequelae associated with heat-injured tissue.[110]

Treatment includes removing the person from the warm environment, if possible, and using a cooling blanket or cool water bath or ice packs on the head, neck, groin, and axillae.[108] Care must be taken to prevent too rapid cooling of the surface, which causes peripheral vasoconstriction and prevents core cooling. Children are more susceptible to heat stroke than adults because (1) they produce more metabolic heat when exercising, (2) they have a greater surface area to body mass ratio, and (3) their sweating capacity is less than that of adults.

Malignant Hyperthermia. **Malignant hyperthermia** is a potentially lethal hypermetabolic complication of a rare inherited muscle disorder. The condition is precipitated by the administration of volatile anesthetics and neuromuscular-blocking agents. There is wide variability in incidence ranging

from 1:5000 to 1:50,000. Malignant hyperthermia is caused by either increased myoplasmic calcium release or decreased calcium uptake with muscle contraction. This allows intracellular calcium levels to rise, producing sustained, uncoordinated muscle contractions, which in turn increase muscle work, oxygen consumption, and lactic acid production. As a result of these contractions, acidosis develops and temperature rises (body temperature may rise 1° C [1.8° F] every 5 minutes); approximately 5% of those who develop malignant hyperthermia do not survive.[111] Malignant hyperthermia occurs most often in children and young adults immediately after the induction of anesthesia. Sympathetic responses and acidosis produce tachycardia and cardiac dysrhythmias, followed by hypotension, decreased cardiac output, and, eventually, cardiac arrest. Increasing temperature, acidosis, hyperkalemia, and hypoxia produce coma-like symptoms in the CNS (including unconsciousness, absent reflexes, fixed pupils, apnea, and sometimes a flat electroencephalogram [EEG]). Oliguria and anuria are common, probably resulting from shock, ischemia, and low cardiac output.[112]

Treatment includes withdrawal of the provoking agents and administration of dantrolene sodium (a skeletal relaxant that inhibits calcium release during muscle contraction). Procainamide (Pronestyl) is used to treat cardiac dysrhythmias. Sodium bicarbonate is used for acidosis. Hyperkalemia can be treated with insulin and glucose. Body temperature can be decreased through use of ice bags, a cooling blanket, and iced saline lavage.

Hypothermia

Hypothermia (core body temperature less than 35° C [95° F]) is caused by prolonged exposure to cold. Hypothermia produces vasoconstriction, shivering, alterations in microcirculation, coagulation, and ischemic tissue damage. In a controlled situation, such as a surgical procedure, most tissues can tolerate temperatures as low as 33° C (91.4° F). In severe hypothermia (less than 28° C [82.4° F]), ice crystals forming on the inside of the cell cause cells to rupture and die. Tissue hypothermia slows the rate of chemical reactions (tissue metabolism), increases the viscosity of the blood, slows blood flow through the microcirculation, facilitates blood coagulation, and stimulates profound vasoconstriction. Hypothermia may be accidental or therapeutic. In accidental hypothermia, high-energy phosphates (e.g., ATP) are depleted, and in therapeutic hypothermia, ATP storage is preserved.[113,114]

Accidental Hypothermia. Accidental hypothermia is generally the result of sudden immersion in cold water or prolonged exposure to cold environments.[114] At particular risk for accidental hypothermia are young persons and older adults, because thermoregulatory mechanisms are altered in these two groups. Also at risk are individuals with conditions that diminish the ability to generate heat. Such conditions include hypothyroidism, hypopituitarism, decreased liver function, malnutrition, Parkinson disease, and rheumatoid arthritis. Other risk factors include chronic increased vasodilation and decreased thermoregulatory control caused by cerebral injuries, ketoacidosis, uremia, and drug overdoses. In acute hypothermia, peripheral vasoconstriction shunts blood away from the cooler skin to the core in an effort to decrease heat loss, which produces peripheral tissue ischemia. Intermittent reperfusion of the extremities (the Lewis phenomenon) helps preserve peripheral oxygenation. Intermittent peripheral perfusion continues until core temperatures drop dramatically.

The hypothalamic center stimulates **shivering** in an effort to increase heat production. Severe shivering occurs at core temperatures of 35° C (95° F) and continues until core temperature drops to about 30° to 32° C (86° to 89.6° F). Prolonged shivering can lead to exhaustion of liver glycogen stores. Thinking becomes sluggish and coordination is decreased at 34° C (93.2° F). As hypothermia deepens, paradoxical undressing may occur as hypothalamic control of vasoconstriction is lost and vasodilation occurs with loss of core heat to the periphery. The hypothermic individual therefore feels suddenly warm and begins to remove clothing.[115]

At 30° C (86° F), the individual becomes stuporous, heart rate and respiratory rate decline, and cardiac output is diminished. Cerebral blood flow is decreased. Metabolic rate declines, further decreasing core temperature. Sinus node depression occurs with slowing of conduction through the atrioventricular node. In severe hypothermia (core temperature of 26° to 28° C [78.8° to 82.4° F]), pulse and respirations may be undetectable. Acidosis is moderate to severe. Coagulopathy, ventricular fibrillation, and asystole are common.[116] Surface cooling may cause frostbite and fat necrosis.

If hypothermia is mild, passive rewarming may be sufficient. If core temperature is greater than 30° C (86° F), active rewarming also may be required. Active rewarming uses warm-water baths, warm blankets, heating pads, and warm oral fluids when the individual is fully alert. Core rewarming may be accomplished through administration of warm intravenous (IV) solutions, warm gastric lavage, warm peritoneal lavage, inhalation of warmed gases, and, in extreme cases, exchange transfusions, warming blood in a pump oxygenator circuit, and mediastinal lavage.[113]

Rewarming generally should proceed no faster than a few degrees per hour. Short-term complications of rewarming include acidosis, rewarming shock, and dysrhythmias. Long-term complications include congestive heart failure, hepatic and renal failure, abnormal erythropoiesis, myocardial infarction, pancreatitis, and neurologic dysfunctions.

Therapeutic Hypothermia. Therapeutic hypothermia is used to slow metabolism and preserve ischemic tissue after brain trauma or during brain surgery, after cardiac arrest, and in neonatal hypoxic encephalopathy.[117] Hypothermia protects the brain by reduction in metabolic rate, ATP consumption, oxidative stress, and the critical threshold for oxygen delivery; modulation of excitotoxic neurotransmitters and calcium antagonism; preservation of protein synthesis and the blood-brain barrier; decreased edema formation; and modulation of the inflammatory response.[118,119]

Trauma

Major body trauma has varying effects on temperature regulation, depending on the body systems involved. Five types

of traumatic injury that usually affect temperature regulation are: (1) CNS trauma (discussed in Chapter 18), (2) accidental injury, (3) hemorrhagic shock, (4) major surgery, and (5) thermal burns.

Central Nervous System Trauma. CNS trauma that causes CNS damage, inflammation, increased intracranial pressures, or intracranial bleeding typically produces a temperature greater than 39° C (102.2° F). This temperature, often referred to as *neurogenic or central fever,* appears with or without relative bradycardia and is not caused by infection. The temperature is sustained, does not induce sweating, and is highly resistant to antipyretic therapy.[120]

Accidental Injuries. Mild accidental injuries may produce a slight elevation in core temperature. Moderate to severe injuries result in peripheral vasoconstriction with decreased surface and core temperatures. Core temperature is thought to be inversely related to the severity of the injury and may be a result of decreased oxygen transport to the tissues. In severe injuries, shivering is absent and some alteration in thermoregulation is evident.[121]

Hemorrhagic Shock. Loss of blood volume in hemorrhage triggers peripheral vasoconstriction and hypoxia, contributing to hypothermia. Risk for subsequent decreases in core temperature occurs when hemorrhagic shock is treated with unwarmed, volume-expanding solutions and surgery. Volume expansion with warmed solutions is recommended to prevent the deleterious effects of hypothermia on cardiac output, cardiac rhythm, and the immune system.

Major Surgery. Major surgery often induces significant hypothermia through exposure of body cavities to the relatively cool operating room environment, irrigation of body cavities with room temperature solutions, infusion of room temperature intravenous solutions, use of drugs that impair thermoregulatory mechanisms, and inhalation of unwarmed anesthetic agents. Anesthesia induces hypothermia, reduces platelet function, and impairs the coagulation cascade, contributing to transfusion requirements and postoperative complications. Use of warmed irrigating and intravenous solutions and perioperative forced air and skin warming procedures reduces intraoperative hypothermia and postoperative complications.[122]

Thermal Burns. Large burn injuries produce significant hypothermia because of the loss of the skin barrier to fluid evaporation and the loss of control of the microcirculation in the skin. Severe burns also compromise the normal insulation of the skin and subcutaneous tissues. (Burns are discussed in Chapter 48.)

SLEEP

Sleep is an active, multiphase, complex brain process that provides restorative functions and promotes memory consolidation. Several areas of the brain are associated with sleep and sleep-wake cycles. A small group of hypothalamic nerve cells, the **suprachiasmatic nucleus (SCN),** controls the timing of the sleep-wake cycle and coordinates this cycle with circadian rhythms (24-hour rhythm cycles) in other areas of the brain and body tissues using electrical, endocrine, and metabolic signaling pathways.[123] Normal sleep has two phases that can be documented by electroencephalography (EEG): rapid eye movement (REM) sleep and non-REM (NREM), or slow-wave, sleep. REM and NREM sleep succeed each other in 90- to 110-minute intervals in a predictable pattern.[124] Four to six cycles occur during a normal sleep period in an adult. NREM sleep is divided into three stages based on changes in the EEG pattern (Figure 16-9) followed by REM sleep[125]:

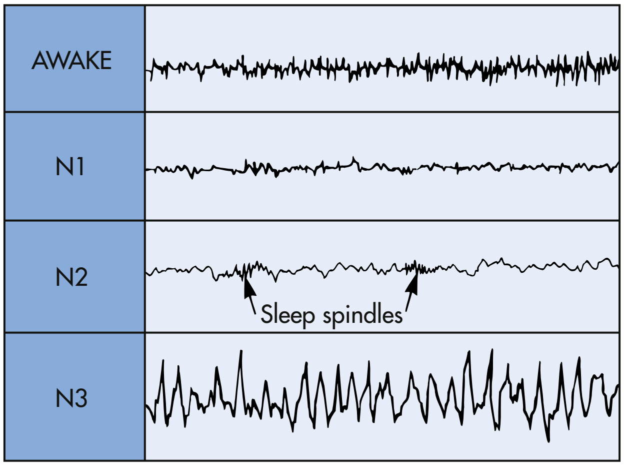

FIGURE 16-9 Electroencephalogram (EEG) Stages of Wakefulness and NREM Sleep. *Awake,* Low-voltage fast activity; *stage N1,* falling asleep; *stage N2,* light sleep with sleep spindles; *stage N3,* slow delta waves. Rapid eye movement (REM) sleep looks similar to awake and stage N1 sleep. Sleep spindles are bursts of brain activity associated with onset of sleep.

- Awake—Wakefulness with eyes closed and predominated by alpha waves (8 to 25 Hz)
- N1—Light sleep, with alpha waves (6 to 8 Hz) interspersed with low-frequency theta waves; slow eye movements (3% to 8% of sleep time)
- N2—Further slowing of the EEG (4 to 7 Hz) with the presence of sleep spindles and slow eye movements (45% to 55% of sleep time)
- N3—Low-frequency (1 to 3 Hz) high-amplitude delta waves with occasional sleep spindles—also known as *slow-wave sleep;* no slow eye movements (15% to 20% of sleep time)
- REM sleep—time of most dreaming (20% to 25% of sleep time)

Non–Rapid Eye Movement (NREM) Sleep

NREM (slow-wave) sleep accounts for 75% to 80% of sleep time and is initiated by the withdrawal of neurotransmitters from the reticular formation and by the inhibition of arousal mechanisms in the cerebral cortex. During NREM sleep, respiration is controlled by metabolic processes.[126] The basal metabolic rate is decreased by 10% to 15%. Temperature is decreased 0.5° to 1° C (0.9° to 1.8° F). Heart rate decreases by 10 to 30 beats per minute. Respiration, blood pressure, and muscle tone all decrease. Knee-jerk reflexes are absent. Pupils are constricted. During stages N1 and N2, cerebral blood flow to the brainstem and cerebellum is decreased. During stage N3, cerebral blood flow to the cortex is decreased.[127] Growth hormone is released during stage N3, and levels of corticosteroids and catecholamines are depressed.

Rapid Eye Movement Sleep

Rapid eye movement (REM) sleep accounts for 20% to 25% of sleep time and is characterized by desynchronized, low-voltage, fast activity that occurs for 5 to 60 minutes about every 90 minutes beginning after 1 to 2 hours of NREM sleep. The brain is quite active in REM sleep with vivid dreaming. REM sleep is also known as *paradoxic sleep* because the EEG pattern is similar to the normal awake pattern. Alternating periods of REM and NREM sleep occur throughout the night, with lengthening intervals of REM sleep and fewer intervals of deeper stages of NREM sleep toward morning. REM sleep is characterized by bursts of conjugate rapid eye movement in all directions; atonia of antigravity muscles; suppressed temperature regulation; alteration in heart rate, blood pressure,[127,128] and respiration; penile erection in men and clitoral engorgement in women; and a high rate of memorable dreams. Steroids are released in short bursts. During REM sleep, respiratory control is thought to be largely independent of metabolic requirements and oxygen variation. Loss of normal voluntary muscle control in the tongue and upper pharynx may produce some respiratory obstruction. Cerebral blood flow to both hemispheres is increased. REM sleep is controlled by the pontine reticular formation.

An individual progresses through REM and NREM sleep in a predictable cycle while asleep. The first cycle of the night begins with stage N1. The individual then progresses through stages N2, N3, and REM sleep. A new cycle, beginning with stage N2, follows each REM sleep. With each successive cycle, the amount of time spent in stage N3 sleep decreases and the amount of time spent in REM sleep increases (Figure 16-10). The individual who is awakened begins the next cycle with stage N1.

The hypothalamus as a major sleep center secretes hypocretins (orexins), neuropeptides that promote wakefulness and REM sleep as well as appetite, energy consumption, and pleasure or reward. In addition to the hypocretins, acetylcholine and glutamate are important waking factors. The preoptic area of the hypothalamus promotes sleep through inhibitory modulation of multiple arousal systems with involvement of the inhibitory neurotransmitter GABA.[129] The reticular formation is primarily responsible for generating REM sleep and projections from the reticular formation and other areas of the mesencephalon and brainstem produce NREM sleep.[127]

Many neurotransmitters are associated with excitatory and inhibitory sleep mechanisms. Sleep-promoting neurotransmitters include prostaglandin D_2, L-tryptophan, serotonin, adenosine, melatonin, GABA, and growth hormones. Awake-promoting neurotransmitters include hypocretin (orexin), acetylcholine, and glutamate.[130] Their mechanism of action is complex and not clearly understood. Growth hormone is associated with initiation of sleep, and cortisol levels rise in the morning just before waking.[131] Acetylcholine and somatostatin play a role in stages of sleep transition. Forced awakenings in the middle of the night may result in increased difficulty returning to sleep or may alter the normal progression of sleep, or both.[130,132] The purpose of sleep is unknown, although restorative processes, particularly neuronal repair and generation of new neural pathways, have been proposed.[133] Loss of REM sleep impairs learning and memory. Sleep is important enough that people spend about one third of their life sleeping.

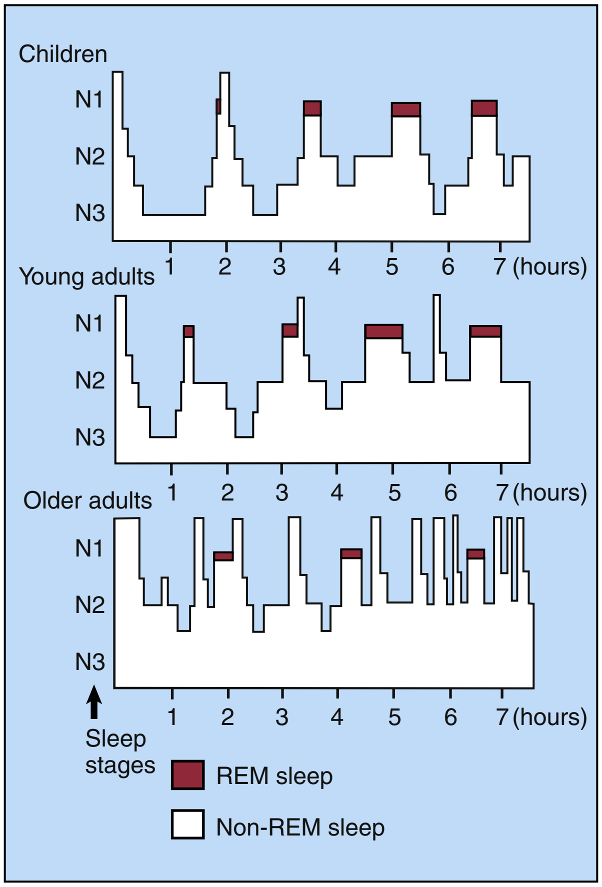

FIGURE 16-10 Normal Sleep Cycles. Rapid eye movement *(REM)* sleep occurs cyclically throughout the night at intervals of approximately 90 minutes in all age groups. REM sleep shows little variation in the different age groups, whereas stage N3 sleep decreases with age. In addition, older adults awaken frequently and show a marked increase in total time awake.

PEDIATRICS AND SLEEP PATTERNS

The sleep patterns of the newborn and young child vary from those of the adult in total sleep time, cycle length, and percentage of time spent in each sleep cycle.[134] Newborns sleep about 16 to 17 hours per day. About 53% of that time is spent in active sleep (REM sleep), 23% in quiet sleep (NREM sleep), and the remainder in an indeterminate phase. The infant sleep cycle is approximately 50 to 60 minutes long, with 20 minutes of NREM sleep and 10 to 45 minutes of REM sleep, in contrast to the adult sleep cycle. Newborns enter REM sleep immediately on falling asleep.[135] At about 1 year of age, an infant spends approximately 45% of total sleep time in quiet sleep and 41% in REM sleep. Total sleep time decreases slightly from birth to 1 year. Bottle-fed infants that do not share sleeping space with the mother increase maximum sleep time from 4 to 5 hours to 8 to 10 hours by 4 months of age. They begin to "sleep through the night." Infants who are breast-fed for up to 2 years and share sleeping space with the mother continue to sleep in short bouts and wake frequently to nurse.[135] In the young child, the sleep

cycle length is 45 to 60 minutes, in contrast to 90 to 100 minutes in the adult. The child assumes the adult sleep pattern at some point during the first 2 to 5 years of life.[136] Sleep for infants and children is important for growth and neurocognitive development. Sleep disorders are common in children and include insomnia and obstructive sleep apnea syndrome (OSAS). OSAS is related to adenotonsillar inflammation (i.e., enlargement of the adenoids and tonsils) or to obesity.[137,138] Sudden infant death syndrome (SIDS) is presented in Chapter 36.

AGING AND SLEEP PATTERNS

The sleep pattern of the older adult differs from that of the younger adult or child. Total sleep time is decreased, and the older individual takes longer to initiate and maintain asleep. Older adults tend to go to sleep earlier in the evening and awaken more frequently during the night and earlier in the morning. REM and slow-wave sleep decreases. Changes in the older adult's sleep pattern may be associated with changes in lifestyle, presence of chronic disease, lack of daily routine, desynchronization of circadian rhythm, and use of medications.[139] Growth hormone and cortisol levels are diminished in the older adult and may affect sleep patterns.[132] The alteration in sleep pattern typically appears about 10 years later in women than in men. Older adults are less able than younger individuals to tolerate sleep deprivation.[140]

The average length of sleep time has declined over the years for both children and adults.[141,142] Daily sleep loss accumulates as a sleep debt that becomes evident in reduced neurobehavioral capability that, in turn, results in decline of executive function and lapses in vigilance.[143,144] Individuals responsible for public health and safety, including but not limited to healthcare workers, often work night shifts and long hours that make them prone to sleep-related errors.[145,146]

Sleep Disorders

Sleep disorders can be primary or secondary and can occur as a result of many medical and psychiatric conditions. The focus of this section is on primary sleep disorders. The classification of primary sleep disorders is complex and a system has been produced by the American Academy of Sleep Medicine[147] that includes four general classifications: (1) dyssomnias (intrinsic and extrinsic sleep disorders and circadian rhythm sleep disorders); (2) parasomnias (arousal and sleep-wake transition disorders and REM sleep disorders); (3) sleep disorders associated with mental, neurologic, or other medical disorder; and (4) proposed sleep disorders. The most common dyssomnias and parasomnias are presented here.

Common Dyssomnias

The **dyssomnias** are sleep disorders related to difficulty in initiating or maintaining sleep or the presence of excessive sleepiness. The most common dyssomnias include insomnia, obstructive sleep apnea syndrome, restless leg syndrome, circadian rhythm disorder, and hypersomnia.

Insomnia is the inability to fall or stay asleep and is more common in women.[148] Primary insomnia may be transient, lasting a few days, and related to travel across time zones, disrupted sleep schedules, or acute stress. Secondary insomnia is associated with drug or alcohol abuse, chronic pain disorders, or chronic depression, obesity, and aging.[149] Drugs known to produce insomnia include amphetamines, steroids, central adrenergic blockers, bronchodilating agents, and caffeine.[150]

Obstructive sleep apnea syndrome (OSAS) is a disorder of breathing during sleep related to upper airway obstruction that is associated with reduced blood oxygen saturation and hypercapnia. The typical classification of the severity of this disease uses the Apnea Hypopnea Index (AHI). This index represents how many apnea (total airway closure) or hypopnea (partial airway closure) episodes occur per night—the number of which is then divided by the night's total sleep time to give an average number of apnea or hypopnea episodes per hour. The AHI severity scale is as follows:

- *Normal:* fewer than 5 episodes of abnormal sleep episodes per hour
- *Mild:* between 5 and 15 episodes of abnormal sleep episodes per hour
- *Moderate:* between 15 and 30 episodes of abnormal sleep episodes per hour
- *Severe:* more than 30 episodes of abnormal sleep episodes per hour

The prevalence of OSAS associated with accompanying daytime sleepiness is common with an occurrence of approximately 3% to 7% for adult men and 2% to 5% for adult women,[151] or approximately 10 million adults in the United States. Some estimates suggest between 12 and 20 million people in the United States have diagnosable OSAS.[152] Risk factors include obesity, male gender, menopause, and age.[153]

OSAS is increasingly prevalent in our rapidly expanding older adult population.[154,155] Premenstrual women may be protected from sleep-disordered breathing because the female hormone progesterone is a respiratory stimulant.[156] The longer pharyngeal airway in males also may contribute to increased risk for OSAS. Obese individuals often have a short, thick neck; pharyngeal airway collapse; impaired respiratory mechanics; and depressed respiratory control, particularly during sleep.[157] **Obesity hypoventilation syndrome** (obesity, daytime hypoventilation, and sleep-disordered breathing not related to other causes) may be related to leptin resistance because leptin is also a respiratory stimulant.[158]

OSAS is, as reflected in the preceding discussion of AHI, characterized by repetitive increases in resistance to airflow within the upper airway with loud snoring, gasping, intervals of apnea lasting from 10 to 30 seconds, fragmented sleep, and chronic daytime sleepiness. The obstruction is caused by the soft palate or base of the tongue, or both, collapsing against the pharyngeal walls because of decreased muscle tone especially during REM sleep. In the supine position, the tongue may fall farther back, obstructing the airway. The level of negative intrathoracic pressure is the most likely stimulus for arousal, possibly mediated by mechanoreceptors in the upper airway. Potentially fatal cardiac and vascular illnesses associated with OSAS include hypertension, pulmonary hypertension, heart failure, nocturnal cardiac dysrhythmias, myocardial infarction, and ischemic stroke.[159]

The pathophysiologic consequences of mechanical and neurochemical responses present during apneic episodes may be causal factors in the cardiovascular disease commonly seen in OSAS. Such hypoxia-induced vascular dysfunction impairs blood flow regulation and compromises tissue perfusion and oxygen delivery during episodes of OSAS. The combination of intermittent hypoxia and hypercapnia, increased number of arousals, increased sympathetic tone, altered baroreflex control during sleep, oxidative stress, hormonal changes, and cardiovascular changes induced by increased negative intrathoracic pressure contribute to these complications.[160] OSAS also contributes to the development of metabolic syndrome, which is associated with cardiovascular disease mortality[161] (see Chapter 22). Many individuals are not aware of their heavy snoring and nocturnal arousals and may remain undiagnosed. Fatigue, decline in cognitive function, car accidents, and poor work performance are common.

Diagnosis of OSAS is confirmed with polysomnography. Treatments include continuous positive airway pressure (CPAP), dental devices that modify the position of the tongue or jaw, upper airway surgical reconstruction, and weight reduction.[162] Treatment with CPAP utilizes positive air pressure to maintain an open airway and has been shown to result in a reversal of abnormalities associated with OSAS, including systemic and pulmonary hypertension and decreased cardiovascular disease mortality.[163,164]

Restless leg syndrome (RLS) is a common sensorimotor disorder associated with unpleasant sensations (prickling, tingling, crawling) that occurs at rest and is worse in the evening or at night. There is a compelling urge to move the legs for relief, with a significant effect on sleep and quality of life. The disorder is more common in women, older adults, and individuals with iron deficiency. RLS has a familial tendency and is associated with a circadian fluctuation of dopamine in the substantia nigra. Iron is a cofactor in dopamine production, and some individuals respond to iron administration as well as dopamine agonists.[165,166]

Hypersomnia is excessive daytime sleepiness and is commonly associated with voluntary sleep deprivation. There may also be an underlying sleep disorder such as OSAS or narcolepsy. Individuals may fall asleep while driving, working, or even conversing, resulting in significant concerns for safety. Treatment is symptomatic with reinforcement of good sleeping habits.

Narcolepsy is characterized by hypersomnia, cataplexy (brief spells of muscle weakness), hallucinations, and sleep paralysis. The disorder is associated with hypothalamic hypocretin (orexin) deficiency and may be related to immune-mediated destruction of hypocretin-secreting cells. There is a genetic component to the disorder in animals.[167]

Circadian rhythm sleep disorders are common disorders of the sleep-wake schedule and include rapid time-zone changes (jet-lag syndrome), alterations in sleep schedule with an advance or a delay of 3 hours or more in sleep time, or changes in total sleep time from day to day. These changes in the timing of established sleep schedules have been shown to desynchronize circadian rhythm.[168] Degree of vigilance, performance of psychomotor tasks, and subjective reports of levels of arousal are markedly depressed after alterations in the sleep-wake schedule. Individuals may experience short sleep episodes called *microsleeps* without being aware of decreased vigilance.[169,170]

It is well established that industrial shift workers exhibit a decrease in accuracy, an increase in accident proneness, and an increase in likelihood of poor work performance.[168] For similar reasons, people suffering from jet-lag syndrome require several days to adapt to a new time zone. Travel across time zones requires 2 days to adjust the sleep-wake schedule, 5 days to adjust the body temperature cycle, and 8 days to adjust cortisol level secretion. Transmeridian travel requires up to 10 days to adjust the body clock when traveling from east to west. Timed bright light exposure and administration of exogenous melatonin provide some success in retiming or resetting the body clock before or after time-zone shifts.[171,172]

Sleep deprivation can result in significant neurocognitive decline, particularly in the domains of executive control, working memory, and attention.[173] Neuropsychologic effects of sleep loss include[174]:

1. A marked impact on performance through decreases in cognitive functions and specific effects on brain regions that support cognitive function
2. Decreased speed of mental processing
3. Declines in attention and vigilance with distinct intraindividual variability
4. Abnormal activation in the prefrontal cortex, parietal lobes, thalamus, and temporal lobes as shown by functional neuroimaging
5. Task performance decreases as sleep debt accumulates in a manner that is "dose dependent"

Common Parasomnias

Parasomnias are complex behaviors related to awakening from REM sleep or partial arousal from NREM sleep and disorders of sleep stage transitions. Three types of parasomnias include *arousal disorders* such as confusional arousals, sleepwalking (somnambulism), night terrors (dream anxiety attacks), rearranging furniture, eating food, violent behavior, bruxism (teeth grinding), and sleep enuresis; *sleep-wake transition disorders* such as rhythmic movements (head banging), sleep talking, and nocturnal leg cramps; and *disorders associated with REM sleep* such as sleep paralysis and nightmares, sleep apnea, and SIDS. SIDS affects children primarily in the first 2 years of life and may be related to central sleep apnea (a disorder of thalamic breathing control) episodes (see Chapter 36). Parasomnias are more common in children and may be familial.[175-177]

Sleep Disorders Associated with Mental, Neurologic, or Medical Disorders

Many mental and physical disorders are associated with alterations in sleep (secondary sleep disorders). Many disorders produce alterations in the quantity and quality of sleep or affect sleep stages, including mental disorders (e.g., depression and anxiety), disorders of neurocognitive function (e.g., dementia or Parkinson disease), and physical disorders (e.g., alterations in thyroid hormone levels, pain, and many acute and chronic diseases). In other instances, sleep stages may contribute to

disease (sleep-provoked disorders) such as chronic obstructive pulmonary disease (COPD), asthma, cardiac ischemia, diabetes mellitus, and gastroesophageal reflux.

REM sleep behavior disorder is loss of normal skeletal muscle atonia during REM sleep and may cause injury from acting-out of dreams. It is more common in older adult men and is associated with Parkinson disease and other neurodegenerative diseases.[178]

Individuals who are depressed have difficulty falling asleep and exhibit less slow-wave sleep, less time spent in REM sleep, early awakening, and less total sleep time. In addition, depressed individuals move through the sleep stages more quickly than do individuals who are not depressed. The same neurotransmitters that may be disturbed in depression also regulate sleep.[175,179]

Coronary artery disease is most affected during REM sleep. During REM, dreams may provoke nocturnal angina, increased heart rate, and electrocardiogram (ECG) changes. In adults, attacks of bronchial asthma may occur at any time during the night. The attacks cause the individual to spend more of the sleep period awake and thus result in a decrease in stage N3 sleep time. In children, bronchial asthma attacks are uncommon during the first one third of the night, when stage N3 sleep predominates, and occur more frequently during the final two thirds of the night. Stage N3 sleep time is decreased overall in the child with bronchial asthma. In addition to these changes, asthmatic individuals may experience bronchial spasm during REM sleep.[180-182]

People with COPD experience significantly lowered oxygen tension and increases in carbon dioxide retention during sleep. The lowered oxygen tension is most significant in the tonic phase of REM sleep when voluntary neuromuscular control, including intercostal muscle function, is depressed. Pulmonary spasm and transient pulmonary hypertension result. These changes are particularly evident in the "blue bloater" individual and may contribute to early pulmonary hypertension and cor pulmonale in these people.[183,184]

Because blood glucose levels vary during sleep, individuals with uncontrolled diabetes may need to pay careful attention to blood glucose levels. Studies show that people with duodenal ulcers secrete 3 to 20 times more gastric acid during REM sleep than do people without duodenal ulcers. This increased gastric acid secretion often produces nocturnal epigastric pain.

SOMATOSENSORY FUNCTION AND THE SPECIAL SENSES

The somatosensory system includes the peripheral receptors and central nervous system pathways that detect internal and external information, which is then processed and interpreted by the brain. This system includes touch, proprioception and vestibular function, and the special senses—sight, hearing, smell, and taste.

Touch

Touch is not a uniform sensory experience. The sensation of touch involves the fusion of several qualities, including modality, intensity, location, and duration of the sensory stimulus. Receptors sensitive to touch are present in the skin. Meissner and pacinian corpuscles are rapidly adapting receptors, whereas Merkel disks and Ruffini endings are slowly adapting touch receptors. Touch receptors are most numerous in the skin of the fingers and lips and are more scarce in the skin of the trunk. Specific sensory input is carried to the higher levels of the CNS by the dorsal column of the spinal cord and the anterior spinothalamic tract.

Much of the development of the cutaneous senses takes place before birth, but structural growth of the cutaneous senses continues into early adulthood at a reduced rate. Then a gradual decline occurs.[185] Studies have documented loss in tactile sensitivity with advancing age.[186,187] This occurs simultaneously with an increase in the size of pacinian corpuscles and a decrease in the number of corpuscles.

Abnormal tactile perception may be caused by alterations at any level of the nervous system, from the receptor to the cerebral cortex. Any factor that interrupts or impairs reception, transmission, perception, or interpretation of touch also alters tactile sensation. Trauma, tumor, infection, metabolic changes, vascular changes, and degenerative diseases thus may cause tactile dysfunction, which may involve heightened or diminished tactile perceptions.

In addition, most tactile sensations evoke affective responses that determine whether the sensation is unpleasant, pleasant, or neutral. Cerebral and hypothalamic centers influence this response. Sedative drugs and prefrontal injury, which interrupt connections between the prefrontal cortex and subcortical centers, diminish the interpretation of tactile sensations.

Proprioception

Perception and awareness of the position of the body and its parts depend on impulses from the inner ear and from receptors in joints and ligaments. The role of muscle, tendon, and cutaneous receptors is indefinite. Sensory data are transmitted to higher centers, primarily through the dorsal columns and the spinocerebellar tracts, with some data passing through the medial lemnisci and thalamic radiations to the cortex. These stimuli are necessary for the coordination of movements, the grading of muscular contraction, and the maintenance of equilibrium.

A progressive loss of proprioception has been reported in older adults with increased risk for falls and injury.[188] Proprioceptive dysfunction may be caused by alterations at any level of the nervous system. As with tactile dysfunction, any factor that interrupts or impairs the reception, transmission, perception, or interpretation of proprioceptive stimuli also alters proprioception. Two common causes of proprioceptive dysfunction are vestibular dysfunction and neuropathy.

Specific vestibular dysfunctions are vestibular nystagmus and vertigo. **Vestibular nystagmus** is the constant, involuntary movement of the eyeball caused by ear disturbances. This condition occurs when the semicircular canal system is overstimulated. **Vertigo** (dizziness) is the sensation of spinning that occurs with inflammation of the semicircular canals in the ear. The individual may feel either that he or she is moving in space or that the world is revolving. Vertigo often causes loss of

balance. Vertigo and nystagmus may occur in a variety of conditions, including labyrinthitis, vestibular neuritis, acute toxic labyrinthitis, benign paroxysmal positional vertigo, migrainous vertigo, and Ménière disease.[189]

Ménière disease (endolymphatic hydrops) is an idiopathic episodic vestibular disorder resulting from abnormalities in the quantity, composition, and pressure of the endolymph in the middle ear.[190] The individual with Ménière disease experiences vertigo, hearing loss, tinnitus, and aural fullness and may have proprioceptive dysfunction. Standing or walking may be impossible because of loss of balance. **Ménière syndrome,** or secondary endolymphatic hydrops, is secondary to other conditions that alter the production or absorption of endolymph.

Peripheral neuropathies also can cause proprioceptive dysfunctions. Neuropathies may be caused by a variety of conditions and commonly are associated with renal disease and diabetes mellitus. Although the exact sequence of events is unknown, neuropathies are thought to be caused by a metabolic disturbance of the neuron itself. The result is a diminished or absent sense of body position or position of body parts. Gait changes often occur. (Neuropathies are further discussed in Chapter 18.)

Vision

The eyes are complex sense organs responsible for vision. Within a protective casing, each eye has receptors, a lens system for focusing light on the receptors, and a system of nerves for conducting impulses from the receptors to the brain. Visual dysfunction may be caused by abnormal ocular movements or alterations in visual acuity, refraction, color vision, or accommodation. Visual dysfunction also may be the secondary effect of another neurologic disorder.

The External Eye

Protective external eye structures include the eyelids (palpebrae), conjunctivae, and lacrimal apparatus (Figure 16-11). The eyelids are used to control the amount of light reaching the eyes, and the conjunctivae line the eyelids. Tears released from the lacrimal apparatus bathe the surface of the eye and prevent friction, maintain hydration, and wash out foreign bodies and other irritants.

Infection and inflammatory responses are the most common conditions affecting the supporting structures of the eyes. **Blepharitis** is an inflammation of the eyelids caused by *Staphylococcus* or seborrheic dermatitis. Redness, edema, tearing, and itching are common symptoms.[191]

An external **hordeolum (stye)** is an infection of the sebaceous glands of the eyelids, and an internal hordeolum is an infection of the eyelid margin. A **chalazion** is a noninfectious lipogranuloma of the meibomian (oil-secreting) gland and may be associated with an internal hordeolum. These conditions present with redness, swelling, and tenderness and are treated symptomatically.[192] **Entropion** is a common eyelid malposition in which the lid margin turns inward against the eyeball. There are both surgical and nonsurgical treatments to reposition the lid margin.

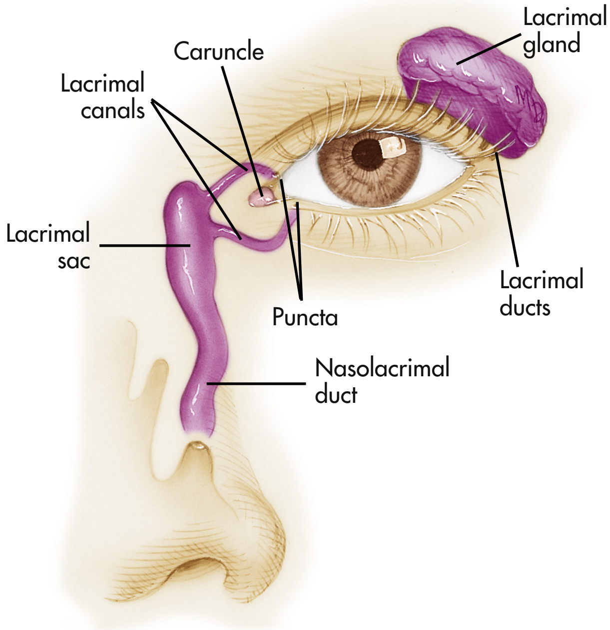

FIGURE 16-11 **Lacrimal Apparatus.** Fluid produced by lacrimal glands (tears) streams across the eye surface, enters the canals, and then passes through the nasolacrimal duct to enter the nose. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

Conjunctivitis

Conjunctivitis is an inflammation of the conjunctiva (mucous membrane covering the front part of the eyeball). Conjunctivitis may be caused by bacteria, viruses, allergies, or chemical irritations. The inflammatory response produces redness, edema, pain, and lacrimation. Treatment is related to cause.[193]

Acute bacterial conjunctivitis (pinkeye) is highly contagious and often is caused by gram-positive organisms *(Staphylococcus, Haemophilus, Proteus),* although other bacteria may be involved. The onset is acute, characterized by mucopurulent drainage from one or both eyes. In children younger than 6 years, *Haemophilus* infection often leads to otitis media (conjunctivitis-otitis syndrome). Preventing spread of the organism with meticulous handwashing and use of separate towels is important. The disease often is self-limiting and resolves spontaneously in 10 to 14 days. Antibiotic eyedrops usually are effective.

Viral conjunctivitis is caused by an adenovirus. Symptoms vary from mild to severe. Some strains of virus cause conjunctivitis and pharyngitis (pharyngoconjunctival fever), and others cause keratoconjunctivitis. Both diseases are contagious, with watering, redness, and photophobia. Treatment is symptomatic.

Allergic conjunctivitis is associated with a variety of antigens, including pollens. Ocular itching is associated with photophobia, burning, and gritty sensations in the eye. Treatment is symptomatic and may include antihistamines, low-dose corticosteroids, mast cell stabilizers, and vasoconstrictors.

Chronic conjunctivitis is the result of any persistent conjunctivitis. The cause requires identification for effective treatment.

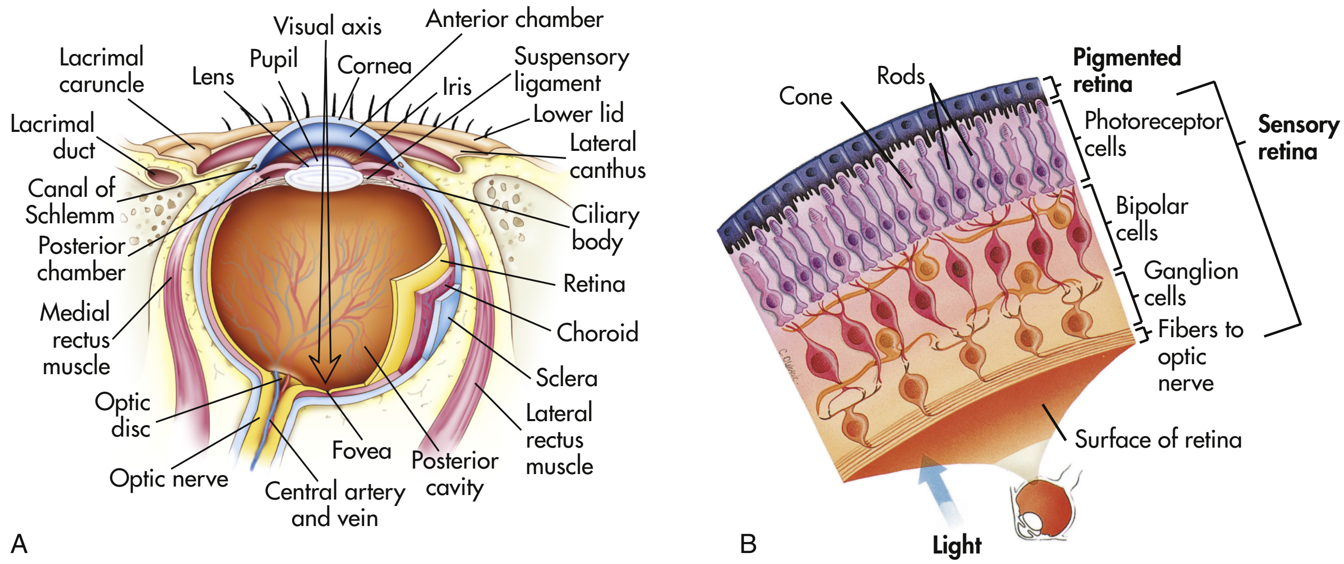

FIGURE 16-12 Structure of the Eyeball and Cell Layers of the Retina. **A,** Horizontal section through the left eyeball. The eye is viewed from above. **B,** Pigmented and sensory layers of the retina. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

Trachoma (chlamydial conjunctivitis) is caused by *Chlamydia trachomatis.* It often is associated with poor hygiene and is the leading cause of preventable blindness in the world. The severity of the disease varies, but it can involve inflammation with scarring of the conjunctiva and eyelids causing distorted lashes to abrade the cornea, leading to corneal scarring and blindness. Chlamydial organisms are sensitive to local or systemic antibiotics. The World Health Organization aims to eliminate trachoma as a public health problem by 2020 using the SAFE Strategy: Surgery for inturned lashes, Antibiotics, Facial cleanliness, and Environmental improvement.[194]

Keratitis. **Keratitis** is an inflammation of the cornea that can be noninfectious or caused by bacteria, viruses, or fungus. Bacterial infections often cause corneal ulceration and require intensive antibiotic treatment. *Staphylococcus aureus* is the most common bacterial infection. Type 1 herpes simplex virus can involve the cornea and conjunctiva. Predisposing factors include contact lens use, trauma, and penetrating keratoplasty (corneal grafting). Common symptoms include photophobia, pain, and lacrimation. Severe ulcerations with residual scarring require corneal transplantation.[195]

The Eye

The wall of the eye is formed of three layers: sclera, choroid, and retina (Figure 16-12). The **sclera** is the thick, white, outermost layer. It becomes transparent at the **cornea,** the portion of the sclera in the central anterior region that allows light to enter the eye. The **choroid** is the deeply pigmented middle layer that prevents light from scattering inside the eye. The **iris,** part of the choroid, has a round opening, the **pupil,** through which light passes. Smooth muscle fibers control the size of the pupil so that in close vision and bright light the pupil constricts and in distant vision and dim light the pupil dilates.

The **retina** is the innermost layer of the eye, and contains millions of rods and cones, special photoreceptors that convert light energy into nerve impulses. **Rods** mediate peripheral and dim light vision and are densest at the periphery. **Cones,** densest in the center of the retina, are color and detail receptors. The photoreceptive rods and cones are distributed over the entire retina, except where the optic nerve leaves the eyeball. Lack of rods and cones in this area results in the **optic disc,** or blind spot. Lateral to each optic disc is the **fovea centralis,** a tiny area that contains only cones and provides the greatest visual acuity (see Figure 16-12).

The **optic nerve** (second cranial nerve) is composed of retinal cell axons. As shown in Figure 16-13, nerve impulses pass through the optic nerves after leaving the retinas. At the optic chiasm the fibers from the inner (nasal) halves of the retinas cross to the opposite side, where they join fibers from the outer (temporal) halves of the retinas to form the optic tracts. The fibers of the optic tracts synapse in the dorsal lateral geniculate nucleus, and from there the geniculocalcarine fibers pass by way of the optic radiation (or geniculocalcarine tract) to the primary visual cortex in the occipital lobe of the brain. Some fibers terminate in the suprachiasmatic nucleus (located above the optic chiasm) and are involved in regulating the sleep-wake cycle.

Light entering the eye is focused on the retina by the **lens**—a flexible, biconvex, crystal-like structure. In youth the lens is transparent and has the consistency of hardened jelly. The flexibility of the lens allows a change in curvature with contraction of the ciliary muscles. This is called **accommodation** and it allows the eye to focus on objects at different distances. Anterior to the lens are the iris and the aqueous chamber, which is filled with **aqueous humor**. The aqueous humor helps to maintain the pressure inside the eye and provides nutrients to the lens and cornea. Aqueous humor is free-flowing fluid, secreted by the ciliary processes and reabsorbed into the canal of Schlemm. If drainage is blocked, pressure within the eye increases (as it does with glaucoma). Posterior to the lens is the vitreous chamber and it is filled with a gel-like substance called **vitreous humor**. Vitreous humor helps prevent the eyeball from collapsing inward.

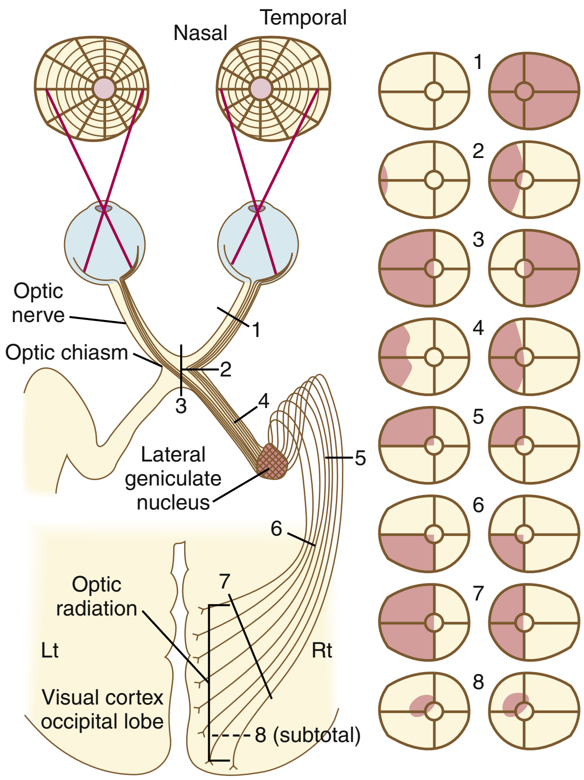

FIGURE 16-13 Visual Fields and Defects That Accompany Damage to the Right Visual Pathways. **1,** Optic nerve: blindness. **2,** Lateral optic chiasm: grossly incongruous, incomplete (contralateral) homonymous hemianopsia. **3,** Central optic chiasm: bitemporal hemianopsia. **4,** Optic tract: incongruous, incomplete homonymous hemianopsia. **5,** Temporal loop of the optic radiation: congruous partial or complete (contralateral) homonymous superior quadrantanopia. **6,** Parietal *(superior)* projection of the optic radiation: congruous partial or complete homonymous inferior quadrantanopia. **7,** Complete parieto-occipital interruption of the optic radiation: complete congruous homonymous hemianopsia with psychophysical shift of the foveal point, often sparing central vision and resulting in "macular sparing." **8,** Incomplete (subtotal) damage to the visual cortex: congruous homonymous scotomas, usually encroaching at least acutely on central vision. (From Goldman C, editor: *Goldman's Cecil medicine,* ed 24, vol 2, Philadelphia, 2012, Saunders.)

The central retinal artery provides blood to the inner retinal surface. Nutrients and oxygen are supplied to the outer surface of the retina by the choroid, a vascular layer that lies between the retina and sclera. Six extrinsic eye muscles, attached to the outer surface of each eye, allow gross eye movements and permit the eyes to follow a moving object (Figure 16-14).

AGING AND VISION

Changes in the visual and motor components of the eye caused by aging begin at an early age, particularly in the lens of the eye. Changes caused by aging are summarized in Table 16-4. Structural changes combined with chronic diseases, including dementias and diabetes mellitus, result in a decline in visual acuity and extraocular motor muscle function.[196,197]

Visual Dysfunction

Alterations in Ocular Movements. Abnormal ocular movements occur as a result of oculomotor, trochlear, or

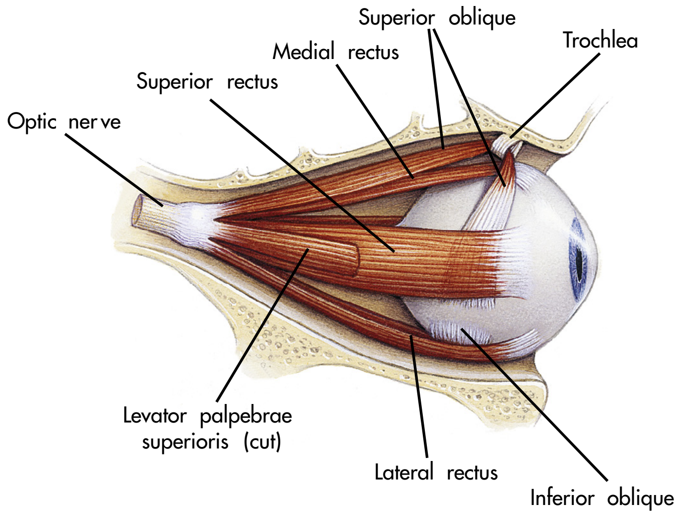

FIGURE 16-14 Extrinsic Muscles of the Right Eye, Superior View. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

abducens cranial nerve dysfunction (see Table 15-6). The three types of eye movement disorders are (1) strabismus, (2) nystagmus, and (3) paralysis of individual extraocular muscles.

Strabismus is the deviation of one eye from the other when a person is looking at an object; it results in failure of the two eyes to simultaneously focus on the same image and therefore loss of binocular vision. The deviation may be upward, downward, inward, or outward, resulting from a weak or hypertonic muscle in one of the eyes. Strabismus may be caused by a neuromuscular disorder of the eye muscle, diseases involving the cerebral hemispheres, or thyroid disease.[198] The primary symptom of strabismus is **diplopia** (double vision). Strabismus in children requires early intervention to prevent the development of amblyopia (reduced vision in the affected eye without ocular pathology and with full optical correction). Surgery may be helpful to both children and adults with strabismus.[199]

Nystagmus is an involuntary unilateral or bilateral rhythmic movement of the eyes and can occur in infants (congenital) or adults (acquired). It may be present at rest, or it may occur with eye movement. The two major forms of nystagmus are pendular nystagmus and jerk nystagmus. **Pendular nystagmus** is characterized by a regular alternating forward and backward movement of the eyes in which both phases of the movement are equal in length. In **jerk nystagmus** one phase of the eye movement is faster than the other. Nystagmus may be caused by an imbalance in the normally coordinated reflex activity of the inner ear, vestibular nuclei (connecting the vestibular nerve with vestibulospinal tracts), cerebellum, medial longitudinal fascicle (connecting the mesencephalon with the upper portion of the spinal cord), or nuclei of the oculomotor, trochlear, and abducens cranial nerves (see Table 15-6). Drugs, retinal disease, and diseases involving the cervical cord also may produce nystagmus. Acquired untreated nystagmus can lead to loss of visual acuity.[200]

Paralysis of specific extraocular muscles may cause a variety of abnormalities, including limited abduction, abnormal closure of the eyelid, ptosis (drooping of the eyelid), and diplopia.

TABLE 16-4 CHANGES IN THE EYE CAUSED BY AGING

STRUCTURE	CHANGE	CONSEQUENCE
Cornea	Thicker and less curved	Increase in astigmatism
	Formation of a gray ring at the edge of cornea (arcus senilis)	Not detrimental to vision
Anterior chamber	Decrease in size and volume caused by thickening of lens	Occasionally exerts pressure on Schlemm canal and may lead to increased intraocular pressure and glaucoma
Lens	Increase in opacity	Decrease in refraction with increased light scattering and decreased color vision (green and blue); decreased dark adaptation; cataracts
	Loss of elasticity	Loss of accommodation (presbyopia: loss of focus for near objects)
Ciliary muscles	Reduction in pupil diameter, atrophy of radial dilation muscles	Persistent constriction (senile miosis); decrease in critical flicker frequency*
Retina	Reduction in number of rods at periphery, loss of rods and associated nerve cells	Increase in the minimum amount of light necessary to see an object
Macula	Atrophy (age-related macular degeneration)	Loss of vision
Vitreous	Liquefaction of vitreous and decrease in gel volume	Posterior vitreous detachment causing "floaters;" risk for retinal detachment

*The rate at which consecutive visual stimuli can be presented and still be perceived as separate.

The abnormalities occur as a result of unopposed muscle activity. Trauma or pressure in the area of the cranial nerves may cause paralysis of specific extraocular muscles. Diseases such as diabetes mellitus and myasthenia gravis also may affect specific extraocular muscles.

Alterations in Visual Acuity. Visual acuity is the ability to see objects in sharp detail. With advancing age the eye's lens becomes less flexible and less adjustable. In addition, the sclera changes shape, causing light to fall on the **macula** (an opaque portion of the cornea). Thus visual acuity declines with age. Visual acuity also may change or diminish for many other reasons. Specific causes of visual acuity changes include: (1) amblyopia, (2) scotoma, (3) cataracts, (4) papilledema, (5) dark adaptation, (6) glaucoma, (7) retinal detachment, and (8) macular degeneration.

Amblyopia (lazy eye) is a reduction or dimness of vision for unknown reasons. It does not result from a change in refraction (i.e., deviation of light rays) or from any visible changes in the eye. Amblyopia is associated with strabismus and anisometropia (refractive error in one eye differs from that of the other eye); with diseases such as diabetes mellitus, renal failure, and malaria; and with toxic substances such as alcohol and tobacco. Amblyopia is the most common cause of vision loss in children and is usually treated either by patching the unaffected eye for extended times to ensure a period of use of the affected eye or by administering atropine eyedrops.[201] Refractive errors are treated with corrective lenses.

A **scotoma** is a circumscribed defect of the central field of vision. It can be a sequel to demyelinating optic neuritis, an inflammatory lesion of the optic nerve frequently associated with optico-spinal multiple sclerosis (see Chapter 18). Age-related macular degeneration is associated with scotoma. Less common causes include the compression of one optic nerve by a retroorbital tumor, neuromyelitis optica (autoantibody-related inflammation of the optic nerve and spinal cord), pernicious anemia, and toxic or metabolic causes such as methyl alcohol poisoning and use of tobacco. The precise mechanisms for these conditions causing a scotoma are uncertain, but the result is always a serious impairment in visual acuity.[202]

A **cataract** is a cloudy or opaque area in the ocular lens and leads to visual loss when located on the visual axis. The incidence of cataracts increases with age as the lens enlarges. Cataracts develop because of alterations of metabolism and transport of nutrients within the lens. Although the most common form of cataract is degenerative, cataracts also may occur congenitally or as a result of infection, radiation, trauma, drugs, or diabetes mellitus. Cataracts cause decreased visual acuity, blurred vision, glare, and decreased color perception. Cataracts are treated by removal of the entire lens and replacement with an intraocular artificial lens.[203]

Dark adaptation also affects visual acuity. Low illumination causes impaired visual acuity, particularly in older adults. The average 80-year-old person needs more than twice as much light as a 20-year-old person to see equally well. Changes in the quantity and quality of rhodopsin, a substance found in the rods and responsible for low-light vision, are thought to be responsible for reduced dark adaptation in older adults.[204] Vitamin A deficiencies can cause the same phenomenon in individuals of any age.

Glaucoma is a leading cause of visual impairment and blindness. It is characterized by intraocular pressures greater than the normal pressures of 12 to 20 mmHg maintained by the aqueous fluid. Family history is a risk factor, and glaucoma can be inherited.[205] The types of glaucoma are summarized in Table 16-5 and Figure 16-15. Open-angle glaucoma is the most common. Chronic increased intraocular pressure causes death of retinal ganglions and optic nerve degeneration with loss of peripheral vision, followed by central vision impairment and blindness. Extremely high pressures can cause blindness within days or hours. Loss of visual acuity results from pressure on the optic nerve, which is believed to block the flow of cytoplasm from neuronal bodies in the retina to peripheral optic nerve fibers entering the brain. Lack of nutrients, ischemia, cytotoxic factors, and altered immune mechanisms may lead to death of the

TABLE 16-5 TYPES OF GLAUCOMA

TYPE	MECHANISM OF INCREASED PRESSURE
Open-angle	Obstruction of outflow of aqueous humor at trabecular meshwork or Schlemm canal; myopia may be a risk factor
Normal or low-tension	Form of open-angle glaucoma with symptomless damage to the optic nerve and gradual vision loss when intraocular pressure is within normal range (12-20 mmHg)
Narrow-angle (angle-closure)	Forward displacement of iris toward cornea with narrowing of iridocorneal angle and obstruction to outflow of aqueous humor from anterior chamber
Acute angle-closure	Acute closure of iridocorneal angle with a sudden rise in intraocular pressure, producing pain, redness, and visual disturbances
Chronic angle-closure	Progressive, permanent closure of anterior chamber angle
Secondary	Open- or closed-angle obstruction caused by, for example, uveitis, hemorrhage, rupture of lens or tumors
Congenital glaucoma	Malformation of trabecular meshwork and excess extracellular matrix in outer meshwork

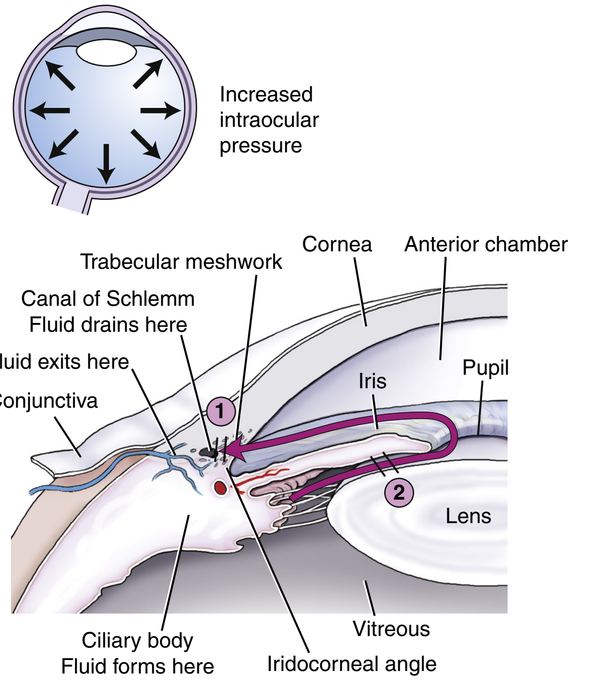

FIGURE 16-15 Glaucoma. **1,** Open-angle glaucoma. The obstruction to aqueous flow lies in the trabecular meshwork. **2,** Closed-angle glaucoma. The iris presses against the lens, blocking aqueous flow into the anterior chamber and raising intraocular pressure.

involved neurons.[206] Acute pain may result and there is loss of peripheral vision and progression to blindness. Early detection and treatment prevent optic neuropathy and visual impairment. Glaucoma often is treated with pharmaceutical eyedrops to reduce secretion or increase absorption of aqueous humor. Surgery may be needed to open the spaces of the trabeculae and reduce intraocular pressure. Neuroprotective therapies are being evaluated.[207]

Retinal detachment is a common cause of visual impairment and blindness. Risk factors include retinal holes and vitreoretinal traction. Fluid (exudate, hemorrhage, or liquid vitreous) separates the photoreceptors from the retinal pigment epithelium. The separation deprives the outer retina of oxygen and nutrients because the diffusion distance is increased. Communication is also disrupted between the pigment epithelium and photoreceptors. **Rhegmatogenous retinal detachment** (retinal breaks caused by vitreoretinal traction) is the most common form of retinal detachment. Causes include intracapsular cataract extraction, severe myopia, lattice degeneration, vitreoretinal traction, and trauma. Contraction of fibrous membranes can cause tractional separation of the retinal layers as occurs in proliferative diabetic retinopathy. Treatment involves surgical retinal reattachment.[208]

Age-related macular degeneration (AMD) is a process in which "drusen" or retinal waste products accumulate within the deep retinal layers. There are two forms of AMD: wet and dry. The *dry* or *atropic form* of AMD is most prevalent and involves loss of retinal pigment epithelium and photoreceptors with overall atrophy of cells. The *wet exudative form* (neovascular AMD) is the more severe form and involves proliferation of abnormal choroidal vessels, which leak and bleed, causing retinal detachment. Hypertension, cigarette smoking, cataract surgery, diabetes mellitus, higher plasma fibrinogen levels, and genetic predisposition are risk factors for AMD.[209] Symptoms include blurred vision, loss of central vision, difficulty reading, and poor night vision. AMD is the major cause of blindness in individuals older than 50 years. Progress is being made in antiangiogenic and vascular endothelial growth factor treatments. Understanding genetic factors contributing to AMD will assist with identifying a biomarker for the disease.[210]

Alterations in Accommodation. Accommodation is the process whereby the thickness of the lens changes with contraction of the ciliary muscles. Accommodation is needed for clear vision and is mediated through the oculomotor nerve (cranial nerve III). Pressure, inflammation, and disease of the oculomotor nerve may alter accommodation. Symptoms include diplopia, blurred vision, and headache. Loss of accommodation in older adults is termed **presbyopia,** a condition in which the ocular lens becomes larger, firmer, and less elastic. The major symptom is reduced near vision, causing the individual to hold reading material at arm's length. Correction of presbyopia is accomplished through reading glasses or bifocal lenses, accommodative intraocular lenses, or surgical treatment.[211]

Alterations in Refraction. Alterations in refraction are the most common visual problem. Errors in refraction are caused by irregularities of the corneal curvature, the focusing power of the lens, and the length of the eye. The major symptoms of refraction alterations are blurred vision and headache. Three types of refraction alterations are myopia, hyperopia, and astigmatism (Figure 16-16).

In **myopia** (nearsightedness), light rays are focused in front of the retina when a person is looking at a distant object, resulting in blurred vision. A concave lens is needed for correction.

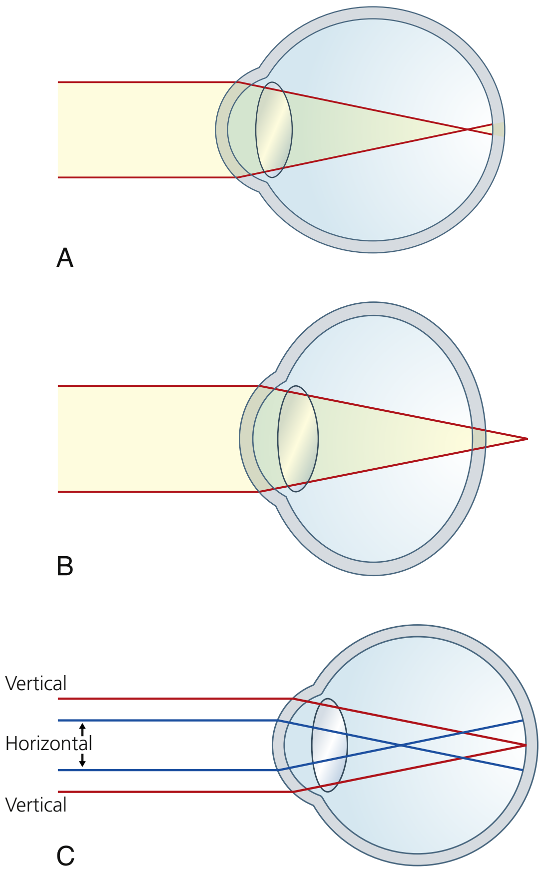

FIGURE 16-16 Alterations in Refraction. **A,** Myopic eye. Parallel rays of light are brought to a focus in front of the retina. **B,** Hyperopic eye. Parallel rays of light come to a focus behind the retina in the nonaccommodative eye. **C,** Simple myopic astigmatism. The vertical bundle of rays is focused on the retina; the horizontal rays are focused in front of the retina and the image is blurred. (From Stein HA, Stein RM, Freeman MI: *The ophthalmic assistant: a text for allied and associated ophthalmic personnel,* ed 9, Philadelphia, 2013, Saunders.)

Myopia requires frequent changes of eyeglasses while the eyeball is lengthening in childhood. Myopia is a risk factor for retinal detachment and cataract formation.

In **hyperopia** (farsightedness), light rays are focused behind the retina when a person is looking at a near object. Hyperopia is corrected with a convex lens. **Astigmatism** is caused by an unequal curvature of the cornea. In astigmatism, light rays are bent unevenly and do not come to a single focus on the retina. Astigmatism may coexist with myopia, hyperopia, or presbyopia. Correction is accomplished with a cylinder lens.

Alterations in Color Vision. Normal sensitivity to color diminishes with age because of the progressive yellowing of the lens that occurs with aging. All colors become less intense, although color discrimination for blue and green is most greatly affected. Color vision deteriorates more rapidly for individuals with diabetes mellitus than for the general population. The deterioration is thought to be an accelerated version of senile color vision deterioration.

Abnormal color vision also may be caused by **color blindness,** an inherited trait. Color blindness is generally an X-linked recessive characteristic affecting 8% of the male population and 0.5% of the female population. Although many forms of color blindness exist, most commonly the affected individual cannot distinguish red from green.[212,213]

Neurologic Disorders Causing Visual Dysfunction. Various neurologic disorders may cause visual dysfunction. Vision may be disrupted at many points along the visual pathway, causing a variety of defects in fields of vision. Visual changes do not always cause defects or blindness in the entire visual field; **hemianopia** is the term that describes defective vision in half of a visual field. (Figure 16-13 illustrates the many areas along the visual pathway that may be damaged and the associated visual changes.) Because of the anatomy of the optic nerves, injury to the optic nerve causes ipsilateral (same side) blindness but a normal contralateral (opposite side) visual field. Injury to the **optic chiasm** (the X-shaped crossing of the optic nerves), often caused by atherosclerotic ischemia or external compression from trauma or aneurysm, can cause a variety of defects, depending on the location of injury. These defects vary because at the optic chiasm, nerve fibers from the medial half of each retina separate from the lateral half and enter the opposite optic tract.

Because of the normal structure of the visual pathways, destruction of one optic tract causes **homonymous hemianopsia** (complete loss of vision in the inner half of one eye and the outer half of the other). Thus, if an injury to the left optic tract occurs, the individual is blind in the right eye's medial (inner) field and the left eye's lateral (outer) field. If the compression of the optic tract is asymmetric, an incongruous (or uneven) homonymous defect results. Injury to one optic radiation (an ocular pathway in the internal capsule, temporal lobe, or occipital lobe) also causes a homonymous (same field) defect. A major injury in the optic radiation causes homonymous hemianopsia. A lesser injury may cause an upper quadrant homonymous defect. Generally the defects are the same size in both eyes. When the homonymous hemianopsia is caused by an occipital lobe lesion, the area of hemianopsia is split. Although visual acuity may remain unimpaired, reading is difficult because of the inability to group words.

Papilledema is edema of the optic nerve at its point of entrance into the eyeball. Papilledema is caused by increased intracranial pressure (e.g., brain tumors, intracranial hemorrhage, hydrocephalus). The subarachnoid space of the brain is continuous with the optic nerve sheath. As cerebrospinal fluid (CSF) pressure increases, the pressure is transmitted to the optic nerve and the optic nerve sheath compresses the nerve and impedes axoplasmic transport. This leads to accumulation of axoplasmic substances at the level of the lamina cribrosa (a meshlike structure in the sclera where the retinal nerves exit the eye and form the optic nerve), resulting in the characteristic swelling of the optic disc. Obliteration of the physiologic cup (a bright area normally located in the center of the optic disc) follows. Later the optic disc becomes raised above the level of the surrounding retina, and the margins become blurred and indistinct. With severe swelling, hemorrhage and patches of white exudate (caused by nerve infarcts) surround the disc margins. The edematous nerves compress the small retinal veins, causing venous stasis and engorgement. Headache is common and

FIGURE 16-17 Retinoblastoma. The tumor occupies a large portion of the inside of the eye globe. (From Damjanov I: *Pathology for the health professions,* ed 3, St Louis, 2006, Saunders. Courtesy Dr. Walter Richardson and Dr. Jamsheed Khan, Kansas City, Kansas.)

there may be no visual changes, blurred vision, or constriction of visual fields.

Retinoblastoma. **Retinoblastoma** is a rare congenital eye tumor of young children that originates in the retina of one or both eyes (Figure 16-17). Retinoblastoma demonstrates both an inherited and an acquired form. Retinoblastoma rarely is diagnosed after the child is 5 years of age. The inherited form of the disease generally is diagnosed during the first year of life and often involves multiple tumors and sometimes both eyes (40%).[214] The acquired disease is commonly diagnosed in children 2 to 3 years of age and involves unilateral disease. Although retinoblastoma is the most common pediatric intraocular tumor, only about 300 cases are diagnosed in the United States each year and 1 in 4 cases involves both eyes.[215]

PATHOPHYSIOLOGY. Approximately 40% of retinoblastomas are inherited as an autosomal dominant disorder caused by mutations in the *RB1* tumor-suppressor gene. The remaining 60% are acquired. In the early 1970s Knudson proposed the "two-hit" hypothesis to explain the occurrence of hereditary and acquired forms of the disease. This hypothesis predicts that two separate transforming events or "hits" must occur in a normal retinoblast cell to cause the cancer. Further, it proposes that in the inherited form the first hit or mutation occurs in the germ cell (inherited from either parent), and the mutation is contained in every cell of the child's body. Only a second, random mutation in a retinoblast cell is necessary to transform that cell into cancer. Multiple tumors are observed in the inherited form because these second mutations are likely to occur in several of the approximately 1 to 2 million retinoblast cells. In contrast, the acquired form of retinoblastoma requires that two independent hits or mutations occur in the same somatic cell (after the egg is fertilized) for transformation to cancer. This is much less likely to happen.[216] Figure 16-18 illustrates the two-mutation model for these two patterns of mutation.

The gene location in which the initial retinoblastoma mutation occurs is on the long arm of chromosome 13, band q14.[216] The gene responsible for retinoblastoma, a tumor-suppressor gene, is called the *RB* gene. The first hit inactivates one allele of the *RB* gene, and the second hit inactivates the other allele of the gene. Without the normal functioning of the *RB* gene, production of protein growth regulators that control retinal cell growth is lacking. Because the gene is inactivated, lack of cell growth control results in unregulated proliferation and tumor development. Epigenic effects are under investigation.[216a]

Retinoblastoma grows as one or more tumors in the retina and extends into the vitreous humor. Free-floating, small tumors in the vitreous humor may attach to the surface of the retina in multiple areas and proliferate (Figure 16-19). The tumor also can invade the optic nerve by infiltrating the cribriform plate of the ethmoid bone or can spread through the sheath around the nerve. In either case the tumor can gain access to the subarachnoid space and the CNS. The tumor spreads into the choroid in 25% of children with retinoblastoma. Because the choroid is highly vascular, metastasis by means of hematogenous spread is possible. When hematogenous spread occurs, metastatic sites include the bone marrow, long bones, lymph nodes, and liver. If the tumor invades the orbit, lymphatic spread is possible. Spontaneous regression occurs, although infrequently, and may be caused by the tumor outgrowing its blood supply.

CLINICAL MANIFESTATIONS. The two most frequent symptoms of retinoblastoma are leukokoria, a white pupillary reflex also called **cat's-eye reflex** caused by the mass behind the lens (see Figure 16-17), and strabismus. At that point, the tumor is large enough that a light shone into the eye is reflected back by the tumor, making the pupil appear white. Note that an ophthalmologic examination is not necessary to detect this tumor but only a simple examination of the pupils with a flashlight. If leukokoria is noted, the child should be referred for a complete dilated ophthalmologic exam. Other signs and symptoms include a red, painful eye and limited vision. Any of these signs and symptoms in a child younger than 4 years of age warrants careful ophthalmologic examination of both eyes. Similarly, any newborn with a known genetic risk for retinoblastoma should have routine ophthalmologic examinations.

EVALUATION AND TREATMENT. Diagnostic evaluation for retinoblastoma includes documentation of family history; complete ophthalmologic examination; and metastatic studies that include bone marrow aspiration, lumbar puncture for spinal fluid examination, bone scan, and additional ultrasound, radiologic, and CT studies of the orbit and brain. Because of the potential hereditary risk to a child's siblings, all siblings younger than 4 years also should receive ophthalmologic evaluations.

Retinoblastoma is a treatable tumor, and dual priorities are saving the child's life and restoring useful vision. Early diagnosis and new chemotherapeutic agents have led to a more conservative approach to treatment. Chemoreduction of the tumor occurs with intravenous chemotherapy to reduce tumor volume. Focal treatments using hyperthermia, laser photocoagulation, or cryotherapy then destroy residual tumor. Large or multiple tumors, indicating more advanced disease, require external beam or plaque radiotherapy and in some cases enucleation (removal) of the eye. Every attempt is made to preserve vision in at least one eye without jeopardizing the child's survival.[217]

The prognosis for most children with retinoblastoma is excellent, with a greater than 90% long-term survival, although children with bilateral or metastatic disease at diagnosis have a poor prognosis. Approximately 75% of children have useful vision in the treated eye.

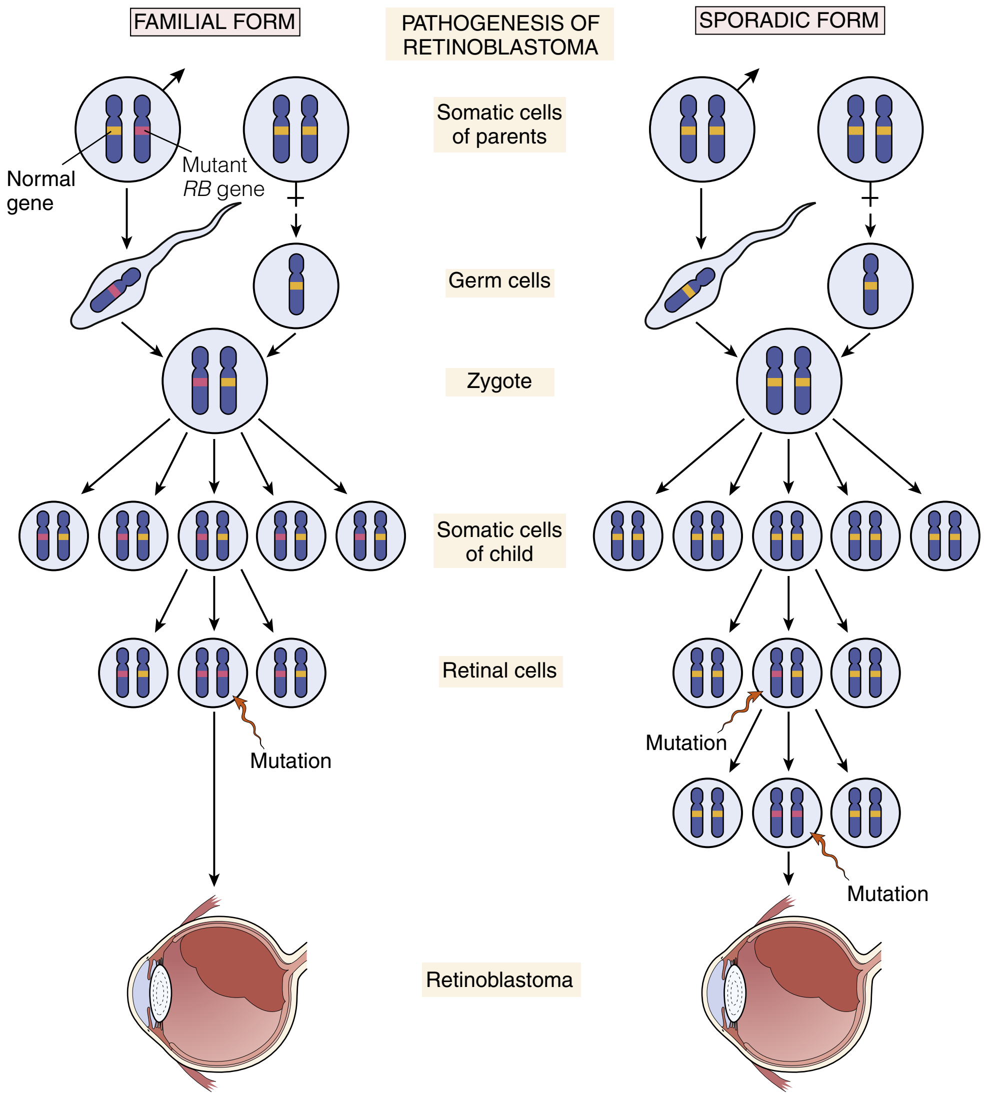

FIGURE 16-18 **The Two-Mutation Model of Retinoblastoma Development.** In inherited (familial) retinoblastoma, mutations of the *RB* locus on chromosome 13q14 lead to neoplastic proliferation of retinal cells. The first mutation is transmitted through the germline of an affected parent. The second mutation occurs somatically in a retinal cell, leading to development of the tumor. In sporadic retinoblastoma, development of a tumor requires two somatic mutations. (From Kumar V, Cotran RS, Robbins SL: *Robbins basic pathology,* ed 8, Philadelphia, 2010, Saunders.)

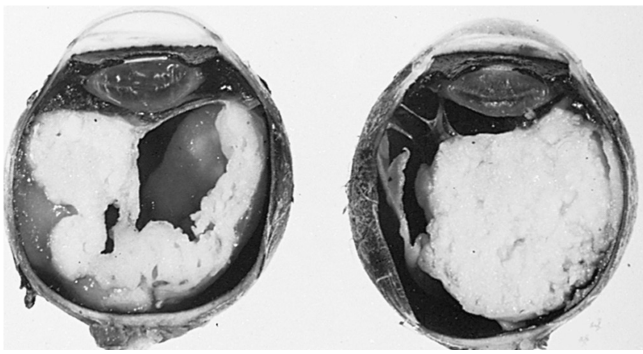

FIGURE 16-19 **Bilateral Retinoblastoma.** Presence of white mass consisting of detached retina and neoplastic tissue immediately behind lens in each eye. (From Kissane JM, editor: *Anderson's pathology,* ed 8, St Louis, 1985, Mosby.)

Hearing

The **external auditory canal** is surrounded by the bones of the cranium. Its opening (meatus) is just above the **mastoid process** (Figure 16-20), which contains air-filled sinuses called **mastoid air cells**. These promote conductivity between the external and the middle ear.

The Ear

The ear is divided into three areas: (1) the external ear, involved only with hearing; (2) the middle ear, involved only with hearing; and (3) the inner ear, involved with both hearing and equilibrium. The external ear is composed of the **pinna** (auricle), which is the visible portion of the ear, and the external auditory canal, a tube that leads to the middle ear (see Figure 16-20). Sound waves entering the external auditory canal hit

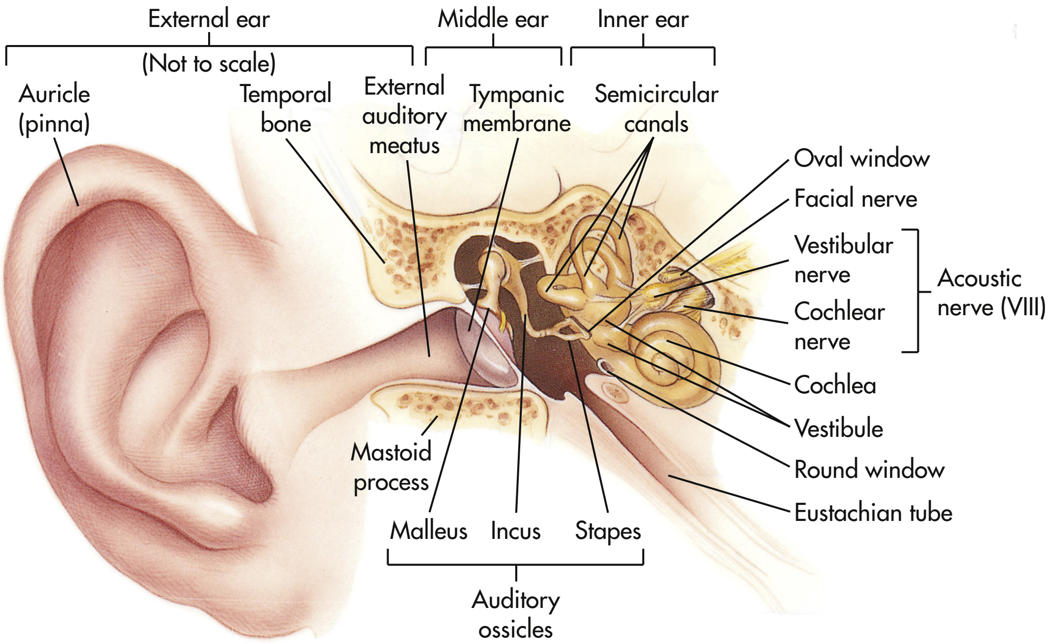

FIGURE 16-20 **The Ear.** External, middle, and inner ear structures. (Anatomic structures are not drawn to scale. Middle and inner ears enlarged for better visualization here.) (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby.)

the **tympanic membrane** (eardrum) and cause it to vibrate. The tympanic membrane separates the external ear from the middle ear.

The middle ear is composed of the **tympanic cavity,** a small chamber in the temporal bone. Three ossicles (small bones) transmit the vibration of the tympanic membrane to the inner ear. The three ossicles are termed the **malleus (hammer), incus (anvil),** and **stapes (stirrup)**. When the tympanic membrane moves, the malleus moves with it and transfers the vibration to the incus, which passes it on to the stapes. The stapes presses against the **oval window,** a small membrane of the inner ear. The movement of the oval window sets the fluids of the inner ear in motion (Figure 16-21).

The **eustachian (pharyngotympanic) tube** connects the middle ear with the thorax. Normally flat and closed, the eustachian tube opens briefly when a person swallows or yawns, and it equalizes the pressure in the middle ear with atmospheric pressure. Equalized pressure permits the tympanic membrane to vibrate freely. Through the eustachian tube the mucosa of the middle ear is contiguous with the mucosal lining of the throat.

The inner ear is a system of osseous labyrinths (bony, mazelike chambers) filled with a fluid called **perilymph.** The bony labyrinth is divided into the **cochlea,** the **vestibule,** and the **semicircular canals** (see Figure 16-21). Suspended in the perilymph is a membranous labyrinth that basically follows the shape of the bony labyrinth. The membranous labyrinth is filled with a thicker fluid called **endolymph.**

Within the cochlea is the **organ of Corti,** which contains **hair cells** (hearing receptors). Sound waves that reach the cochlea through vibrations of the tympanic membrane, ossicles, and oval window set the cochlear fluids into motion. Receptor cells on the basilar membrane are stimulated when their hairs are bent or pulled by the movement. Once stimulated, hair cells transmit impulses along the cochlear nerve (a division of the vestibulocochlear nerve) to the auditory cortex of the temporal lobe in the brain (see Figure 16-21), where interpretation of the sound occurs. Directional hearing is controlled by the angle of the sound source to both ears and by the axonal delay in conduction in groups of neurons.

The semicircular canals and vestibule of the inner ear contain **equilibrium receptors.** In the semicircular canals the dynamic equilibrium receptors respond to changes in direction of movement. Within each semicircular canal is the **crista ampullaris,** a receptor region composed of a tuft of hair cells covered by a gelatinous cupula. When the head is rotated, the endolymph in the canal lags behind and moves in the direction opposite to the head's movement. The hair cells are stimulated, and impulses are transmitted through the vestibular nerve (a division of the vestibulocochlear nerve) to the cerebellum.

The vestibule in the inner ear contains maculae, receptors essential to the body's sense of static equilibrium. As the head moves, **otoliths** (small pieces of calcium salts) move in a gel-like material in response to changes in the pull of gravity. The otoliths pull on the gel, which in turn pulls on the hair cells in the maculae. Nerve impulses in the hair cells are triggered and transmitted to the brain (see Figure 16-21). Thus the ear not only permits the hearing of a large range of sounds but also assists with maintaining balance through the sensitive equilibrium receptors.

AGING AND HEARING

Auditory changes caused by aging are common and incremental. Changes in hearing with aging are summarized in Table 16-6. Approximately one third of people older than 65 years have hearing loss caused by genetic and environmental

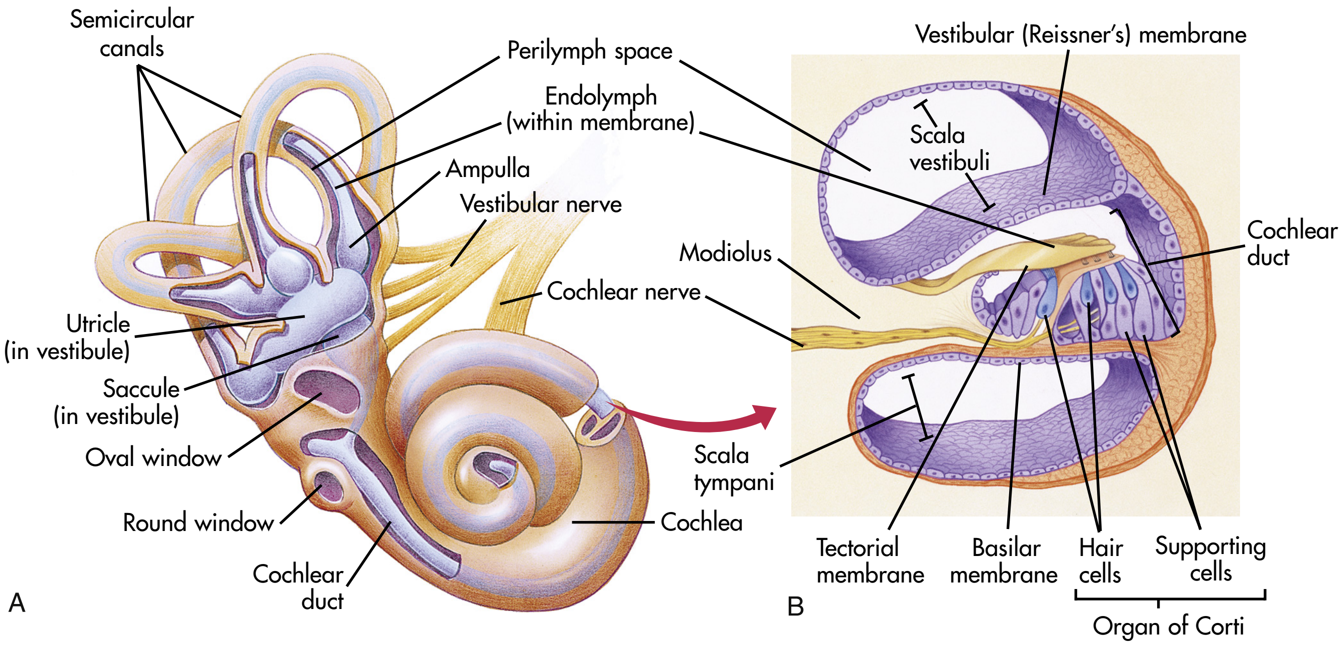

FIGURE 16-21 The Inner Ear. **A,** The bony labyrinth *(orange)* is the hard outer wall of the entire inner ear and includes semicircular canals, vestibule, and cochlea. Within the bony labyrinth is the membranous labyrinth *(purple),* which is surrounded by perilymph and filled with endolymph. Each ampulla in the vestibule contains a crista ampullaris that detects changes in head position and sends sensory impulses through the vestibular nerve to the brain. **B,** The inset shows a section of the membranous cochlea. Hair cells in the organ of Corti detect sound and send the information through the cochlear nerve. The vestibular and cochlear nerves join to form the eighth cranial nerve. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

TABLE 16-6 CHANGES IN HEARING CAUSED BY AGING

CHANGES IN STRUCTURE	CHANGES IN FUNCTION
Cochlear hair cell degeneration	Inability to hear high-frequency sounds (presbycusis, sensorineural loss); interferes with understanding speech; hearing may be lost in both ears at different times
Loss of auditory neurons in spiral ganglia of organ of Corti	Inability to hear high-frequency sounds (presbycusis, sensorineural loss); interferes with understanding speech; hearing may be lost in both ears at different times
Degeneration of basilar (cochlear) conductive membrane of cochlea	Inability to hear at all frequencies, but more pronounced at higher frequencies (cochlear conductive loss)
Decreased vascularity of cochlea	Equal loss of hearing at all frequencies (strial loss); inability to disseminate localization of sound
Loss of cortical auditory neurons	Equal loss of hearing at all frequencies (strial loss); inability to disseminate localization of sound

factors.[218] Changes may occur in the structural and functional components of the peripheral or central auditory system. Loss of hearing for sounds in the high-frequency range (**presbycusis**) is most common and interferes with understanding speech, particularly high-frequency consonant sounds (e.g., *s, sh, f*). Hearing may be lost in both ears but not at the same time. Older adults from rural areas have less hearing loss than those in noisy cities. The ability to discriminate localization of sound varies with high and low frequencies and diminishes with age.[219] In the low-frequency range, sound localization is a function of the timing of sound arrival between the two ears; localization of high-frequency sounds is a function of sound intensity. Because older adults tend to lose high-frequency hearing first, they may have difficulty localizing high-frequency sounds.

Ear Infections

Otitis Externa. Ear infections can occur in the ear canal (otitis externa) or in the middle ear (otitis media). Otitis media is the leading cause of healthcare visits and drug prescriptions throughout the world with 50% occurring in the under 5-year age group.[220]

Otitis externa is the most common infection of the outer ear usually caused by bacteria and less commonly a fungus.[221] The most frequently found microorganisms are *Pseudomonas, Escherichia coli,* and *Staphylococcus aureus.* Infection usually follows prolonged exposure to moisture (swimmer's ear). The earliest symptoms are inflammation with swelling and clear drainage progressing to purulent drainage with obstruction of the canal. Tenderness and pain with earlobe retraction accompany inflammation.

Otitis Media. **Otitis media** is an infection of the middle ear and is the most common infection of infants and children. Most children have one episode by 3 years of age. The most common pathogens are *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis.* Respiratory viruses also may have an etiologic role.[222] Predisposing factors include

allergy, sinusitis, submucous cleft palate, adenoidal hypertrophy, and immune deficiency. Breast-feeding is a protective factor.

Acute otitis media (AOM) is associated with ear pain, fever, irritability, inflamed tympanic membrane, and fluid in the middle ear. The tympanic membrane progresses from erythema to opaqueness with bulging as fluid accumulates. An increasing prevalence of AOM is caused by methicillin-resistant microorganisms. Otitis media with effusion (OME) is the presence of fluid in the middle ear without symptoms of acute infection. Treatment includes antimicrobial therapy for AOM, particularly in children 2 years and younger.

Chronic otitis media is persistent or recurring infection of the middle ear. Placement of tympanostomy tubes is considered when bilateral effusion persists for 3 months and for significant hearing loss.[223] Mastoidectomy combined with tympanostomy tubes may be required when there is cholesteatoma (skin growth into the middle ear associated with perforation of the eardrum).[224] Complications include mastoiditis, brain abscess, meningitis, and chronic otitis media with hearing loss. Speech, language, and cognitive disabilities may be affected by persistent middle ear effusions.

Auditory Dysfunction

Between 5% and 10% of the general population have a hearing impairment. The major categories of auditory dysfunction are conductive hearing loss, sensorineural hearing loss, mixed hearing loss, and functional hearing loss.

Conductive Hearing Loss. **Conductive hearing loss** occurs when a change in the outer or middle ear impairs sound from being conducted from the outer to the inner ear. Conductive hearing loss occurs when there is interference in air conduction. Conditions that commonly cause a conductive hearing loss include impacted cerumen, foreign bodies lodged in the ear canal, benign tumors of the middle ear, carcinoma of the external auditory canal or middle ear, eustachian tube dysfunction, otitis media, acute viral otitis media, chronic suppurative otitis media, cholesteatoma, and otosclerosis (impaired mobility of the stapes footplate in the presence of dense sclerotic bone).

Symptoms of conductive hearing loss include diminished hearing and soft speaking voice. The voice is soft because often the individual hears his or her voice, conducted by bone, as loud. In addition, although the cause is unknown, the individual often hears better in a noisy environment than in a quiet one (a condition called *paracusia willisiana*). Treatment of the underlying cause generally improves hearing and a hearing aid can improve quality of life.[225]

Sensorineural Hearing Loss. A **sensorineural hearing loss** is caused by impairment of the organ of Corti or its central connections. The hearing loss may be gradual or sudden. Conditions that commonly cause sensorineural hearing loss include congenital and hereditary factors, noise exposure, aging, Ménière disease, ototoxicity, and systemic disease (syphilis, Paget disease, collagen diseases, diabetes mellitus). Congenital and neonatal sensorineural hearing loss may be caused by maternal rubella, ototoxic drugs, prematurity, traumatic delivery, erythroblastosis fetalis, and congenital hereditary malfunction. Diagnosis often is made when delayed speech development is noted.

Presbycusis is age-related hearing loss usually in the high frequencies. It is the most common form of sensorineural hearing loss and is especially common in older adutls.[218] Presbycusis may occur because of atrophy of the basal end of the organ of Corti, a loss in the number of auditory receptors, changes in vasculature, or stiffening of the basilar membranes. Because of the slow progression of hearing loss, onset of symptoms is gradual. In addition, drug ototoxicities (drugs that cause destruction of auditory function) have been observed after exposure to a variety of chemicals, for example, antibiotics such as streptomycin, neomycin, gentamicin, and vancomycin; diuretics such as ethacrynic acid and furosemide; and chemicals such as salicylate, quinine, carbon monoxide, nitrogen mustard, arsenic, mercury, gold, tobacco, and alcohol. Because of increased concentrations of antibiotics in the endolymph, these drugs generally cause damage to the cells of the cristae and maculae (located in the inner ear) or the cells of the organ of Corti. The increased concentration of drugs in the endolymph is preferentially toxic to the cells.

Diuretics affect hearing primarily by altering the sodium-potassium balance, causing extracellular fluid accumulation and changes in the microstructure of secretory cells. Quinine, mercury, and lead affect the neural pathways of hearing, including the spinal ganglia, the eighth cranial nerve, and the cochlear nucleus. The site of action for the other chemicals, including alcohol and tobacco, has not yet been determined. In most instances the drugs and chemicals listed previously initially cause **tinnitus** (ringing in the ear), followed by a progressive high-tone sensorineural hearing loss. Care is aimed at prevention of further hearing loss because the loss is usually permanent.

Mixed Hearing Loss. A **mixed hearing loss** is caused by a combination of conductive and sensorineural losses.

Functional Hearing Loss. A **functional hearing loss** occurs for no organic reason. The individual does not respond to voice and appears not to hear. Functional hearing loss is thought to be caused by emotional or psychologic factors. It occurs only rarely.

Olfaction and Taste

Olfaction (smell) dysfunction and taste (gustation) dysfunction may occur separately or jointly. The strong relationship between smell and taste creates the sensation of flavor. If either sensation is impaired, the perception of flavor is altered. (Olfactory structures are illustrated in Figure 16-22.)

Olfaction is a function of cranial nerve I (olfactory) and part of cranial nerve V (trigeminal). The receptor cells for smell are located in the olfactory epithelium. Seven primary classes of olfactory stimulants have been identified: (1) camphoraceous, (2) musky, (3) floral, (4) peppermint, (5) ethereal, (6) pungent, and (7) putrid.

Olfactory dysfunctions include hyposmia, anosmia, hallucinations, and parosmia. **Hyposmia** is the impaired sense of smell, and **anosmia** is the complete loss of smell. Both conditions are associated with aging, neurodegenerative and nasal/sinus disorders, and head trauma.[226] When hyposmia or anosmia occurs bilaterally, it is usually the result of rhinitis

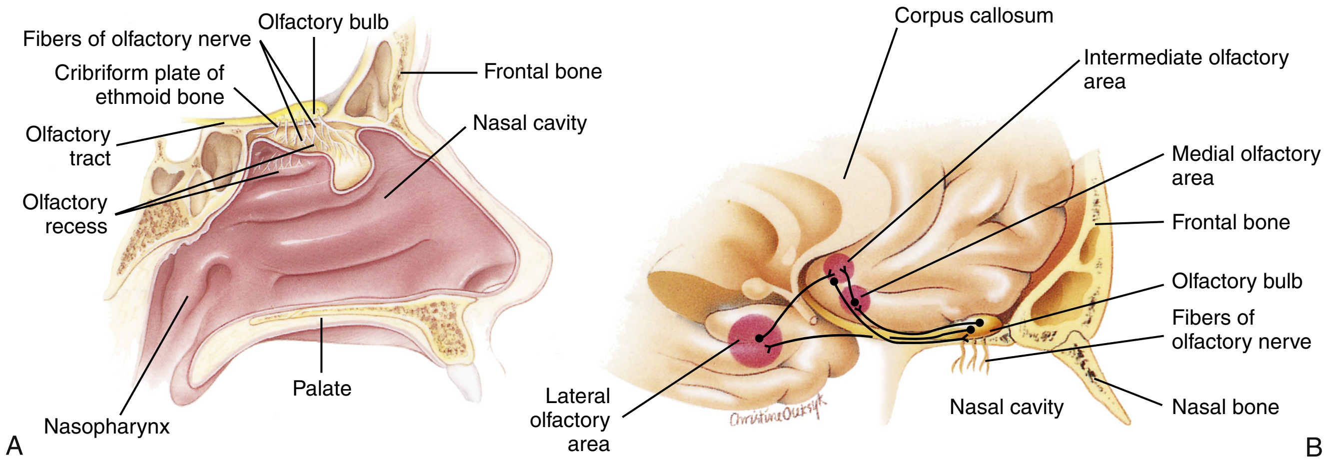

FIGURE 16-22 Olfaction. Location of olfactory epithelium, olfactory bulb, and neuronal pathways involved in olfaction. **A,** Midsagittal section of the nasal area shows the locations of major olfactory sensory structures. **B,** Major olfactory integration centers of the brain. (Modified from Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

(inflammation of nasal mucosa), sinusitis, nasal polyps, or excessive smoking. Unilateral hyposmia or anosmia may indicate compression of one olfactory bulb (a bulblike portion of the olfactory nerves) or nerve tract (olfactory nerve pathway), possibly by tumor or head trauma. **Olfactory hallucinations** arise from hyperactivity in cortical neurons and involve smelling odors that are not really present. They are associated with temporal lobe seizures and rarely with schizophrenia. **Parosmia,** an abnormal or perverted sense of smell, may occur with severe depression.[227]

Taste is a function of multiple nerves in the tongue, soft palate, uvula, pharynx, and upper esophagus, including cranial nerves VII (facial) and IX (glossopharyngeal). The primary sensations of taste are sour, salty, sweet, bitter, and umami (savoriness). Taste buds sensitive to each of the primary sensations are located on the circumvallate, fungiform, and foliate papillae in specific areas of the tongue. Taste receptors also are found on airway smooth muscle (bitter) and in the gastrointestinal tract (bitter and sweet). Their function is not for taste. In the lung they stimulate bronchodilation and in the gastrointestinal tract they may participate in metabolic and digestive regulation.[228,229]

Alterations in taste can be caused by injury, medications, oral infections, or aging. A change in taste also may be attributable to impairment of smell associated with injury near the hippocampus.

Hypogeusia is a decrease in taste sensation, and **ageusia** is the absence of taste. Ageusia affecting the entire tongue may follow head injury. Damage to the glossopharyngeal nerve (cranial nerve IX, which innervates the posterior one third of the tongue) causes the loss of the ability to detect bitterness. This loss occurs because the receptors for bitter are located on the base of the tongue. Damage to the facial nerve (cranial nerve VII, which innervates the anterior two thirds of the tongue) causes loss of the ability to detect sour, sweet, and salty tastes. Only bitter tastes can be detected. These losses occur because sour, sweet, and salt receptors are located on the anterior portion of the tongue. **Parageusia** is a perversion of taste in which substances possess an unpleasant flavor. Parageusia occasionally develops for no apparent reason in older adults and is common in individuals receiving chemotherapy for cancer. In both cases, parageusia often leads to anorexia and malnutrition.

AGING AND OLFACTION AND TASTE

Sensitivity to odors declines steadily with aging.[230,231a] A study of odor identification indicates an increasing ability from childhood to adolescence and then a decline after 60 years of age. The sense of smell begins to degenerate with loss of olfactory sensory neurons and loss of cells from the olfactory bulbs. Loss of olfactory sensitivity and odor identification may diminish appetite and food selection and thus may lead to malnutrition. Safety also may be compromised by an inability to smell spoiled food or hazardous gases.[226]

The decline in taste sensation is more gradual than that of smell and is associated with loss of olfaction. Higher concentrations of flavors are required, and older adults have difficulty differentiating combinations of flavors. Taste changes with aging are associated with decline in the number of fungiform papillae on the tongue, and changes in taste receptor function.[231] Taste also may be affected by decreased salivary gland secretion. Amylase, contained in saliva, facilitates perception of sweet flavors.

SUMMARY REVIEW

Pain

1. Pain is a protective and a complex phenomenon composed of sensory experiences (time, space, intensity) and emotion, cognition, and motivation.
2. The gate control theory of pain describes the modulation of pain in the dorsal horn of the spinal cord by sensory afferent stimulation and central descending impulses that influence the "pain gate" within the substantia gelatinosa of the spinal cord.
3. The neuromatrix theory proposes that sensory inputs to the brain produce patterns of pain but the stimuli may originate independently in the brain with no external input.
4. The portions of the nervous system responsible for the sensation and perception of pain may be divided into three areas: (a) the afferent fibers, (b) the afferent pathways, and (c) the CNS.
5. The afferent system is composed of nociceptors, Aδ and C fibers (first-order neurons); the dorsal horn of the spinal column (second-order neurons); and afferent neurons in the spinothalamic tract (third-order neurons).
6. Nociceptors detect a wide range of stimuli and respond to chemical, mechanical, and thermal stimulation.
7. Myelinated Aδ receptor transmission is fast and conveys mechanical and thermal, sharp, localized pain. Unmyelinated polymodal C fiber transmission is slower and conveys diffuse burning and aching sensations. These primary-order neurons terminate on second-order neurons.
8. Three classes of second-order neurons modulate pain transmission: projection cells, excitatory interneurons, and inhibitory interneurons. The second-order neurons are located in the spinal cord laminae and function as a pain gate to regulate pain transmission.
9. Second-order neurons cross over the cord and ascend primarily in the lateral spinothalamic tract to projection centers including the thalamus, reticular formation, and PAG matter.
10. Third-order neurons carry information to the sensory cortex and reticular and limbic systems for pain processing and interpretation.
11. Efferent pathways from the PAG are responsible for modulation or inhibition of afferent pain signals. The thalamus, cortex, and postcentral gyrus perceive, describe, and localize pain. The reticular formation and limbic system control the emotional and affective response to pain.
12. Pain can be modulated by segmental inhibition, which is the peripheral stimulation of nociceptors by touch, vibration, or pressure resulting in closure of the spinal cord pain gate. The higher brain center also can influence painful stimuli (heterosegmental control of nociception) as well as inhibition from the caudal medulla (diffuse noxious inhibitory controls). Thus pain can be modulated with stimulation from the periphery or by descending impulses from the brain.
13. Pain neurotransmitters can be classified as inflammatory, excitatory, and inhibitory modulators of pain. Inflammatory neurotransmitters are usually excitatory.
14. Pain threshold is the point at which pain is perceived. Pain threshold does not vary significantly among people or within the same person over time.
15. Pain tolerance is the duration of time or the intensity of pain that an individual will endure before initiating overt pain response. Tolerance varies widely among individuals and in the same individual over time.
16. Classifications of pain include nociceptive pain (with a known physiologic cause), non-nociceptive pain (neuropathic pain), acute pain (signal to the person of a harmful stimulus), and chronic pain (persistence of pain of unknown cause or unusual response to therapy).
17. Acute pain may be (a) somatic (superficial), (b) visceral (internal), or (c) referred (present in an area distant from its origin).
18. Somatic pain arises from connective tissue, muscle, bone, and skin and is sharp and localized.
19. Visceral pain is from internal organs and is transmitted by sympathetic afferents and is poorly localized.
20. Referred pain usually arises from the viscera and terminates in an area of the spinal cord that is conjoined with fibers originating in the skin and other areas and thereby produces the perception of pain at the referred site.
21. Physiologic responses to acute pain include increased heart rate, respiratory rate, and blood pressure; pallor or flushing; dilated pupils; and diaphoresis. Blood glucose level is elevated; gastric secretion and motility are decreased; and blood flow to the viscera and skin is decreased.
22. Chronic pain generally lasts at least 3 months and may be persistent, for example, low back pain or intermittent migraine headache pain, myofascial pain syndromes, chronic postoperative pain, and chronic pain associated with cancer.
23. Neuropathic pain is usually chronic, results from nerve trauma or disease, and leads to abnormal peripheral and central pain processing. Types of neuropathic pain include deafferentation pain, sympathetically maintained pain, central pain, and phantom pain.
24. Newborns and young children have the anatomic and functional ability to perceive pain. Pain experienced by infants may have prolonged effects on brain organization and responses to pain.
25. Older individuals may or may not have an increased pain threshold. In all age groups, women appear to be more sensitive to pain than are men.
26. Pain in older adults is influenced by liver and renal function, including alterations in the metabolism of drugs and metabolites.

Temperature Regulation

1. Temperature regulation (thermoregulation) is achieved through precise balancing of heat production, heat conservation, and heat loss. Body temperature is maintained around 37° C (98.6° F).
2. Temperature regulation is mediated by the hypothalamus. Peripheral thermoreceptors in the skin and central

SUMMARY REVIEW—cont'd

thermoreceptors in the hypothalamus, spinal cord, and abdominal organs provide the hypothalamus with information about skin and core temperatures.
3. Heat is produced through chemical reactions of metabolism, skeletal muscle contraction (shivering), and chemical thermogenesis.
4. Heat is lost through radiation, conduction, convection, vasodilation, decreased muscle tone, evaporation of sweat, increased ventilation, and voluntary mechanisms.
5. Heat conservation is accomplished through vasoconstriction and voluntary mechanisms.
6. Fever is triggered by the release of pyrogens from leukocytes and other cells involved in the immune response (endogenous pyrogens) and bacteria (exogenous pyrogens). Fever is both a symptom of a disease and a normal immunologic mechanism.
7. Fever involves resetting the hypothalamic thermostat to a higher level. When a fever breaks, the set point is returned to normal.
8. Fever production aids responses to infectious processes. Higher temperatures kill many microorganisms and decrease serum levels of iron, zinc, and copper that are needed for bacterial replication.
9. Infants and older adults require special attention to maintenance of body temperature. Because of their greater body surface area to mass ratio and decreased subcutaneous fat, infants do not conserve heat well. Older individuals have poor responses to environmental temperature extremes as a result of slowed blood circulation, structural and functional changes in skin, and an overall decrease in heat-producing activities.
10. Hyperthermia (marked warming of core temperature) can produce nerve damage, coagulation of cell proteins, and death. Forms of accidental hyperthermia include heat cramps, heat exhaustion, heat stroke, and malignant hyperthermia. Heat stroke and malignant hyperthermia are potentially lethal developments.
11. Hypothermia (marked cooling of core temperature) slows the rate of chemical reaction (tissue metabolism), increases the viscosity of the blood, slows blood flow through the microcirculation, facilitates blood coagulation, and stimulates profound vasoconstriction. Hypothermia may be accidental or therapeutic.

Sleep

1. Sleep may be divided into REM and NREM stages, each of which has its own series of stages. While asleep, an individual progresses through the three stages of NREM (slow-wave) sleep and REM sleep in a predictable cycle.
2. NREM sleep is initiated by the withdrawal of neurotransmitters from the afferent formation and by the inhibition of arousal mechanisms in the cerebral cortex. REM sleep is controlled by mechanisms in the hypothalamus and pontine reticular formation.
3. During sleep the body is actively engaged in restoring and repairing itself. Sleep deprivation can cause profound changes in personality and functioning.
4. The restorative, reparative, and growth processes occur during slow-wave sleep.
5. The sleep patterns of the newborn and young child vary from those of the adult in total sleep time, cycle length, and percentage of time spent in each sleep cycle. Older adults experience a total decrease in sleep time.
6. Sleep disorders include: (a) dyssomnias, (b) parasomnias, (c) sleep disorders associated with mental, neurologic, or other medical disorder, and (d) proposed sleep disorders.
7. Common dyssomnias include insomnia, OSAS, RLS, circadian rhythm disorder, and hypersomnia.
8. Common parasomnias include arousal disorders, sleep-wake transition disorder, and disorders associated with REM sleep.
9. Sleep and disease are interrelated. Some diseases may produce alterations in the quantity and quality of sleep or affect sleep stages. These are referred to as *secondary sleep disorders.* In some instances sleep stages produce alterations in certain disease states. These are referred to as *sleep-provoked disorders.*

Somatosensory Function and the Special Senses

Somatosensory Function

1. The sensation of touch involves the fusion of several qualities, including modality, intensity, location, and duration of the sensory stimulus.
2. Receptors sensitive to touch are present in the skin; these include Meissner and pacinian corpuscles and Merkel disks and Ruffini endings. The sensory response is conducted to the brain through the dorsal column and anterior spinothalamic tract.
3. Abnormal tactile perception may be caused by alterations at any level of the nervous system, from the receptor to the cerebral cortex.
4. Proprioception is the perception of the position and location of the body and its parts. Proprioceptors are located in the inner ear, joints, and ligaments. Proprioceptive stimuli are necessary for balance, coordinated movement, and grading of muscular contraction.
5. Disorders of proprioception can be caused by alterations at any level of the nervous system. Two common causes of proprioceptive dysfunction are vestibular dysfunction and neuropathy.

Vision

1. The eyelids, conjunctivae, and lacrimal apparatus protect the eye. Infections are the most common disorders; they include blepharitis, conjunctivitis, chalazion, and hordeolum.
2. Conjunctivitis can be acute or chronic, bacterial, viral, or allergic. Redness, edema, pain, and lacrimation are common symptoms. Trachoma (chlamydial conjunctivitis) is

SUMMARY REVIEW—cont'd

the leading cause of blindness in the world and is associated with poor sanitary conditions.
3. Keratitis is a bacterial or viral infection of the cornea that can lead to corneal ulceration. Photophobia, pain, and tearing are common symptoms.
4. The wall of the eye has three layers: sclera, choroid, and retina. The retina contains millions of photoreceptors known as rods and cones that receive light through the lens and then convey signals to the optic nerve and subsequently to the visual cortex of the brain.
5. The eye is filled with vitreous and aqueous humor, which prevent it from collapsing.
6. Structural eye changes caused by aging or chronic disease result in decreased visual acuity.
7. The major alterations in ocular movement include strabismus, nystagmus, and paralysis of the extraocular muscles.
8. Alterations in visual acuity can be caused by amblyopia, scotoma, cataracts, papilledema, macular degeneration, retinal detachment, and glaucoma.
9. Alterations in accommodation develop with increased intraocular pressure, inflammation, and disease of the oculomotor nerve. Presbyopia is loss of accommodation caused by loss of lens elasticity with aging.
10. Alterations in refraction, including myopia, hyperopia, and astigmatism, are the most common visual disorders.
11. Alterations in color vision occur with disorders of the cornea and the inherited trait of color blindness.
12. Trauma or disease of the optic nerve pathways, or optic radiations, can cause blindness in the visual fields. Homonymous hemianopsia is caused by damage of one optic tract.
13. Retinoblastoma is a congenital eye tumor that has a hereditary and a nonhereditary form.

Hearing

1. The ear is composed of external, middle, and inner structures. The external structures are the pinna, auditory canal, and tympanic membrane. The tympanic cavity (containing three bones: malleus, incus, and stapes), oval window, eustachian tube, and fluid comprise the middle ear and transmit sound vibrations to the inner ear.
2. The inner ear includes the bony and membranous labyrinths that transmit sound waves through the cochlea to the division of the eighth cranial nerve (i.e., vestibulocochlear). The semicircular canals and vestibule help maintain balance through the equilibrium receptors.
3. Approximately one third of all people older than 65 years have hearing loss.
4. Otitis externa is an infection of the outer ear. Otitis media, an infection of the middle ear, is common in children and can be acute or chronic.
5. Acute otitis media is an infection of the middle ear associated with ear pain, fever, an inflamed tympanic membrane, and fluid in the middle ear.
6. Chronic otitis media is persistent or recurrent middle ear infection.
7. Hearing loss can be classified as conductive, sensorineural, mixed, or functional.
8. Conductive hearing loss occurs when sound waves cannot be conducted through the middle ear.
9. Sensorineural hearing loss develops with impairment of the organ of Corti or its central connections. Presbycusis is age-related hearing loss and is the most common form of sensorineural hearing loss.
10. A combination of conductive and sensorineural loss is a mixed hearing loss.
11. Loss of hearing with no known organic cause is a functional hearing loss.

Olfaction and Taste

1. The perception of flavor is altered if olfaction or taste dysfunctions occur. Sensitivity to odor and taste decreases with aging.
2. Hyposmia is a decrease in the sense of smell, and anosmia is the complete loss of smell. Inflammation of the nasal mucosa and trauma or tumors of the olfactory nerve lead to a diminished sense of smell.
3. Hypogeusia is a decrease in taste sensation, and ageusia is the absence of taste. Loss of taste buds or trauma to the facial or glossopharyngeal nerves decreases taste sensation.

CHAPTER OUTLINE

A person achieves functional adequacy (competence) through complex integrated processes. Three major neural systems account for this functional adequacy: cognitive systems, sensory systems, and motor systems. Alterations in any or all of these affect functional adequacy. Alterations in cognitive and sensory systems and motor function are associated with many central and peripheral nervous system injuries and pathologies. The purpose of this chapter is to present the concepts and processes of these alterations as an approach to understanding the manifestation of neurologic dysfunction. Some specific diseases are also presented (i.e., Parkinson disease, Huntington disease, and amyotrophic lateral sclerosis) because they fit best here. The manifestations of these concepts and processes are integrated with specific central and peripheral nervous system disorders and are presented in Chapter 18. Alterations in sensory function are presented in Chapter 16.

The neural systems essential to cognitive function are: (1) attentional systems that provide arousal and maintenance of attention over time; (2) memory and language systems by which information is communicated; and (3) affective or emotive systems that mediate mood, emotion, and intention. These core systems are fundamental to the processes of abstract thinking and reasoning. The products of abstraction and reasoning are organized and made operational through the executive attentional networks. The normal functioning of these systems manifests through the motor system in a behavioral array viewed by others as being appropriate to human activity and successful living. Nervous system disorders can be acquired (i.e., from trauma, infection, or related to systemic disease) or have a genetic basis.

ALTERATIONS IN COGNITIVE SYSTEMS

Full **consciousness** is a state of awareness both of oneself and of the environment and appropriate responses to that environment. The fully conscious individual responds to external stimuli with a wide array of responses. Any decrease in this state of awareness and varied responses is thus a decrease in consciousness.

Consciousness has two distinct components: arousal (state of awakeness) and awareness (content of thought). **Arousal** is mediated by the reticular activating system, which regulates aspects of attention and information processing and maintains consciousness (see Figure 15-6). Cognitive cerebral functions require a functioning reticular activating system. **Awareness** encompasses all cognitive functions and is mediated by attentional systems, memory systems, language systems, and executive systems.

Alterations in Arousal

Alterations in level of arousal may be caused by structural, metabolic, or psychogenic (functional) disorders.

PATHOPHYSIOLOGY. **Structural alterations in arousal** are divided according to original location of the pathologic condition or lesion: supratentorial (above the tentorium cerebelli); infratentorial (subtentorial, below the tentorium cerebelli); subdural (below the dura mater [see Figure 17-17]); extracerebral (outside the brain tissue); and intracerebral (within the brain tissue). Structural alterations can be caused by infectious, vascular, neoplastic, traumatic, congenital (developmental), degenerative, genetic, and metabolic disorders.

Supratentorial disorders produce changes in arousal by either diffuse or localized dysfunction. Diffuse dysfunction may be caused by disease processes affecting the cerebral cortex or the underlying subcortical white matter (e.g., encephalitis). Disorders outside the brain but within the cranial vault (extracerebral) also can produce diffuse dysfunction, including neoplasms, closed-head trauma with subsequent bleeding, and subdural empyema (accumulation of pus). Localized dysfunction is generally caused by masses that directly impinge on diencephalic structures (i.e., thalamus and hypothalamus) or that secondarily compress these structures in the process of herniation. Disorders within the brain substance (intracerebral)—bleeding, infarcts, emboli, and tumors—function primarily as masses. Such localized destructive processes directly impair function of the thalamic or hypothalamic activating systems.

Infratentorial disorders produce a decline in arousal in one of two ways: (1) there may be a direct destruction of the reticular activating system (RAS) and its pathways, or (2) the brainstem may be destroyed either by direct invasion or by indirect impairment of its blood supply. The most common cause of direct destruction is cerebrovascular disease. Demyelinating diseases, neoplasms, granulomas, abscesses, and head injury also may cause brainstem destruction by tissue compression. This compression may occur because of (1) direct pressure on the pons and midbrain, producing ischemia and edema of the neurons of the RAS; (2) upward herniation of the cerebellum through the tentorial notch, thus compressing the upper midbrain and diencephalon; or (3) downward herniation of the cerebellum through the foramen magnum, compressing and displacing the medulla oblongata.

Metabolic alterations in arousal are caused by alterations in delivery of energy substrates (e.g., hypoxia, electrolyte disturbances, or hypoglycemia) or alterations in neuronal excitability caused by drugs and toxins (both exogenous and endogenous [e.g., liver or renal failure]). All the systemic diseases that eventually produce nervous system dysfunction are part of this metabolic category.

Psychogenic alterations in arousal (unresponsiveness), although uncommon, may signal general psychiatric disorders (see Chapter 19). Despite apparent unconsciousness, the person actually is physiologically awake and the neurologic examination reflects a normal response.

CLINICAL MANIFESTATIONS AND EVALUATION. Patterns of clinical manifestations assist in determining the extent of brain dysfunction and serve as indexes for identifying increasing or decreasing central nervous system (CNS) function. Distinctions are made between metabolic and structurally induced manifestations (Table 17-1). The types of manifestations suggest the

TABLE 17-1 CLINICAL MANIFESTATIONS OF METABOLIC AND STRUCTURAL CAUSES OF ALTERED AROUSAL

MANIFESTATION	METABOLICALLY INDUCED	STRUCTURALLY INDUCED
Blink to threat (cranial nerves II, VII)	Equal	Asymmetric
Discs (cranial nerve II)	Flat, good pulsation	Papilledema
Extraocular movement (cranial nerves III, IV, VI)	Roving eye movements; normal doll's eyes and calorics	Gaze paresis, nerve III palsy, medial longitudinal fasciculus (MLF) syndrome (internuclear ophthalmoplegia)
Pupils (cranial nerves II, III)	Equal and reactive; may be large (e.g., atropine), pinpoint (e.g., opiates), or midposition and fixed (e.g., glutethimide [Doriden])	Asymmetric and/or nonreactive; may be midposition (midbrain injury), pinpoint (pons injury), large (tectal injury)
Corneal reflex (cranial nerves V, VII)	Symmetric response	Asymmetric response
Grimace to pain (cranial nerve VII)	Symmetric response	Asymmetric response
Motor function movement	Symmetric	Asymmetric
Tone	Symmetric	Paratonic, spastic, flaccid, especially if asymmetric
Posture	Symmetric	Decorticate, especially if symmetric; decerebrate, especially if asymmetric
Deep tendon reflexes	Symmetric	Asymmetric
Babinski sign	Absent or symmetric response	Present
Sensation	Symmetric	Asymmetric

cause of the altered arousal state (Table 17-2). Five categories of neurologic function are critical to the evaluation process: (1) level of consciousness, (2) pattern of breathing, (3) pupillary changes, (4) oculomotor responses, and (5) motor responses.

Level of Consciousness

Level of consciousness is the most critical clinical index of nervous system function or dysfunction. Changes can indicate either improvement or deterioration of the individual's condition and state of awakeness. A person who is alert and oriented to self, others, place, and time is considered to be functioning at the highest level of consciousness, which implies full use of all the person's cognitive capacities. From this normal alert state, levels of consciousness diminish in stages from confusion to coma, each of which is clinically defined (Table 17-3).

Pattern of Breathing

Respiratory patterns help to evaluate level of brain dysfunction and level of coma. Rate, rhythm, and pattern of breathing should be assessed. The breathing patterns can be categorized as hemispheric or brainstem breathing patterns (Table 17-4 and Figure 17-1).

With normal breathing, a neural center in the forebrain (cerebrum) produces a rhythmic breathing pattern. When consciousness decreases, lower brainstem centers regulate the breathing pattern by responding only to changes in $Paco_2$ levels. This irregular breathing pattern is called **posthyperventilation apnea (PHVA).**

Cheyne-Stokes respiration is an abnormal rhythm of breathing (periodic breathing) with alternating periods of hyperventilation and apnea (crescendo-decrescendo pattern).

TABLE 17-2 DIFFERENTIAL CHARACTERISTICS OF DISORDERS CAUSING ALTERED AROUSAL

MECHANISM	MANIFESTATIONS
Supratentorial mass lesions compressing or displacing diencephalons or brainstem	Initiating signs usually of focal cerebral dysfunction Signs of dysfunction progress rostral to caudal Neurologic signs at any given time point to one anatomic area (e.g., diencephalon, mesencephalon, medulla) Motor signs often asymmetric
Infratentorial mass of destruction, causing coma	History of preceding brainstem dysfunction or sudden onset of coma Localizing brainstem signs precede or accompany onset of coma and always include oculovestibular abnormality Cranial nerve palsies; usually manifest "bizarre" respiratory patterns that appear at onset
Metabolic coma Exogenous toxins (drugs) Endogenous toxins (organ system failure)	Confusion and stupor commonly precede motor signs Motor signs usually are symmetric Pupillary reactions usually are preserved Asterixis, myoclonus, tremor, and seizures are common Acid-base imbalance with hyperventilation or hypoventilation is common
Psychiatric unresponsiveness	Lids close actively Pupils reactive or dilated (cycloplegics) Oculocephalic reflexes are unpredictable; oculovestibular reflexes are physiologic (nystagmus is present) Motor tone is inconsistent or normal Eupnea or hyperventilation is usual No pathologic reflexes are present Electroencephalogram (EEG) is normal

TABLE 17-3 LEVELS OF ALTERED CONSCIOUSNESS

STATE	DEFINITION
Confusion	Loss of ability to think rapidly and clearly; impaired judgment and decision making
Disorientation	Beginning loss of consciousness; disorientation to time followed by disorientation to place and impaired memory; lost last is recognition of self
Lethargy	Limited spontaneous movement or speech; easy arousal with normal speech or touch; may not be oriented to time, place, or person
Obtundation	Mild to moderate reduction in arousal (awakeness) with limited response to the environment; falls asleep unless stimulated verbally or tactilely; answers questions with minimum response
Stupor	A condition of deep sleep or unresponsiveness from which the person may be aroused or caused to open eyes only by vigorous and repeated stimulation; response is often withdrawal or grabbing at stimulus
Coma	No verbal response to the external environment or to any stimuli; noxious stimuli such as deep pain or suctioning yields motor movement
Light coma	Associated with purposeful movement on stimulation
Coma	Associated with nonpurposeful movement only on stimulation
Deep coma	Associated with unresponsiveness or no response to any stimulus

TABLE 17-4 PATTERNS OF BREATHING

BREATHING PATTERN	DESCRIPTION	LOCATION OF INJURY
Hemispheric Breathing Patterns		
Normal	After a period of hyperventilation that lowers the arterial carbon dioxide pressure (Pa_{CO_2}), the individual continues to breathe regularly but with a reduced depth.	Response of the nervous system to an external stressor—not associated with injury to the CNS
Posthyperventilation apnea	Respirations stop after hyperventilation has lowered the P_{CO_2} level below normal. Rhythmic breathing returns when the P_{CO_2} level returns to normal. (Usually an intact cerebral cortex will trigger breathing within 10 seconds regardless of P_{CO_2}.)	Associated with diffuse bilateral metabolic or structural disease of the cerebrum
Cheyne-Stokes respirations	Breathing pattern has a smooth increase (crescendo) in the rate and depth of breathing (hyperpnea), which peaks and is followed by a gradual smooth decrease (decrescendo) in the rate and depth of breathing to the point of apnea when the cycle repeats itself. The hyperpneic phase lasts longer than the apneic phase (represents an amplitude change).	Bilateral dysfunction of the deep cerebral or diencephalic structures; seen with supratentorial injury and metabolically induced coma states unrelated to neurologic dysfunction; may see also in CHF
Brainstem Breathing Patterns		
Central reflex hyperpnea (central neurogenic hyperventilation)	A sustained deep rapid but regular pattern (hyperpnea) occurs, with a decreased Pa_{CO_2} and a corresponding increase in pH and increased P_{O_2}.	May result from CNS damage or disease that involves the lower midbrain and upper pons; seen after increased intracranial pressure and blunt head trauma
Apneusis	A prolonged inspiratory cramp (a pause at full inspiration) occurs. A common variant of this is a brief end-inspiratory pause of 2 or 3 seconds, often alternating with an end-expiratory pause.	Indicates damage to the respiratory control mechanism located at the pontine level; most commonly associated with pontine infarction but documented with hypoglycemia, anoxia, and meningitis
Cluster breathing	A cluster of breaths has a disordered sequence with irregular pauses between breaths.	Dysfunction in the lower pontine and high medullary areas
Ataxic breathing	Completely irregular breathing occurs, with random shallow and deep breaths and irregular pauses. Often the rate is slow.	Originates from a primary dysfunction of the lower pons or upper medulla
Gasping breathing pattern (agonal gasps)	A pattern of deep "all-or-none" breaths is accompanied by a slow respiratory rate.	Indicative of a failing medullary respiratory center

CHF, Congestive heart failure; *CNS,* central nervous system.

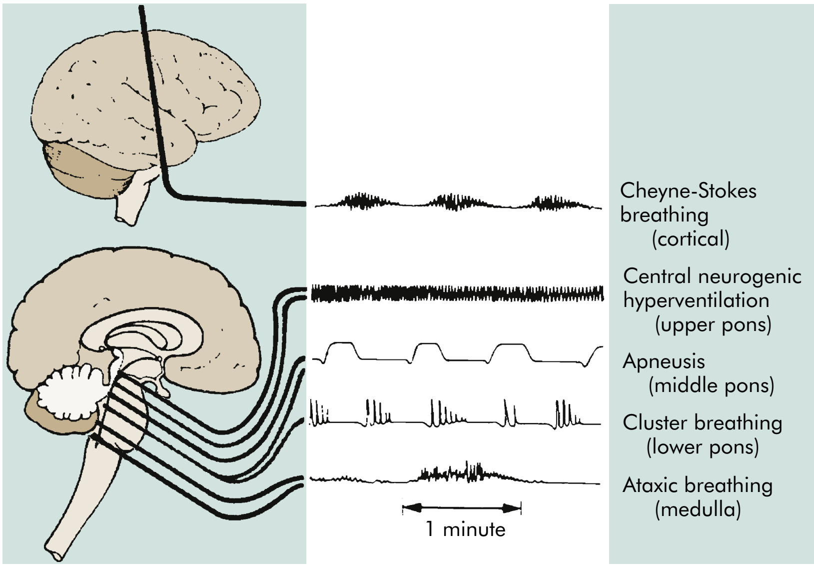

FIGURE 17-1 Abnormal Respiratory Patterns with Corresponding Level of Central Nervous System Activity.

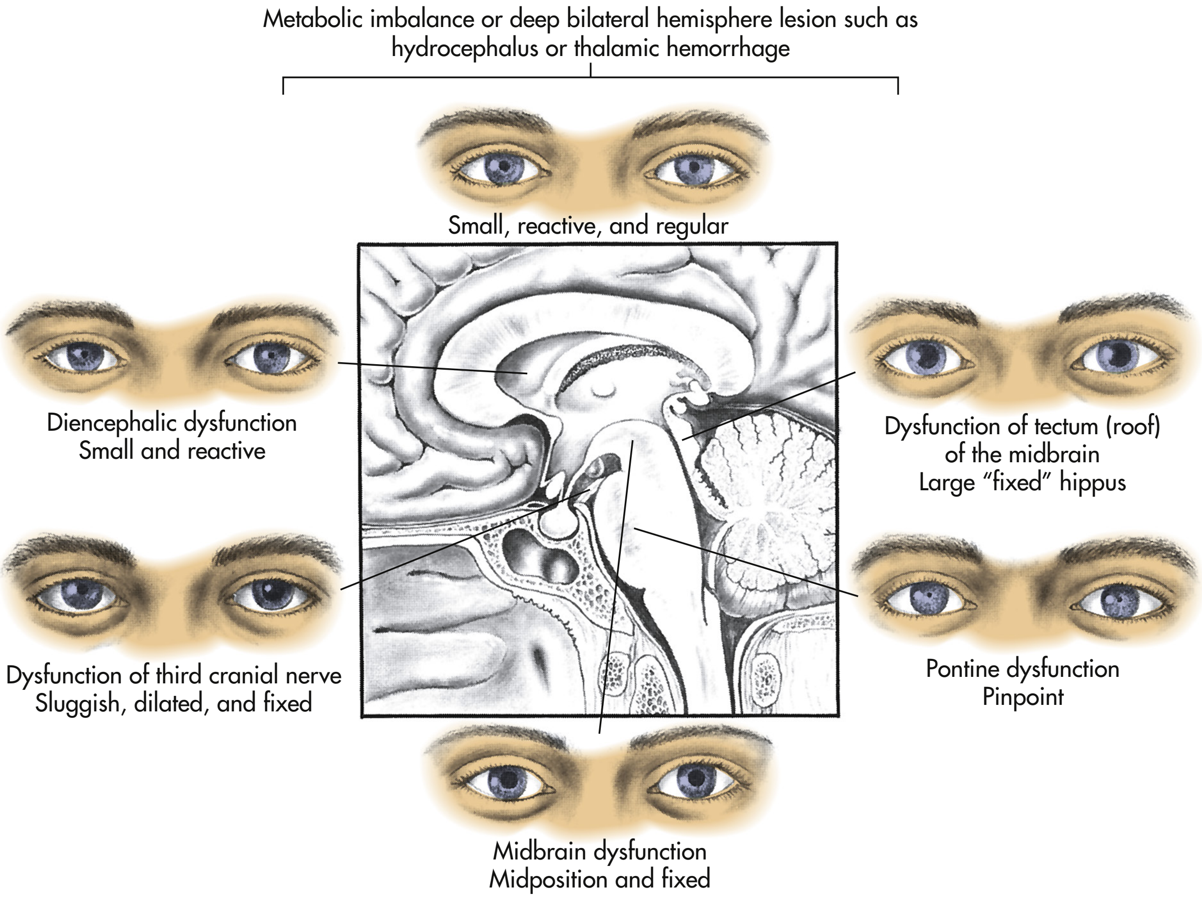

FIGURE 17-2 Appearance of Pupils at Different Levels of Consciousness.

TABLE 17-5 CHANGES IN OCULOMOTOR RESPONSES

STATE	RESTING AND SPONTANEOUS EYE MOVEMENTS	REFLEXIVE EYE MOVEMENTS
Full consciousness	Eyes at rest, still (cortical gaze centers inhibit spontaneous roving eye movements)	Eyes move as the head turns Oculocephalic responses not elicited or inconsistently elicited (frontal gaze centers inhibit brainstem reflexes that fix gaze straight ahead) Oculovestibular (caloric) stimulation produces nystagmus
Cortical dysfunction or disruption of efferent pathways	Conjugate, horizontal, roving eye movements may well be present (cortical gaze centers no longer inhibit these brainstem-generated roving eye movements)	Gaze fixed straight ahead regardless of head position—positive doll's eyes reaction (normal oculocephalic reflexes are no longer inhibited by frontal gaze centers)
Diffuse anoxic damage to cortex	"Ocular dipping"—slow, dysrhythmic downward movement followed by faster, upward movement	Nystagmus is no longer induced by caloric stimulation (normally a cold-water stimulus produces deviation of the eyes opposite the irrigated ear; a warm-water stimulus deviates the eyes to the same [ipsilateral] side) With an injury that depresses cortical gaze center function, the eyes (and often the entire head) deviate or appear to look toward the side of the injured hemisphere With an injury that irritates (stimulates) the neurons of the cortical gaze center, the eyes (and often the entire head) deviate away from the injured hemisphere (all fibers from the frontal gaze centers decussate and therefore control the function of the contralateral pontine gaze center, which moves the eyes in the ipsilateral direction)
Mesencephalon dysfunction	Roving eye movements cease and the eyes become immobile and directed ahead (roving eye movements require an intact brainstem) Eyes may turn down and inward	Oculovestibular reflexes become inconsistent and abnormal Loss of Bell phenomenon (upward deviation of eyes on stimulation) (requires intact eye movement pathways from the mesencephalon to pons)
Pontine dysfunction	Loss of spontaneous blinking (requires an intact pons) "Ocular bobbing"—brisk, conjugate, downward movement of eyes with loss of horizontal eye movements	

The pathophysiology of Cheyne-Stokes respiration involves a hyperventilatory response to carbon dioxide stimulation. In the damaged brain, higher levels of $Paco_2$ (hypercapnia) are required to stimulate ventilation, and the response is hyperventilation. As a result, the $Paco_2$ level decreases to below normal and breathing stops (PHVA) until carbon dioxide reaccumulates and stimulates hyperventilation. In cases of opiate or sedative drug overdose, the respiratory center is depressed and the rate of breathing gradually decreases until respiratory failure occurs.

Central neurogenic hyperventilation is a respiratory pattern of sustained hyperventilation caused by a lesion in the central pons. **Apneustic respirations** have prolonged inspiratory and expiratory phases caused by injury to the pons or upper medulla. **Cluster respirations** are characterized by periods or clusters of rapid respirations of near equal depth resulting from trauma or compression to the medulla or from chronic opioid abuse. **Ataxic respirations** are irregular respirations with prolonged periods of apnea associated with damage to the medulla (see Figure 17-1).

Pupillary Changes

Brainstem areas that control arousal are adjacent to areas that control the pupils. Pupillary changes thus are a valuable guide to evaluating the presence and level of brainstem dysfunction (Figure 17-2).

Some drugs affect pupils and must be considered in the evaluation of pupillary responses in comatose states. Large doses of atropine, scopolamine, amphetamines, mydriatics, and cycloplegics can fully dilate and fix pupils. Sedatives (e.g., glutethimide) in sufficient amounts to produce a coma cause the pupils to become midposition or moderately dilated (4 to 5 mm in diameter), unequal, and frequently fixed to light. Opiates (heroin and morphine) and barbiturates, as well as extensive pontine damage, cause pinhole pupils (1 mm). Severe barbiturate intoxication may produce fixed pupils.

Severe ischemia and hypoxia produce bilaterally wide (5 mm) and fixed pupils usually caused by severe midbrain damage. Occasionally the pupils remain small (1 to 2.5 mm) or midposition even in the presence of profound hypoxia. Hypothermia also may cause fixed pupils.

Oculomotor Responses

Resting, spontaneous, and reflexive eye movements and oculovestibular (caloric) reflexes change at various levels of brain dysfunction (Table 17-5). Persons with metabolically induced coma, except in cases of barbiturate-hypnotic and phenytoin (Dilantin) poisoning, generally retain ocular reflexes, however, even when other signs of brainstem damage, such as central neurogenic hyperventilation, are present.

The presence of brisk oculocephalic reflexes and roving eye movements, as well as the failure to elicit nystagmus with instillation of cold or warm water into the external ear canal, indicates a decrease in consciousness (loss of cortical influence) but an intact brainstem (Figures 17-3 and 17-4).

Destructive or compressive injury to the brainstem causes specific abnormalities of the oculocephalic and oculovestibular reflexes. For example, a skewed deviation, in which one eye diverges downward and the other looks upward, indicates brainstem dysfunction. Destructive or compressive disease processes that involve an oculomotor nucleus or nerve cause the involved eye to deviate outward, producing a resting dysconjugate lateral position of the eyes (each eye diverges laterally). Unilateral abducens paralysis (paralysis of cranial nerve VI) results in an upward deviation of the ipsilateral eye. With bilateral abducens paralysis, the eyes come together (converge). Reflexive eye movements may be suppressed by drugs, most commonly phenytoin, tricyclics, and barbiturates. Occasionally alcohol, phenothiazines, and diazepam may alter reflex eye movements.

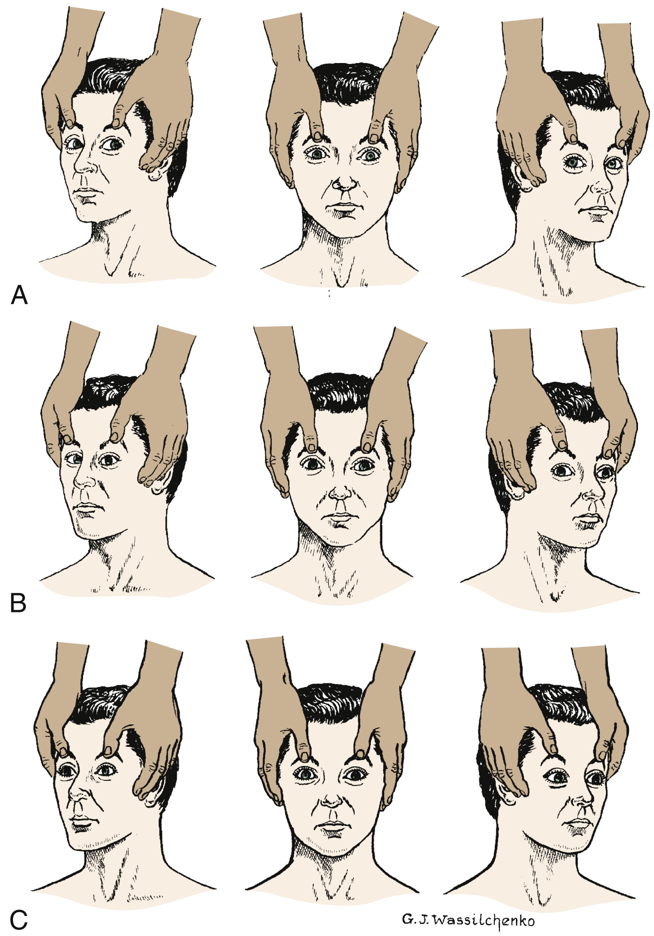

FIGURE 17-3 Test for Oculocephalic Reflex Response (Doll's Eyes Phenomenon). **A,** Normal response—eyes turn together to side opposite from turn of head. **B,** Abnormal response—eyes do not turn in conjugate manner. **C,** Absent response—eyes do not turn as head position changes. (**A** and **C** from Rudy EB: *Advanced neurological and neurosurgical nursing,* St Louis, 1984, Mosby.)

Motor Responses

Assessment of motor responses helps to evaluate the level of brain dysfunction and determine the side of the brain that is maximally damaged. The pattern of response noted may be (1) purposeful (a defensive or withdrawal movement of limbs to noxious stimuli); (2) inappropriate, or not purposeful (generalized motor movement, posturing, grimacing, or groaning); or (3) not present (unresponsive, no motor response).

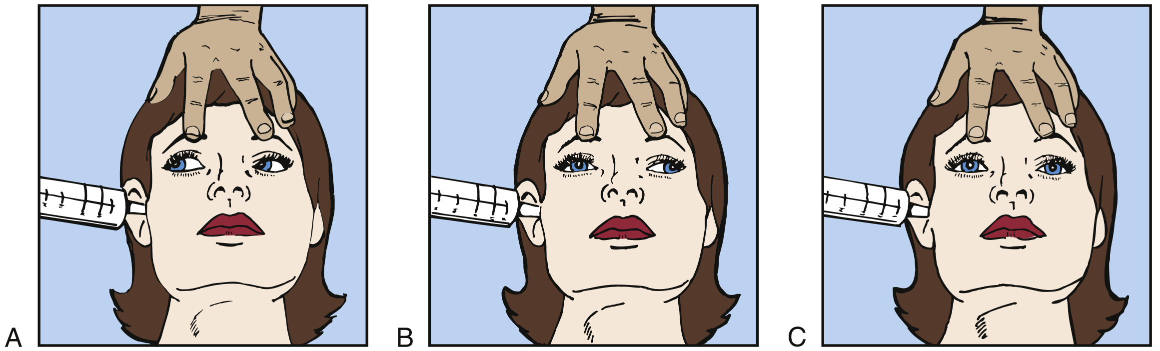

FIGURE 17-4 Test for Oculovestibular Reflex (Caloric Ice-Water Test). **A,** Normal response—conjugate eye movements. **B,** Abnormal response—dysconjugate or asymmetric eye movements. **C,** Absent response—no eye movements.

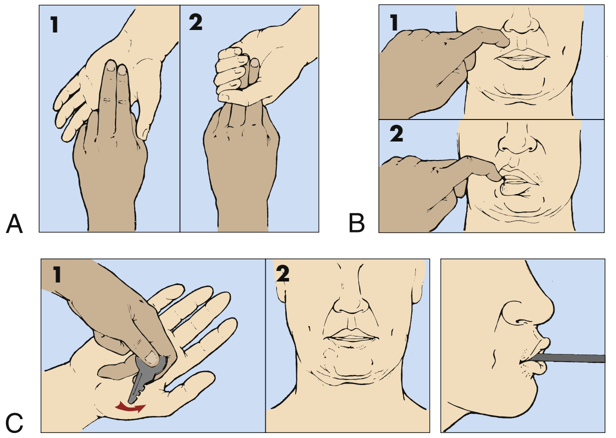

FIGURE 17-5 Pathologic Reflexes. **A,** Grasp reflex. **B,** Snout reflex. **C,** Palmomental reflex. **D,** Suck reflex.

Purposeful movement requires an intact corticospinal system. Nonpurposeful movement is evidence of severe dysfunction of the corticospinal system.

Motor signs indicating loss of cortical inhibition are commonly associated with decreased consciousness. These signs include contralateral or bilateral (depending on whether the process is localized or diffuse) reflex grasping, reflex sucking, snout reflex, palmomental reflex, and rigidity (paratonia) (Figure 17-5). Abnormal flexor and extensor responses, particularly in the upper extremities, are defined in Table 17-6 and illustrated in Figure 17-6.

Vomiting, yawning, and **hiccups** are complex reflex-like motor responses that are integrated by neural mechanisms in the lower brainstem. These responses may be produced by compression or diseases involving tissues of the medulla oblongata (e.g., infection, neoplasm, infarct, or other more benign stimuli to the vagal nerve). Most CNS disorders produce nausea and vomiting. Vomiting without nausea indicates direct involvement of the central neural mechanism (or pyloric obstruction). Vomiting often accompanies CNS injuries that (1) involve the vestibular nuclei or its immediate projections, particularly when double vision (diplopia) also is present; (2) impinge directly on the floor of the fourth ventricle; or (3) produce brainstem compression secondary to increased intracranial pressure.

Outcomes of Alterations in Arousal

Outcomes of alterations in arousal fall into two categories: *extent of disability (morbidity)* and *mortality*. Outcomes depend on the cause and extent of brain damage and the duration of coma. Some individuals may recover consciousness and an original level of function, some may have permanent disability, and some may never regain consciousness and experience neurologic death. Two forms of neurologic death—brain death and cerebral death—result from severe pathologic conditions and are associated with irreversible coma. Other possible outcomes include a vegetative state, a minimally conscious state, akinetic mutism, or locked-in syndrome. Extent of disability has four subcategories: recovery of consciousness, recovery of residual cognitive function, recovery of psychologic function, and recovery of vocational function.

Brain death (total brain death) occurs when irreversible brain damage is so extensive that the brain has no potential for recovery and no longer can maintain the body's internal homeostasis. State laws define brain death as irreversible cessation of function of the entire brain, including the brainstem and cerebellum. The brain is autolyzing (self-digesting) or already autolyzed on postmortem examination.

Clinical criteria for brain death include the absence of discernible evidence of cerebral hemisphere function or function of the brainstem's vital centers for an extended period. There is no detectable function above the level of the foramen magnum so there is whole brain death. In addition, the abnormality of brain function must result from structural or known metabolic disease and *not* be caused by a depressant drug, alcohol poisoning, neuromuscular blockage, or hypothermia. An isoelectric, or flat, electroencephalogram (EEG) (electrocerebral silence) for a period of 6 to 12 hours in a person who is not hypothermic and has not ingested depressant drugs indicates that no mental recovery is possible. This usually means that the brain is already dead. A task force to determine brain death in children recommended the same criteria as those used for adults[1] but with a longer observation period.

The following summary of medical criteria determines brain death[2-5]:

1. Completion of all appropriate and therapeutic procedures with no possibility of brain function recovery
2. Unresponsive coma (absence of motor and reflex movements)

TABLE 17-6 ABNORMAL MOTOR RESPONSES WITH DECREASED RESPONSIVENESS

MOTOR RESPONSE	DESCRIPTION OF MOTOR RESPONSES	LOCATION OF INJURY
Decorticate posturing/rigidity: upper extremity flexion, lower extremity extension (Figure 17-6)	Slowly developing flexion of the arm, wrist, and fingers with abduction in the upper extremity and extension, internal rotation, and plantar flexion of the lower extremity	Hemispheric damage above midbrain releasing medullary and pontine reticulospinal systems
Decerebrate posturing/rigidity: upper and lower extremity extensor responses (Figure 17-6)	Opisthotonos (hyperextension of the vertebral column) with clenching of the teeth; extension, abduction, and hyperpronation of the arms; and extension of the lower extremities	Associated with severe damage involving midbrain or upper pons
	In acute brain injury, shivering and hyperpnea may accompany unelicited recurrent decerebrate spasms	Acute brain injury may cause limb extension regardless of location
Extensor responses in the upper extremities accompanied by flexion in the lower extremities		Pons
Flaccid state with little or no motor response to stimuli		Lower pons and upper medulla

Data from Goetz CG: *Textbook of clinical neurology,* ed 3, Philadelphia, 2007, Saunders; Nadeau SE et al: *Medical neuroscience,* Philadelphia, 2004, Saunders.

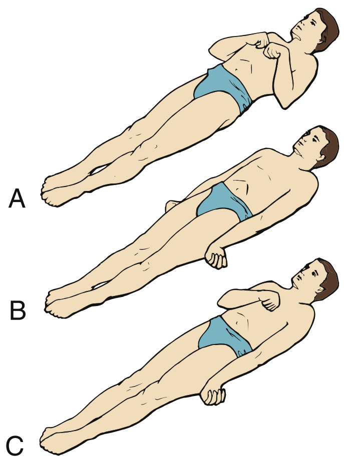

FIGURE 17-6 Decorticate and Decerebrate Responses. **A,** *Decorticate response (flexor posturing):* bilateral flexion of elbows and wrists with shoulder adduction in upper extremities. Extension, internal rotation of lower extremities. **B,** *Decerebrate response (extensor posturing):* all four extremities in rigid extension, internal rotation of shoulders with hyperpronation of forearms. **C,** *Decorticate response on right side of body and decerebrate response on left side of body:* the most pronounced response differences are in the upper body. (From Rudy EB: *Advanced neurological and neurosurgical nursing,* St Louis, 1984, Mosby.)

3. No spontaneous respiration (apnea)—a $Paco_2$ that rises above 60 mmHg without breathing efforts, providing evidence of a nonfunctioning respiratory center (apnea challenge)
4. No brainstem function (ocular responses to head turning or caloric stimulation; dilated, fixed pupils; no gag or corneal reflex)
5. Isoelectric (flat) EEG (electrocerebral silence)
6. Persistence of these signs for an appropriate observation period

Cerebral death or **irreversible coma** is death of the cerebral hemispheres exclusive of the brainstem and cerebellum. Brain damage is permanent and sufficiently severe that the individual is unable to ever respond behaviorally in any significant way to the environment. The brainstem may continue to maintain internal homeostasis (normal respiratory and cardiovascular functions, normal temperature control, and normal gastrointestinal function). The person does not follow commands, speak, or have voluntary movement.

The recovery spectrum after severe brain injury includes: (1) coma, (2) vegetative state, (3) akinetic mutism, (4) minimally conscious state, and (5) locked-in syndrome (Table 17-7). The survivor of cerebral death may remain in a coma or emerge into a vegetative state. In coma (a state of unarousable neurobehavioral unresponsiveness) the eyes are usually closed with no evidence of eye opening either spontaneously or in response to external stimuli. The person does not follow commands, does not verbalize or mouth words, and has no goal-directed or volitional behavior. There are no sustained visual pursuit movements beyond a 45-degree arc.

A **persistent vegetative state (VS)** is complete unawareness of the self or surrounding environment and complete loss of cognitive function. The Multi-Society Task Force on Persistent Vegetative States (MSTF) identified the diagnostic criteria for VS as: (1) periods of eye opening (spontaneous or following stimulation); (2) the potential for subcortical responses to external stimuli, including generalized physiologic responses to pain, such as posturing, tachycardia, and diaphoresis, and subcortical motor responses, such as grasp reflex; (3) return of so-called vegetative (autonomic) functions, including sleep-wake cycles and normalization of respiratory and digestive system functions; and (4) occasional roving eye movements without concomitant visual tracking ability.[6] The person's eyes open spontaneously or following stimulation, or both. There may be random hand, extremity, or head movements. The individual maintains blood pressure and breathing without support. Brainstem reflexes (pupillary, oculocephalic, chewing, swallowing) are intact. No discrete localizing motor responses are present, and the individual does not speak any comprehensible words or follow commands.[7]

TABLE 17-7 COMPARATIVE CLINICAL FEATURES OF ALTERATIONS IN LEVELS OF AROUSAL

DIAGNOSIS	AROUSAL	AWARENESS	COMMUNICATION
Coma	Eyes do not open spontaneously or in response to stimulation	No evidence of perception, communication ability, only reflexes and postural responses	None
Persistent vegetative state	Eyes open spontaneously; no visual tracking; sleep-wake cycle resumes or state of chronic wakefulness; arousal often sluggish	No evidence of cognitive function or purposeful motor activity	None
Akinetic mutism	Eyes open spontaneously; normal sleep-wake cycle; arousal level is normal	Visual tracking present; little or no following of commands	Little or no volitional speech or movement
Minimally conscious state	Eyes open spontaneously; normal to abnormal sleep-wake cycle; arousal level ranges from obtunded to normal	Inconsistent evidence of perception, communication ability, or purposeful motor activity; visual tracking often intact	Inconsistent verbalization, and gesturing
Locked-in syndrome	Full arousal; sleep-wake cycle present; quadriplegic	Perceptions and emotions intact	Cannot speak or move muscles except vertical eye movement and blinking

Data from Giacino JT et al: *Neurology* 58(3):349-353, 2002; Owen AM: *Ann N Y Acad Sci* 1125:225–238, 2008.

In a **minimally conscious state (MCS),** an individual demonstrates minimal but defined behavioral evidence of self or environmental awareness.[6,8] The clinical features include: (1) following simple commands, (2) manipulating objects, (3) responding with gestural or verbal "yes/no" responses, (4) demonstrating intelligible verbalization, and (5) blinking and smiling that occur in a meaningful relationship to the eliciting stimulus and are not attributable to reflexive activity.

Akinetic mutism (AM) is a neurobehavioral state characterized by a severe disturbance in behavioral drive (motivation). Generally, these individuals evidence eye opening with visual tracking and have little or no spontaneous speech or following of commands. Little movement is present. This is not attributable to decreased wakefulness or motor weakness or impairment. The pathology involves damage to the frontal lobe or cingulate gyrus (a component of the limbic system) (also see p. 538).[9]

With **locked-in syndrome** there is complete paralysis of voluntary muscles with the exception of eye movement. Content of thought and level of arousal are intact but the efferent pathways are disrupted (injury at the base of the pons with the reticular formation intact, often caused by basilar artery occlusion).[10] Thus the individual cannot communicate either through speech or through body movement but is fully conscious, with intact cognitive function. The upper cranial nerves (I through IV) often are preserved, so that the person possesses vertical eye movement and blinking as a means of communication.

Alterations in Awareness

Awareness (content of thought) encompasses all cognitive functions, including awareness of self, environment, and affective states (i.e., moods). Awareness is mediated by the core networks (selective attention and memory) under the guidance of executive attention networks (i.e., the networks that involve abstract reasoning, planning, decision making, judgment, error correction, and self-control). Each attentional function is not localized in a single brain area but is a network of interconnected brain circuits.

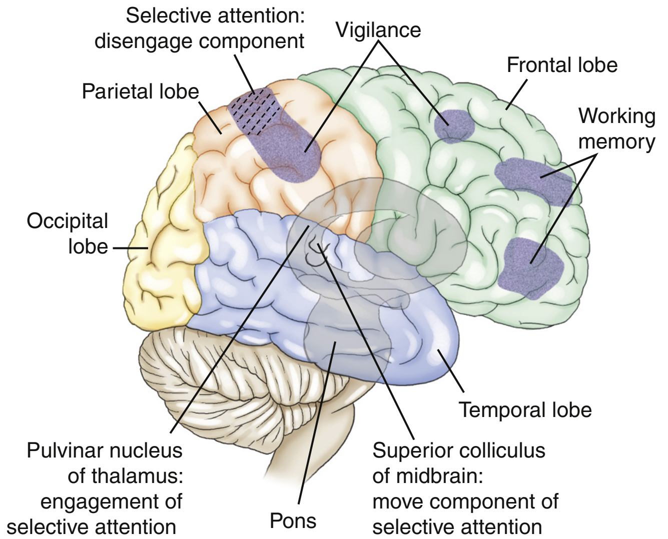

FIGURE 17-7 Right Cortical, Subcortical, and Brainstem Areas of the Brain-Mediating Cognitive Functions. (From Boss BJ, Wilkerson R: Communication: language and pragmatics. In Hoeman SP, editor: *Rehabilitation nursing: prevention, intervention, & outcomes,* ed 4, p 508, St Louis, 2008, Mosby.)

Selective attention (orienting) refers to the ability to select specific information to be processed from available, competing environmental and internal stimuli and to focus on those stimuli.[11] Frontal and parietal regions of the right hemisphere contribute to selective attention. The engage component is mediated by the pulvinar nucleus of the thalamus (Figure 17-7). The disengagement mechanism is mediated by the right parietal lobe. The move component is mediated by the superior colliculi for visual orienting. A weak orienting network results in a neglect syndrome.

Sensory inattentiveness is a form of neglect and may be visual, auditory, or tactile. The person with sensory inattentiveness is able to recognize individual sensory input from the dysfunctional side when asked to do so but ignores (i.e., neglects, extinguishes) the sensory input from the dysfunctional side

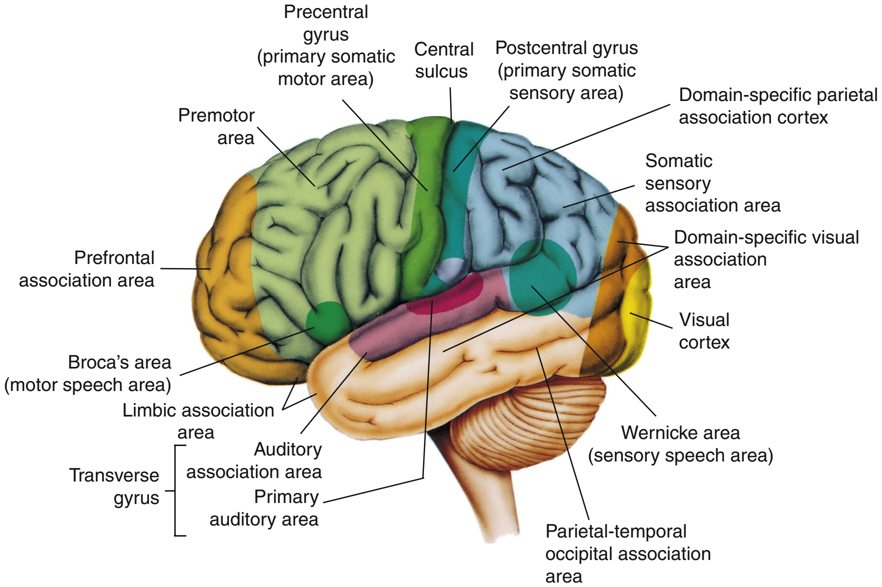

FIGURE 17-8 **Cortical Areas of the Left (Dominant) Hemisphere.** (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

when stimulated from both sides. This phenomenon is called **extinction.** The entire complex of denial of dysfunction, loss of recognition of one's own body parts, and extinction is sometimes referred to as the **unilateral neglect syndrome** and is common after stroke.

An isolated (pure) **selective attention deficit (orientation),** which manifests as a neglect syndrome, rarely, if ever, occurs clinically because typically other deficits also are present. A neglect syndrome may appear temporarily as a result of seizure activity or a postictal state. Temporary or permanent deficits may occur with contusions or subdural hematomas, encephalitis, and ischemic stroke. Progressive neglect deficits may be found with gliomas or metastatic tumor and in Alzheimer and Pick diseases.

Memory is the recording, retention, and retrieval of knowledge. Two types of memory exist: declarative and nondeclarative (Figure 17-10). **Declarative memory** involves the learning and remembrance of *episodic memories* (personal history, events, and experiences) and *semantic memories* (facts and information). Declarative memory is mediated by domain-specific cortical areas of the association areas. This includes: (1) areas of the temporal, parietal, and occipital lobes (Figure 17-8), where long-term memories are thought to be stored; and (2) domain-independent areas of the medial temporal lobe (i.e., hippocampus), the diencephalon (thalamic structures and hypothalamus), and the basal forebrain (located ventral to the striatum and produces acetylcholine) (Figure 17-9), where it is thought distinct domain-specific features of an experience are related or bound.[12]

Nondeclarative memory (nonconscious), also called *reflexive, procedural,* or *implicit memory,* is the memory for actions, behaviors (habits), skills, and outcomes.[13] It is not a language memory but a motor memory. Nondeclarative memory involves the construction of the motor pattern for the motor performance so that the action, behavior, or skill becomes increasingly more automatic. The striatum of the basal ganglia supports this learning across trials (stimulus-response learning), as well as probabilistic classification learning, which supports outcome prediction.[14] All skills and habits are stored in this memory network. *Cerebellar memory* was originally thought to be related to only motor learning but it is now believed to involve nonmotor functions of cognition, emotion, and memory.[15] *Emotional memory* is mediated by the amygdala (located on the inner surface of the temporal lobe) (see Figure 17-9). The amygdala attaches positive (e.g., pleasure) or negative (e.g., fear) dispositions to stimuli in the absence of conscious recollection of the circumstances of the emotional experience. Additionally, the amygdala modulates the event memory during and after the event (memory-enhancing effect).[16] The reflex pathways mediate nonassociative learning (e.g., habituation [decreased response to a stimulus] and sensitization [increased response to a stimulus]) (see Figure 17-10).

Dysmnesia is a disorder of the domain-independent declarative memory network. Dysmnesia is defined as the loss of past memories (retrograde amnesia) coupled with an inability to form new memories (anterograde amnesia) despite intact attentional networks. The hippocampus and other temporal lobe structures are often involved. *Isolated (pure) domain-independent dysmnesia* is caused by only a limited number of conditions, such as transient global dysmnesia (episodic global dysmnesia), amnestic stroke, and Korsakoff psychosis (amnestic or dysmnesic syndrome), as well as after temporal lobectomy. Many disorders may temporarily or permanently produce domain-independent dysmnesia that accompanies other deficits of the cognitive systems.[16a] A *temporary domain-independent dysmnesia* is found during complex partial seizures that persist for a time in the postictal state, in postconcussive states, and in mild posttraumatic brain injury states. A *permanent domain-independent dysmnesia* may be seen in several

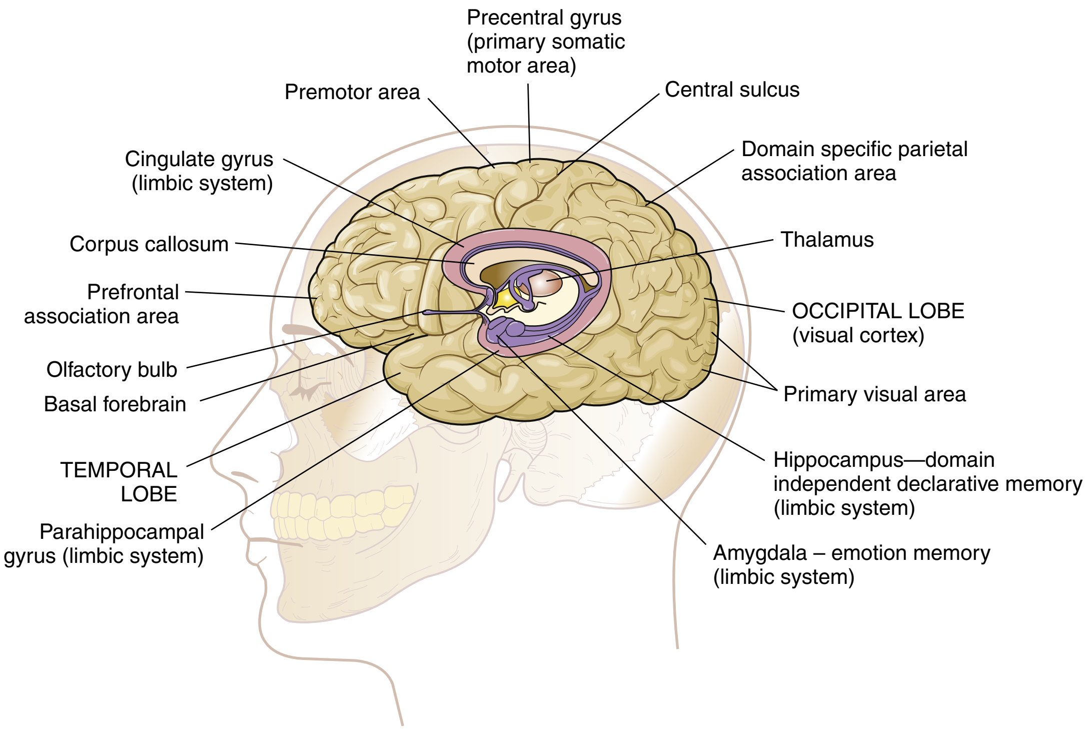

FIGURE 17-9 Midline Cortical and Deep Areas of the Cerebral Hemisphere.

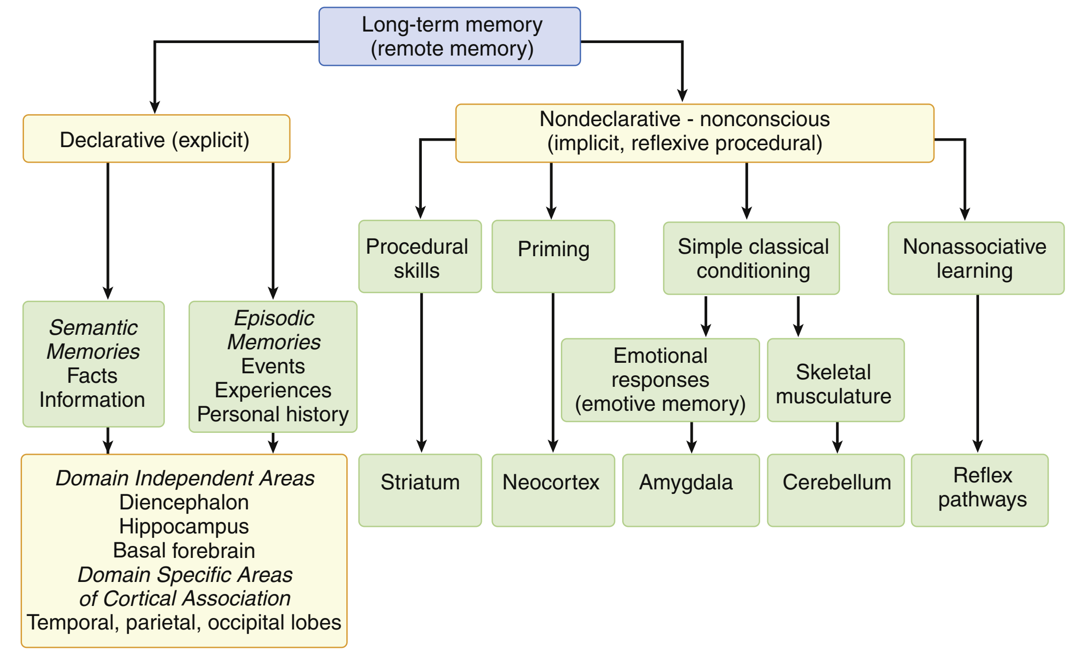

FIGURE 17-10 Types of Memory and Associated Brain Systems. (From Miller RD et al: *Miller's anesthesia,* ed 7, Philadelphia, 2010, Churchill Livingstone.)

disorders including subarachnoid hemorrhage or moderate or severe posttraumatic brain injury states; carbon dioxide poisoning and other hypoxic or anoxic states; Wernicke encephalopathy, viral encephalitis, and granulomatous meningitides; tumors; and Alzheimer and Pick diseases.

A pure *auditory* or *visual domain–specific declarative memory deficit* manifests as an isolated agnosia (see Table 17-9). An isolated (pure) domain-specific declarative memory deficit of tactile sensations rarely occurs clinically because selective attention would likely be affected as well. A temporary auditory, visual, or tactile pattern recognition (remote memory) deficit may appear as a result of seizure activity or a postictal state. A temporary or permanent deficit can occur with temporal, occipital, or parietal lobe contusion; with subdural hematoma or ischemic stroke; and in encephalitis. A *progressive domain-specific declarative memory deficit* may occur in temporal,

occipital, or parietal gliomas; in metastatic tumors; and in Alzheimer and Pick diseases.

The prefrontal areas mediate several cognitive functions, called *executive attention functions* (planning, problem solving, goal setting). The *vigilance system* provides the person with the ability to maintain a sustained state of alertness for searching and scanning activities and involves the right frontal areas and the locus ceruleus (LC) (located in the rostral pons) (see Figure 17-7). Through the neurotransmitter norepinephrine from the LC, the speed of the orienting (selective attention) network is increased and the detection function of the anterior cingulate gyrus (see Figure 17-9) is decreased.

Detection is the recognition of the object's identity and the realization that the object fulfills a desired goal (i.e., target selection among competing, complex contingencies). There is conscious execution of an instruction, ensuring that the instructions are followed. The anterior cingulate cortex inhibits automatic responses so that a less routine response can be given. The basal ganglia and cingulate, as well as other frontal areas, function in color, motion, and form detection.

The anterior cingulate plus the ventrolateral and dorsolateral prefrontal cortex (see Figure 17-7) are involved in the representations of information in the absence of a stimulus, such as spatial position of visual events in memory when the event is removed from view (i.e., *working memory* [short-term representation memory]). Control of activation of such memories is also in these areas. This gives the person control over information processing. These temporary storage areas permit the brain to retrieve instructions and other information needed to guide behavior. A person holds and manipulates information in working memory for a short period of time.

Isolated (pure) vigilance deficit, detection deficit and **working memory deficits** are uncommon because these deficits generally are present simultaneously. **Akinetic mutism** is a condition where a person can neither speak nor move and it exemplifies a detection deficit from disease or injury to the frontal lobe. The person orients to external stimuli and can follow with his or her eyes but does not initiate other voluntary activity. There are no goals generated and no plans for carrying out the goals. The combination of vigilance, detection, and working memory deficits, accompanied by other deficits of the cognitive systems, is much more common. Whether the deficits are temporary or permanent depends on the cause and severity of injury. Deficits caused by CNS-depressant drugs, by seizure activity, and (it is hoped) by neurosurgical procedures involving retraction of the frontal lobes are temporary. Deficits in postconcussive and mild traumatic brain injury states may prove to be temporary and resolve over time. Permanent deficits are more likely to be found with frontal lobe contusions, moderate or severe posttraumatic brain injury states, ischemic frontal lobe stroke, and neurosurgery that required frontal lobe resection. Progressive deficits in vigilance, detection, and working memory functions are caused by frontal lobe gliomas, frontal lobe infarcts associated with hypertensive vascular disease, and late stages of Alzheimer and Pick diseases. People with schizophrenia have difficulty in clearing working memory of information that is irrelevant to the task. Additionally, recently encountered visual material that is no longer in plain view cannot be preserved in working memory.

Higher-level thought involves the same neural areas used for sensory-specific computations, but when used voluntarily in thought, these areas are activated from the detection and work memory networks (top-down processing from the prefrontal cortex) rather than from bottom-up automatic processing (from the medial temporal lobe) beginning in sensory areas with a specific sensory stimulus. There is a voluntary search for a feature. By reordering component computation, a person produces novel thoughts.

PATHOPHYSIOLOGY. Individuals with a disease affecting the superior colliculi (positioned below the thalamus) have a disturbance in the move component of selective attention, which manifests as a slowness in orienting attention.[17] People with parietal lobe disease may experience selective attention deficits related to disengagement from a stimulus. Those with right parietal lobe dysfunction also may experience a unilateral neglect syndrome, the prototype of a selective attention disorder. People with a disease affecting the pulvinar of the thalamus (posterior part of the thalamus) have a disturbance in the engage component of selective attention (see Figure 17-9).

A disorder in vigilance may be produced by disease in the right frontal areas. A pathologic condition in the frontal areas also may produce detection and working memory deficits. Impaired higher-level thought may result from a pathologic process in the cortical association areas of the parietal, temporal, and occipital lobes.

The exact pathophysiologic mechanisms of the various disorders of cognitive systems are not fully known. Researchers are studying the defects in the elementary operations (components) of each cognitive system. In the past, pathophysiology related to the memory systems was the most studied component.

As a highly general statement, the primary pathophysiologic mechanisms that operate in cognitive system disorders are: (1) direct destruction because of direct ischemia and hypoxia or indirect destruction as a result of compression and (2) the effects of toxins and chemicals or metabolic derangement. Disinhibition resulting in overactivity, such as seen in some drug withdrawal states, is a pathologic mechanism that can produce detection deficits or a hypervigilant state. The pathophysiologic processes are summarized in Figure 17-11.

CLINICAL MANIFESTATIONS. Clinical manifestations of selective attention deficits; domain-independent and domain-specific declarative deficits; and vigilance, detection, and working memory deficits are presented in Table 17-8.

EVALUATION AND TREATMENT. Immediate medical management is directed at diagnosing the cause and treating reversible factors. Rehabilitative measures for cognitive system deficits generally are either compensatory or restorative in nature and have been greatly facilitated by computer technology and other electronic-assisted devices. Approaches based on behavioral techniques tend to be compensatory, whereas process-oriented approaches, it is hoped, are restorative.

Selective attention and executive attention deficits masquerade as other cognitive deficits. Differential diagnosis of

other cognitive deficits is blocked, and learning potential is largely obscured, by the presence of an attention deficit. Therefore, diagnosis and treatment of attention deficits are fundamental.

Data Processing Deficits

Data processing deficits include specific disorders of awareness (content of thought): agnosias, dysphasias, acute confusional states, and dementias including Alzheimer disease.

Agnosia

Agnosia is a defect of pattern recognition—a failure to recognize the form and nature of objects. The disorder involves the loss of recognition through one sense, although the object or person may still be recognized by other senses. Agnosia can be tactile, visual, or auditory. For example, an individual may be unable to identify a safety pin by touching it with a hand but able to name it when looking at it. Agnosia may be as minimal as a finger agnosia (failure to identify by name the fingers of one's hand) or more extensive, such as a color agnosia.

Agnosia is produced by dysfunction in the primary sensory area or in the interpretive areas of the cerebral cortex (temporo-occipital area) (see Figure 17-8). The types of agnosia and the associated area that is most commonly involved with each are presented in Table 17-9. Although agnosia most commonly is associated with cerebrovascular accidents, it may arise from any pathologic process that injures these specific areas of the brain.

Dysphasia

Dysphasia is impairment of comprehension or production of language (semantic processing). With dysphasia, comprehension or use of symbols, in either written or verbal language, is disturbed or lost. **Aphasia** is loss of comprehension or production of language.

Dysphasias usually are associated with cerebrovascular accidents involving the middle cerebral artery or one of its many

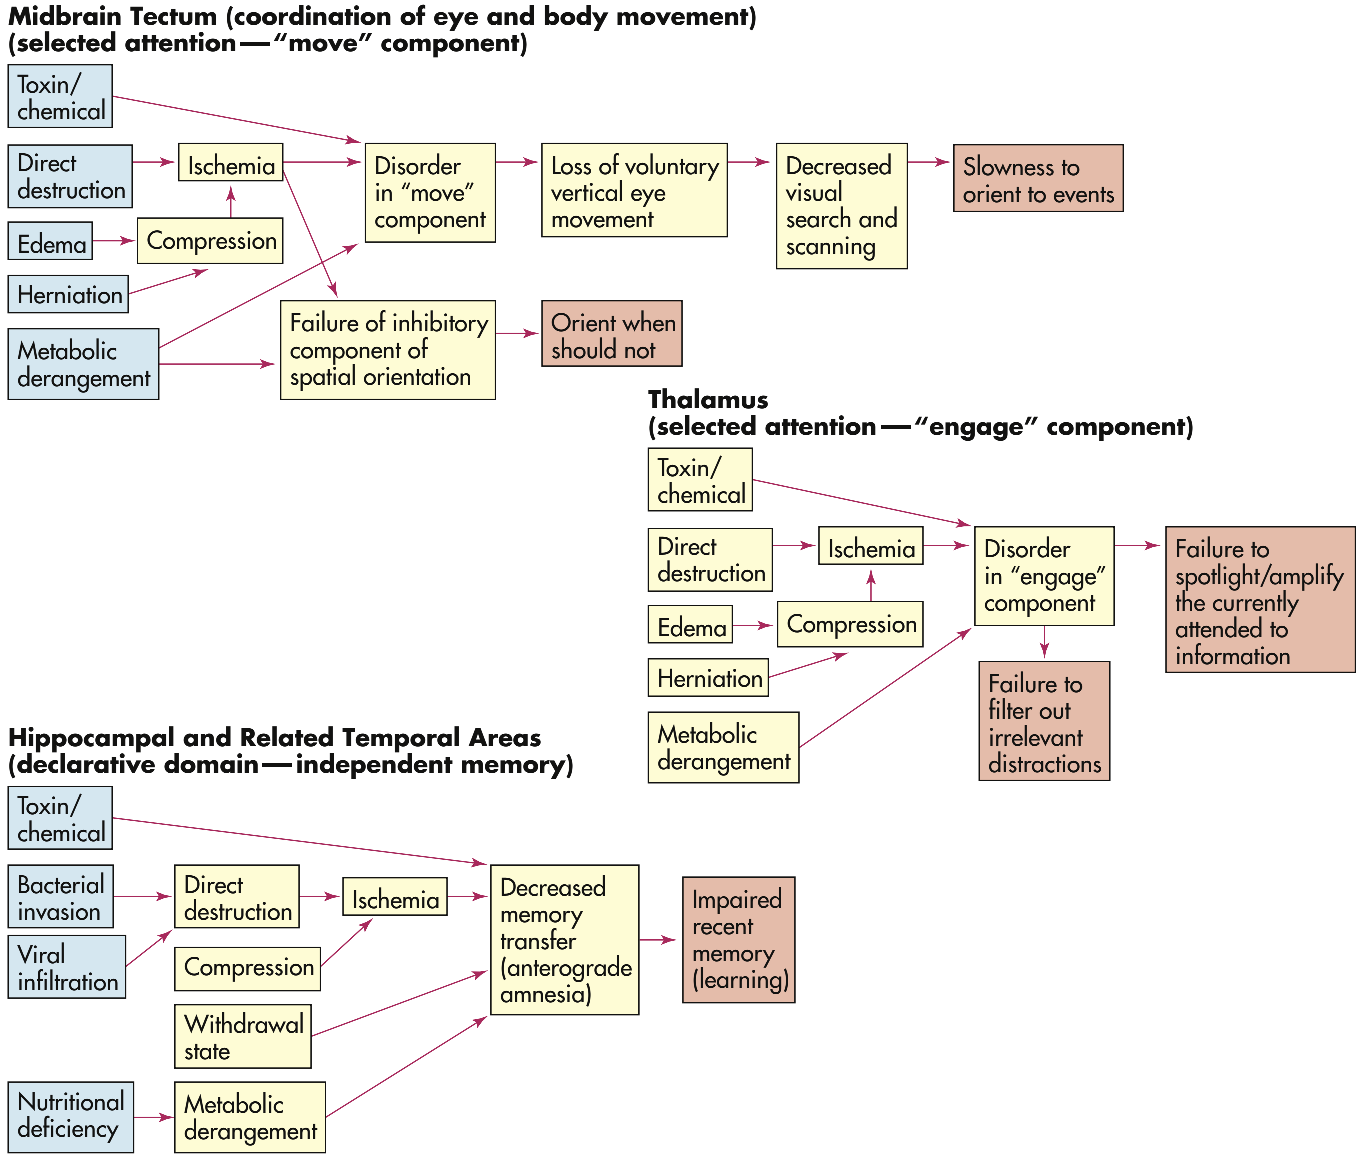

FIGURE 17-11 Cognitive Network Deficits. General pathophysiologic mechanisms underlying cognitive network deficits.

Continued

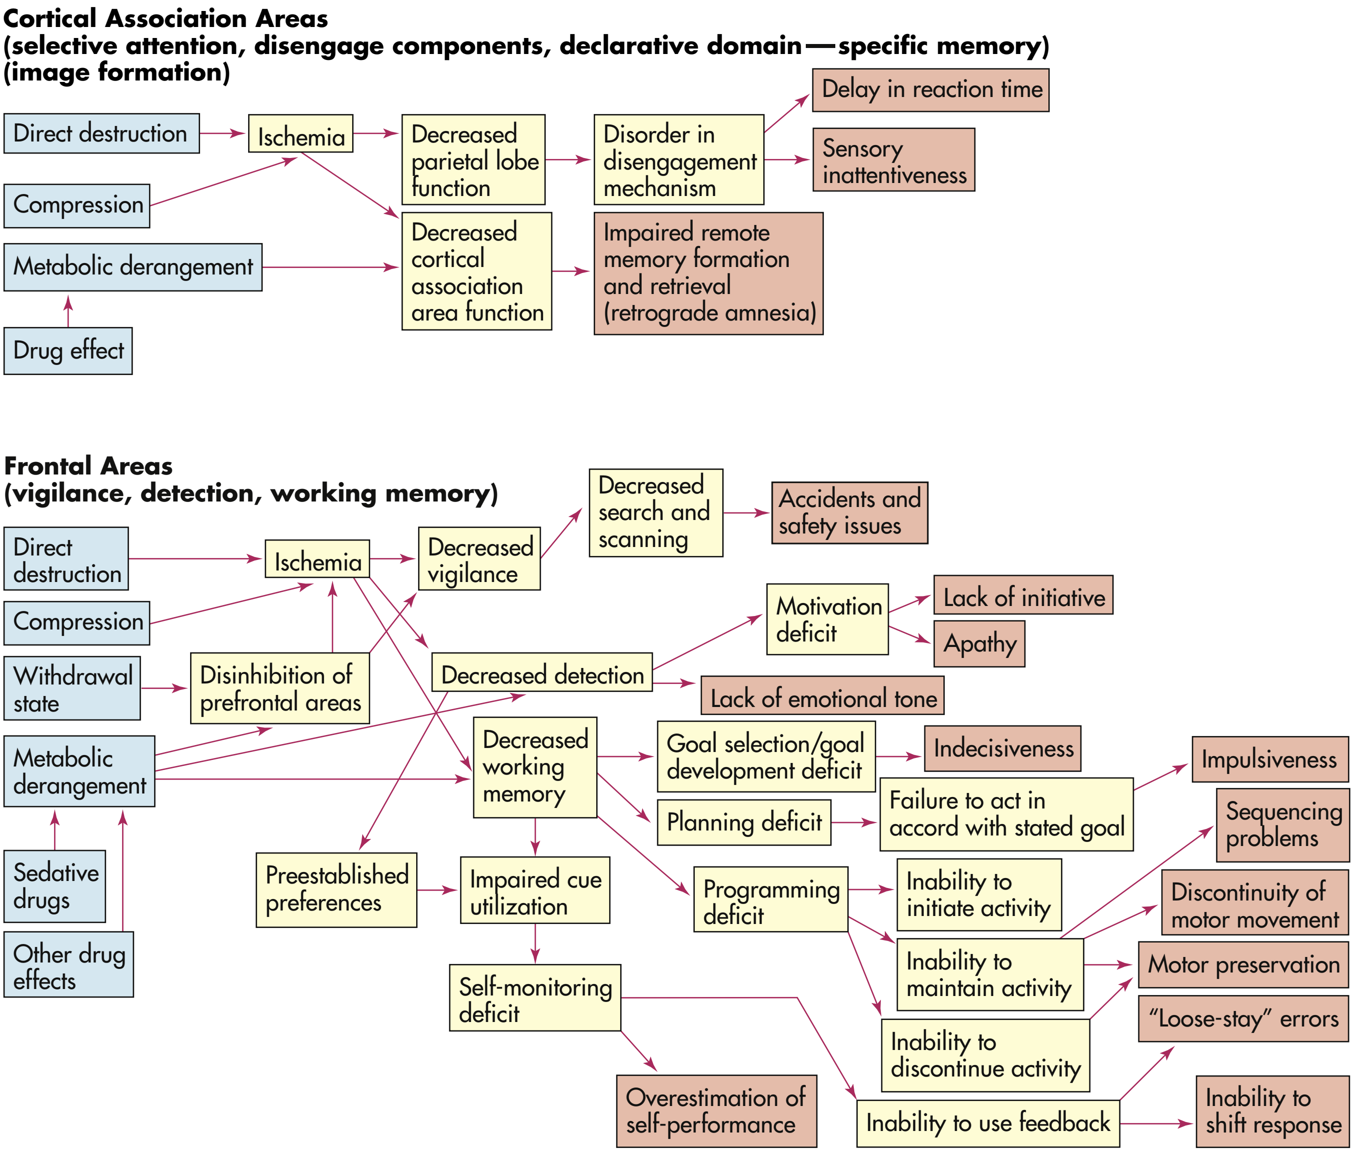

FIGURE 17-11, cont'd Cognitive Network Deficits.

branches. The language disorders, however, may arise from a variety of injuries and diseases—vascular, neoplastic, traumatic, degenerative, metabolic, or infectious. Dysphasia results from dysfunction in the left cerebral hemisphere, most commonly in the frontotemporal region, particularly around the insula (insular cortex) deep within the lateral sulcus. Genes located on several chromosomes have been linked to language development and disorders.[18] Most language disorders are caused by acute processes that either resolve or cause a chronic residual deficit. Some language disorders are caused by degenerative disorders that make the dysfunction progressive.

Dysphasias have been classified anatomically and functionally. Other classifications are linguistic and describe fluency, volume, or quantity of speech. Pure forms of any language dysfunction, however, are rare. Expressive dysphasias are characterized primarily by expressive deficits, but a verbal comprehension (auditory-receptive element) deficit may be present. Receptive dysphasias may have expressive deficits. (Table 17-10 compares types of dysphasias; Table 17-11 illustrates some of the language disturbances.)

Dysphasias referred to as **transcortical dysphasias (transcortical sensory dysphasia, mixed transcortical dysphasia, isolated speech center)** involve the ability to repeat (called **echolalia**) and recite. Speech is fluent but with striking paraphrases. The individual cannot read and write, and comprehension is impaired.

Transcortical dysphasias are caused by hypoxia from prolonged hypotension, carbon monoxide poisoning, or other mechanisms that destroy the border zone (watershed area) of the anterior, middle, and posterior cerebral arteries (see Figure 15-20). Blood supply is marginal in this region. Hypoxia in this area occasionally may isolate the posterior speech areas or all the speech areas from the remainder of the cortex, although both areas remain intact. The sensory and motor speech areas therefore are functional, but connections with other sensory or motor areas are impaired. Information from the remaining areas of the cortex cannot be transmitted to the Wernicke area to be transformed into language.

TABLE 17-8 CLINICAL MANIFESTATIONS OF COGNITIVE NETWORK DEFICITS

DEFICIT	CLINICAL SIGNS	SYMPTOMS
Attention		
Selective attention (orienting)	Inability to focus attention; decreased eye, head, and body movements associated with focusing on the stimuli; decreased search and scanning; faulty orientation to stimuli causing safety problems	Person reports inability to focus attention, failure to perceive objects and other stimuli (history of injuries, falls, and safety problems)
Memory (Long Term, Remote)		
Domain-independent declarative	*Left hemisphere:* disorientation to time, situation, place, name, person (verbal identification); impaired language memory (e.g., names of objects); impaired semantic memory *Right hemisphere:* disorientation to self, person (visual), place (visual); impaired episodic memory (personal history); impaired emotional memory *Either or both hemispheres:* confusion; behavioral change	Person reports disorientation, confusion, "not listening," "not remembering"; reports by others of person being disoriented, not able to remember, not able to learn new information
Domain-specific declarative	*Left hemisphere:* inability to retrieve personal history, past medical history; unaware of recent current events *Right hemisphere:* inability to recognize persons, places, objects, music, etc. from the past	Person reports remote memory problems; others report that person cannot recall formerly known information
Image processing (semantic processing)	Inability to categorize (identify similarities and differences), sort; inability to form concepts; inability to analyze relationships; misinterpretation; inability to interpret proverbs	Reports by others of frequent misinterpretation of data; failure to conceptualize or generalize information
	Inability to perform deductive reasoning (convergent reasoning); inability to perform inductive reasoning (divergent reasoning); inability to abstract; concrete reasoning demonstrated; delusions	Reports by others of predominantly concrete thinking; lack of understanding of everyday situations, healthcare regimens, delusional thinking
Executive Attentional Network		
Vigilance	Failure to search and scan environment	Person reports accidents, safety issues
Detection	Lack of initiative (anergy); lack of ambition; lack of motivation; flat affect; no awareness of feelings; appears depressed, apathetic, and emotionless; fails to appreciate deficit; disinterested in appearance; lacks concern about childish or crude behavior	Reports by others of laziness or apathy, flat affect or lack of emotional expression, failing to exhibit or be aware of feelings
Mild	Responds to immediate environment but no new ideas; grooming and social graces are lacking	Reports by others of lack of ambition, motivation, or initiative, failure to carry out adult tasks, lack of social graces and new ideas
Severe	Motionless, lack of responding to even internal cues; does not respond to physical needs; does not interact with surroundings	Reports by others of failure to groom or toilet self, unawareness of surroundings and own physical needs
	Inability to use feedback regarding behavior; failure to recognize omissions and errors in self-care, speech, writing, and arithmetic; impaired cue utilization; overestimation of performance	Reports by others of not changing behavior when requested; unawareness of limitations; does not recognize and correct errors in dressing, grooming, toileting, eating; fails to recognize speech and arithmetic errors; careless speech
	Failure to shift response set; failure to change behavior when conditions change; cue utilization may be impaired	Reports by others of failure to use feedback; inability to incorporate feedback (does not correct when feedback is given)
Working memory (recent memory, short-term memory)	Inability to set goals or form goals; indecisiveness	Reports by others of failure to set goals, indecisiveness
	Failure to make plans; inability to produce a complete line of reasoning; inability to make up a story; appears impulsive	Reports by others of failure to plan, impulsiveness, "does not think things through"
	Failure to initiate behavior; failure to maintain behavior; failure to discontinue behavior; slowness to alternate response for the next step; motor perseveration	Reports by others of not knowing where to begin, inability to carry out sequential acts (maintain a behavior), inability to cease a behavior

TABLE 17-9 TYPES OF AGNOSIA (CONCEPT DISORDERS)

TYPE OF AGNOSIA	DEFINITION	LOCATION OF INJURY
Tactile agnosia (astereognosis)	Inability to recognize objects by touch	Parietal lobe
Spatial agnosia	Incapacity to find one's way around familiar places; disturbance of perception of space (disorders of [1] topographic [extrapersonal] orientation or [2] topographic and geographic memory [construction])	Parietal lobe
Gerstmann syndrome	Loss of spatial orientation of fingers, body, sides, and numbers	Left angular gyrus (parietal lobe)
Finger agnosia (digital agnosia)	Inability to identify the names of one's fingers	
Right-left confusion	Inability to distinguish right from left	
Agraphia	Inability to write	
Acalculia	Inability to perform mathematic calculations	
Visual agnosia		
Object agnosia	Inability to recognize objects and pictures	Temporo-occipital area
Prosopagnosia	Inability to recognize faces	Temporo-occipital ventromesial region
Color agnosia	Inability to understand colors as qualities of objects; faulty color concepts and inability to evoke color images in the absence of color blindness; specific types: (1) "hue" problem, (2) color anomia (cannot name color)	Inferior occipital cortex in left hemisphere
Body image agnosias (may be spatial)		
Anosognosia	Ignorance or denial of existence of the disease	Right parietal lobe
Autotopagnosia	Loss of ability to identify the body, in whole or in part, or to recognize relationships among various parts	Right parietal lobe
Word blindness (alexia/dyslexia)	Inability to recognize written symbols	Left parietotemporal region
Auditory agnosia (pure word deafness)	Inability to recognize speech sounds	Superior temporal area
Amusia (music deafness)	Loss of capacity to recognize tones and melodies	Right superior temporal area

Acute Confusional States

Acute confusional states (ACSs) (also may be known as acute organic brain syndromes) are transient disorders of awareness. They are associated with cerebral dysfunction secondary to drug intoxication, alcohol or drug withdrawal, metabolic disorders (hypoglycemia, thyroid storm), nervous system disease, trauma or surgery (following anesthesia), febrile illnesses or heat stroke, and electrolyte imbalance; in addition, ACSs may be associated with systemic diseases (such as heart, kidney, or liver failure), head injury, anesthesia administration, or the presence of certain focal cerebral lesions.[19] The complex of symptoms is characterized by deficits in attention and coherence of thoughts and actions. Often the symptoms are associated with an altered level of arousal, global cognitive dysfunction, perceptual disturbances, sleep-wake cycle disruption, affective disturbance, and emotional liability. Hospitalized older individuals are at greatest risk for ACS.[20]

PATHOPHYSIOLOGY. Acute confusional states arise from disruption of a widely distributed neural network involving the reticular activating system of the upper brainstem and its projections to the thalamus, basal ganglion, and specific association areas of the cortex and limbic areas. **Delirium** (hyperkinetic confusional state) is an acute state of brain dysfunction associated with right middle temporal gyrus or left temporo-occipital junction disruption.[21] These areas receive extensive input from the limbic areas and modulate motivational and affective aspects of attention. Several neurotransmitters are involved, including increased levels of acetylcholine, dopamine, and serotonin, and increased or decreased levels of gamma-aminobutyric acid (GABA). Inflammatory cytokines, including interleukins, interferon, and tumor necrosis factor-alpha (TNF-α), may contribute to delirium by altering the blood-brain barrier permeability and further affecting the neurotransmission and subsequent neurobehavioral and cognitive symptoms.[22]

Excited delirium syndrome (ExDS), also known as agitated delirium, is a type of hyperkinetic delirium that can lead to sudden death. The exact signs and symptoms are difficult to precisely define. There is altered mental status, combativeness, aggressiveness, tolerance to significant pain, rapid breathing, sweating, severe agitation, elevated temperature, noncompliance or poor awareness to direction from police or medical personnel, lack of fatiguing, unusual or superhuman strength, and inappropriate clothing for the current environment. Hypoglycemia, thyroid storm, certain kinds of seizures, cocaine or methamphetamine intoxication, and/or catecholamine-induced fatal arrhythmias are associated with ExDS. Individuals with ExDS are at high risk for sudden death and represent a true medical emergency.[23]

Hypokinetic confusional states (hypokinetic delirium) are more likely associated with right-sided frontal–basal ganglion disruption.[21] These areas modulate motor exploratory aspects of attention. Most metabolic disturbances that produce a confusional state interfere with neuronal metabolism or synaptic transmission. Many drugs and toxins also interfere with neurotransmission function at the synapse. Cholinergic pathways critical for attention and arousal are often disrupted.

CLINICAL MANIFESTATIONS. The predominant feature of an acute confusional state is impaired or lost detection. Symptoms can fluctuate and include confusion, inability to focus or maintain attention, delusions, and hallucinations. Because of dysfunction of the anterior cingulate gyrus (see Figure 17-9 and Figure 15-7, *B*), the ability to focus, sustain, or shift attention is seriously impaired or completely lost. The person is highly distractible and unable to concentrate on incoming sensory information or on any particular mental or motor task, and loses coherence of thought and actions. The person may persist in thoughts or actions that are no longer appropriate (perseveration) and be unable to monitor the

TABLE 17-10 MAJOR TYPES OF DYSPHASIA

TYPE	EXPRESSION	VERBAL COMPREHENSION	REPETITION	NAME	READING COMPREHENSION	WRITING	LOCATION OF LESION	CAUSE OF LESION
Expressive (Broca Dysphasia, Motor)								
	Nonfluent; impairment of ability to find words, difficulty in writing	Relatively intact	Impaired	Impaired	Variable	Impaired	Left posteroinferior frontal lobe (Broca area)	Occlusion of one or several branches of middle cerebral artery, trauma, tumor, infection, abscess
Receptive								
Wernicke dysphasia, sensory	Fluent: able to produce verbal language but language is meaningless; words are often inappropriate; words with similar sounds or words with similar meaning are substituted for the correct words; words that are not part of the language may be present; these neologisms may be so extensive as to make the speech entirely incomprehensible; because the person has no means to monitor the language for correctness, errors are not recognized; intonation, accent, cadence, rhythm, and articulation are normal	Impaired (disturbance in understanding all language)	Impaired	Impaired	Impaired	Impaired	Left posterosuperior temporal lobe (Wernicke area)	Occlusion of inferior division of left middle cerebral artery, temporal abscess
Global (sensorimotor receptive-expressive)	Nonfluent, produces little speech; at best speaks a few words or phrases	Impaired or completely lost; person understands only the simplest things said	Impaired; not able to repeat	Impaired	Reading out loud—impaired or completely lost Reading silently intact	Impaired; produces little written language	Frontotemporal lobe (left sylvian region); anterior and posterior speech areas extensively impaired	Occlusion of the left middle cerebral artery of left internal carotid artery; trauma, infection, tumors, other mass lesions, and hemorrhage may be the cause

TABLE 17-10 MAJOR TYPES OF DYSPHASIA—cont'd

TYPE	EXPRESSION	VERBAL COMPREHENSION	REPETITION	NAME	READING COMPREHENSION	WRITING	LOCATION OF LESION	CAUSE OF LESION
Conduction	Fluent but with paraphrasia in self-initiated speech and writing or reading aloud	Relatively intact	Impaired; unable to repeat	Impaired	Variable	Impaired	Arcuate fasciculus, deep in supramarginal gyrus, disruption of the large bundle of fibers that arise from the temporal lobe and pass posteriorly around the sylvian fissure and then project anteriorly to the premotor area	Typical cause is embolic occlusion of the ascending parietal or posterior temporal branch of the middle cerebral artery, angular branch of middle cerebral artery
Anomic, nominal, amnesic (anomia)	Fluent but impaired ability to name objects, persons, qualities, or characteristics; knows what he or she wants to say but cannot find words; may even use desired word in another context but still cannot isolate word when needed	Relatively intact; able to recognize word when it is given	Intact	Impaired	Variable	Variable	Angular gyrus—posterosuperior temporal lobe	Residual of other aphasias, degenerative disorders
Transcortical motor	Nonfluent	Relatively intact	Intact	Impaired	Variable	Impaired	Left dorsolateral frontal cortex (anterior presylvian fissure)	Occlusion of left anterior cerebral artery or anterior border zone vascular infarct
Transcortical sensory	Fluent	Impaired	Intact	Impaired	Impaired	Impaired	Left temporo-parietooccipital junction (posterior presylvian fissure)	Occlusion of left internal carotid with posterior border zone infarct, tumor, trauma, intracerebral hemorrhage, and degenerative disease

TABLE 17-11 EXAMPLES OF LANGUAGE DISTURBANCES

DISORDER		EXAMPLE
Verbal paraphrasia	Question:	What did the car do?
	Response:	The car would spit sweetly down the road. (The car sped swiftly down the road.)
Literal paraphrasia	Request:	Say "persistence is essential to success."
	Response:	Mesastence is instans to success.
Neologism	Question:	What do you call this? (Pointing to a plant.)
	Response:	It's a logper.
Circumlocution	Question:	What do you call this? (Pointing to a plant.)
	Response:	Something that grows.
Anomia	Question:	What do you call this? (Pointing to a plant.)
	Response:	It's… *Or*
	Question:	What did you do this morning?
	Response:	Reading.
	Question:	Were you reading a book or a newspaper?
	Response:	One of those.
Telegraphic style	Question:	Where is your daughter?
	Response:	New Orleans…home…Monday.

TABLE 17-12 COMPARISON OF DELIRIUM AND DEMENTIA

FEATURE	DELIRIUM	DEMENTIA
Age	Usually older	Usually older
Onset	Acute—common during hospitalization	Usually insidious; acute in some cases of strokes/trauma
Associated conditions	Urinary tract infection, thyroid disorders, hypoxia, hypoglycemia, toxicity, fluid-electrolyte imbalance, renal insufficiency, trauma, multiple medications	May have no other conditions Brain trauma
Course	Fluctuating; remits with treatment	Chronic slow decline
Duration	Hours to weeks	Months to years
Attention	Impaired	Intact early; often impaired late
Sleep-wake cycle	Disrupted	Usually normal or fragmented
Alertness	Impaired	Normal
Orientation	Impaired	Intact early; impaired late
Behavior	Agitated, withdrawn/depressed	Intact early
Speech	Incoherent, rapid/slowed	Word-finding problems
Thoughts	Disorganized, delusions	Impoverished
Perceptions	Hallucinations/illusions	Usually intact early

Adapted from Caplan JP, Rabinowitz T: *Med Clin North Am* 94(6):1103–1116, ix, 2010.

environment for events of importance (impaired vigilance). The person demonstrates irrelevant or inappropriate responses.

The onset of an acute confusional state usually is abrupt rather than insidious. Later there are top-down processing problems, including misperceptions, delusions, and hallucinations. Obsessions, compulsive behavior, and rituals may be evident.

Delirium is associated with autonomic nervous system overactivity and typically develops over 2 to 3 days, most commonly in critical care units, after surgery, or during withdrawal from central nervous system depressants (e.g., alcohol or narcotic agents). Delirium initially manifests as difficulty in concentrating, restlessness, irritability, insomnia, tremulousness, and poor appetite. Some persons experience seizures. Unpleasant, even terrifying, dreams or hallucinations may occur. In a fully developed delirium state, the individual is completely inattentive and perceptions are grossly altered with delusions or hallucinations. The person appears distressed and often perplexed; conversation is incoherent. Frank tremor and high levels of restless movement are common. Violent behavior may be present. The individual cannot sleep, is flushed, and has dilated pupils, a rapid pulse rate (tachycardia), temperature elevation, and profuse sweating (diaphoresis). Delirium typically abates suddenly or gradually in 2 to 3 days, although delirium states occasionally persist for weeks.

In hypokinetic acute confusional states (hypokinetic/hypoactive delirium), the individual exhibits decreases in mental function. Alertness is decreased, as are attention span, accurate perception, and interpretation of the environment. Forgetfulness is prominent. Reactions to the environment are slowed and indecisive. The individual dozes frequently. Hypoactive ACS can be mistaken for depression or dementia although individuals may have underlying depression or dementia with an incident of ACS.

EVALUATION AND TREATMENT. An ACS is an acute medical problem. The initial goal is to establish that the individual is confused, and to identify the cause and contributing factors. Hypokinetic delirium will need to be differentiated from depression. An underlying dementia may be present (Table 17-12). A complete history and physical examination, as well as laboratory tests, is needed including an electrocardiogram and blood, urine, cerebral spinal fluid (CSF), and radiologic studies. Several assessment scales are available to guide evaluation.[24]

Once the cause is established, treatment is directed at controlling the primary disorder. In an acute confusional state, all drugs that may be contributing to or causing the condition are discontinued unless the problem is the result of drug withdrawal. Supportive measures are designed to enhance coping skills and to minimize the individual's need for altered cortical functions. Supportive and protective management also involves maintaining the person's intact cortical functions by promoting use of these functions. Delirium is preventable in some individuals.[25,26]

Dementia

Dementia is the progressive failure (an acquired deterioration) of many cerebral functions that includes impairment of intellectual function with a decrease in orienting, memory,

BOX 17-1 CAUSES OF DEMENTIA

Potentially Reversible Causes of Dementia

- Infection
  - Encephalitis
  - Meningitis
  - Neurosyphilis
- Normal Pressure Hydrocephalus
- Chronic Subdural Hematoma
- Nutritional Deficiencies
  - Vitamin B_1 (thiamine) deficiency
  - Vitamin B_{12} (cobalamin) deficiency
  - Nicotinic acid (pellagra) deficiency
- Chronic Drug Intoxication
  - Alcohol*
  - Sedatives
- Metabolic Disorders
  - Thyroid abnormalities
  - Chronic hepatic encephalopathy
  - Cerebral vasculitis
  - Sarcoidosis
- Some Types of Tumors
  - Frontal and temporal lobe
  - Pseudodementia of depression
- Medical Side Effects
  - Anticholinergics
  - Antihypertensives
  - Antihistamines

Irreversible Causes of Dementia

- Neurodegenerative Disorders
  - Alzheimer disease*
  - Dementia with Lewy bodies
  - Frontotemporal dementia
  - Pick disease
  - Huntington disease
  - Parkinson disease
- Vascular Disease
  - Vascular dementia*
  - Multi-infarct
  - Strategic single infarct
  - Binswanger disease* (diffuse white matter disease)
  - Amyloid angiopathy
- Infection
  - Creutzfeldt-Jakob disease (CJD)
  - Postencephalitic dementia
  - Dementia associated with HIV

*Most common; *HIV*, human immunodeficiency virus.

language, executive attentional functions, and alterations in behavior. The greatest risk factor is age.[27] More than 26 million people in the world have Alzheimer disease and by 2050 the number is expected to triple with nearly 50% requiring a high level of care.[28]

Dementias can be classified according to etiologic factors (e.g., trauma, tumors, vascular disorders, infections) and to associated clinical and laboratory signs. Dementing processes have been grouped as cortical, subcortical, or both. Box 17-1 lists the potentially reversible and irreversible causes of dementia. Alzheimer disease (AD) is the most common cause followed by vascular disease, then dementia associated with Lewy bodies (i.e., Parkinson disease).[27] In people younger than 60 years, frontotemporal dementia (FTD) rivals AD in terms of frequency.[29] Disruption in cerebral neural circuits is present. The culmination of a progressive dementing process is nerve cell degeneration and brain atrophy involving the cerebral cortex, diencephalon, and basal ganglia.

PATHOPHYSIOLOGY. Mechanisms leading to dementia include: (1) neurodegeneration, possibly caused by genetics, inflammation, or biochemical alterations; (2) atherosclerosis, multiple foci of infarction throughout the thalami, basal ganglia, cerebral projection pathways, and associated areas; (3) trauma, lesions in the cerebral convolutions (mainly frontal and temporal), corpus callosum, and mesencephalon; and (4) compression, increased intracranial pressure, and chronic hydrocephalus. Genetic predisposition associated with neurodegenerative diseases is summarized in Table 17-13. CNS infections, including the human immunodeficiency virus (HIV) and Creutzfeldt-Jakob disease (human prion disease or transmissible spongiform encephalopathies), are associated with dementia in addition to changes in motor function (i.e., ataxia, rigidity, and shuffling gait). Progressive dementias produce nerve cell degeneration and brain atrophy.

CLINICAL MANIFESTATIONS. A summary of the clinical manifestations of the degenerative dementias is presented in Table 17-14.

EVALUATION AND TREATMENT. Establishing the cause for a dementing process may be complicated, but anyone evidencing the clinical manifestations of dementia should be evaluated with laboratory and neuropsychologic testing and brain imaging.

If a specific treatable cause is identified, the appropriate treatment is initiated. For example, an infectious process requires the appropriate antibiotic, and a potentially resectable mass may require neurosurgery. Nutritional deficiencies are corrected. If the cause is metabolic, the imbalance is corrected or the metabolic disorder is treated, or both.

Unfortunately no specific treatment or cure exists for most progressive dementias. The goal is to discover the pathogenetic mechanisms underlying dementia and to delay the conversion of cognitive decline and mild cognitive impairment to full dementia. Therapy is directed at maintaining and maximizing the remaining capacities, restoring functions if possible, accommodating to lost abilities, and controlling behavioral changes.[30] Delusions, paranoia, and hallucinations often respond to neuroleptic medications. If coexisting depression is suspected, a trial of antidepressants is appropriate. Assisting the family to understand the dementing process and to learn ways to assist the demented individual is an essential component of supportive management.

Alzheimer Disease

Alzheimer disease (dementia of Alzheimer type [DAT], senile disease complex) is the leading cause of dementia and one of the most common causes of severe cognitive dysfunction in older adults. Nonhereditary, or sporadic, late-onset AD (70% of cases) is the most prevalent form. It is estimated that 5.4 million Americans have AD and by 2050 the numbers are expected to range from 11 to 16 million.[31] The greatest risk factors are age and family history. Other proposed risk factors include diabetes, midlife hypertension, hyperlipidemia, midlife obesity, smoking, depression, cognitive inactivity or low educational attainment, female gender, estrogen deficit at the time of menopause, physical inactivity, head trauma, elevated serum homocysteine and cholesterol levels, oxidative stress, and neuroinflammation (Figure 17-12). Proposed protective factors include lifelong activity, the presence of *apoE2* and antioxidant substances, estrogen replacement at the time of menopause, low-calorie diet, and use of nonsteroidal anti-inflammatory agents. Statins are being investigated for their role in preventing AD.[32-34]

PATHOPHYSIOLOGY. The exact cause of AD is unknown and there is no clear understanding of this complex disease process. Early-onset familial Alzheimer disease (FAD) is autosomal dominant and has been linked to three gene defects: amyloid precursor protein *(APP)* gene on chromosome 21, presenilin 1 *(PSEN1)* on chromosome 14, and *PSEN2* on chromosome 1.[35,36] Late-onset AD may be associated with chromosome 19 involved with

TABLE 17-13 THE MOLECULAR BASIS FOR DEGENERATIVE DEMENTIA

DEMENTIA	MOLEULAR MECHANISM	CAUSAL GENES (CHROMOSOME)	SUSCEPTIBILITY GENES (CHROMOSOME)	PATHOLOGY
Alzheimer disease (familial)	Amyloid beta protein (AB)	*Early onset: autosomal dominant:* <2% carry these mutations *APP* (21), *PSEN1* (14), *PSEN2* (1) (most mutations are in *PSEN1*)	*Late onset: risk gene apoE4* (19) *CUGBP2* (10p)	Amyloid plaques, neurofibrillary tangles; neuronal and synaptic loss in the brain
Creutzfeldt-Jakob disease (hereditary form)	PrP^{SC} proteins type 1 and 2	Prion (20) (up to 15% of cases carry these dominant mutations)	*PRNP* codon 129 homozygosity for methionine or valine	Tau inclusions, spongiform changes, gliosis
Dementia with Lewy bodies	Alpha-synuclein	Very rare alpha-synuclein (4) (dominant)	Unknown	Alpha-synuclein inclusions (Lewy bodies)
Behavioral variant frontotemporal dementia	Microtubule-associated protein tau (MAPT) Progranulin (PGRN)	Tau exon and intron mutation (17) (about 10% of familial cases) *PGRN* (17) (10% of familial cases)	Tau haplotypes *(H1* and *H2)*	Tau inclusions, Pick bodies, neurofibrillary tangles
Huntington disease (autosomal dominant)	Huntingtin protein (polyglutamine)	*Autosomal dominant: HD-IT15* (4) (trinucleotide repeat expansion)	None known	Neuronal degeneration, astrogliosis
Parkinson disease dementia	*Autosomal dominant:* Alpha-synuclein Leucine-rich repeat kinase 2 *Autosomal recessive:* Parkin (juvenile onset) DJ-1 protein PTEN-induced putative kinase 1	*Autosomal dominant:* *SNCA-PARK1* (4) *LRRK2-PARK8* (12) *Autosomal recessive:* *PARK2* (4) oncogene DJ-1 *(PARK7)* *PINK1 (PARK6)*	*GBA* (glucosidase beta acid) *SNCAIP* (alpha-synuclein interacting protein) *NR4A2* (orphan nuclear receptor) *UCH-L1 (PARK5)* ubiquitin C-terminal hydrolase Other low-risk genes	Neuronal degeneration, alpha-synuclein inclusions (Lewy bodies), gliosis; neuronal degeneration

TABLE 17-14 CLINICAL DIFFERENTIATION OF THE MAJOR DEGENERATIVE DEMENTIAS

DISEASE	MENTAL STATUS	NEUROBEHAVIOR	NEUROLOGIC EXAMINATION
Alzheimer disease	Memory loss, disorientation to place and time, loss of facial recognition	Initially normal; progressive cognitive, language, abstraction, and judgment impairment	Initially normal
Creutzfeldt-Jakob disease	Variable, frontal/executive, focal cortical, memory	Depression, anxiety, decreased cognitive function and memory loss	Myoclonus, rigidity, parkinsonism
Dementia with Lewy body (Lewy body dementia)	Initially affects concentration and attention, then memory or cognition loss but unpredictable levels of ability, attention, or alertness; delirium prone	Visual hallucinations, depression, sleep disorder, delusions, transient loss of consciousness	Parkinsonism Changes in walking or movement may present first
Frontotemporal disorders/ degeneration/ dementia	PPA variant Language loss with talking less and speech becoming hesitant or loss of understanding of language, may precede memory loss; spares drawing	Behavioral variant FTD Loss of empathy (emotional blunting), apathy, increased inappropriate or decline in personal or social conduct, loss of judgment and reasoning, hyperorality, euphoria, depression	Caused by CBD and PSP variants
Huntington disease		Apathy, loss of interest early; impaired cognition, judgment, and memory occur later	Chorea, bradykinesia, dystonia
Vascular dementia	Frontal/executive, cognitive slowing; memory can be intact	Often but not always sudden, usually within 3 months of a stroke; variable; apathy, falls, focal weakness, delusions, anxiety	Usually motor slowing, spasticity; can be normal or may have symptom improvement with stroke recovery

CBD, Cortical basal degeneration; *FTP,* frontotemporal dementia; *PPA,* primary progressive aphasia; *PSP,* progressive supranuclear palsy.

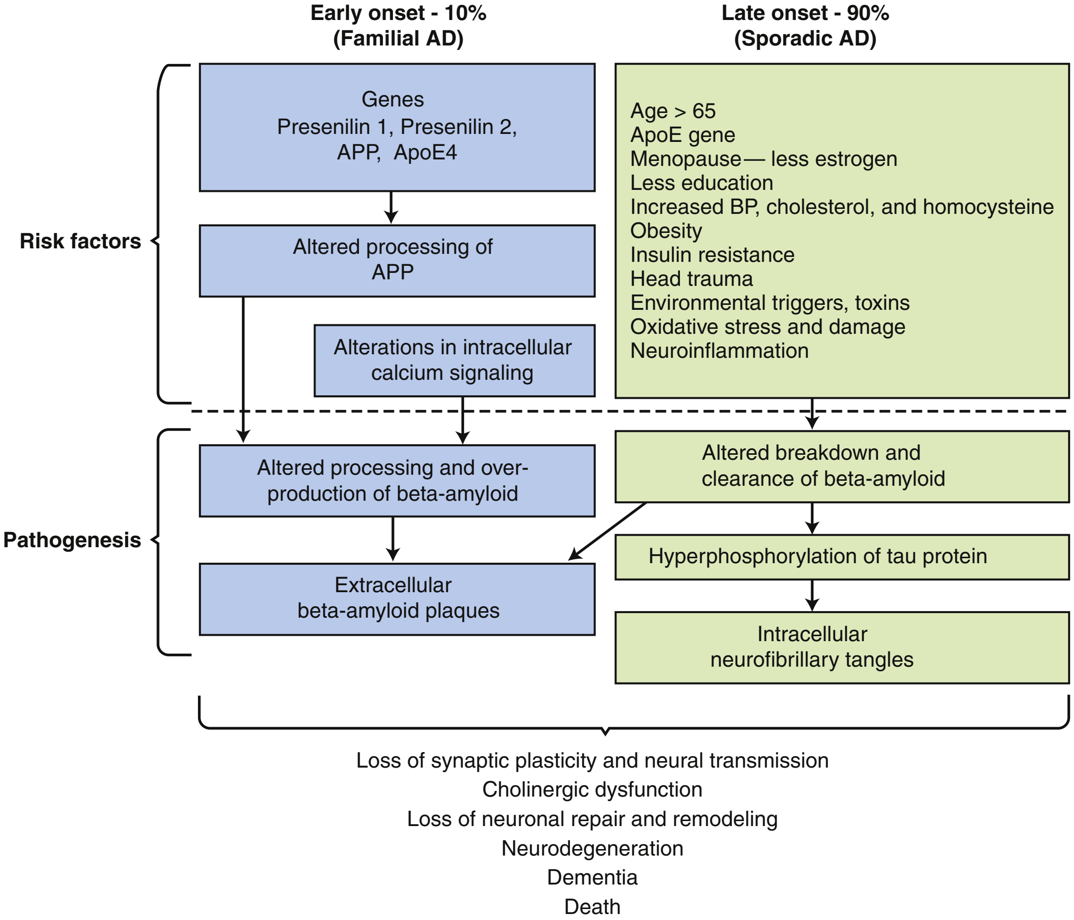

FIGURE 17-12 **Proposed Risk Factors and Pathogenesis of Alzheimer Disease.** *ApoE,* Apolipoprotein E; *APP,* amyloid precursor protein; *BP,* blood pressure. the apolipoprotein E gene-allele 4 *(apoE4)*.[37] Sporadic AD is the most common and does not have a specific genetic association; however, the cellular pathologic mechanisms are the same as those seen in early- and late-onset AD. Pathologic alterations in the brain include the formation of **neuritic plaques** containing a core of amyloid beta protein, the formation of neurofibrillary tangles, and the degeneration of basal forebrain cholinergic neurons with loss of acetylcholine. Failure to process and clear amyloid precursor protein results in the accumulation of toxic fragments of amyloid beta protein that leads to formation of diffuse neuritic plaques, disruption of nerve impulse transmission, and death of neurons. Amyloid also is deposited in cerebral arteries, causing an amyloid angiopathy and disturbance in blood flow (Figure 17-13). The tau protein, a microtubule-binding protein, in neurons detaches and forms an insoluble filament called a **neurofibrillary tangle,** which contributes to neuronal death. Tangles are flame shaped (Figure 17-14). Senile plaques and neurofibrillary tangles are more concentrated in the cerebral cortex and hippocampus (important for memory). The loss of neurons results in brain atrophy with decreases in

FIGURE 17-15 Alzheimer Disease. The brain decreases in volume and weight, the sulci widen, and the gyri thin, especially in the temporal and frontal lobes. The ventricles enlarge to fill the space. (From Kumar V, Cotran RS, Robbins SL: *Robbins basic pathology,* ed 7, p 843, Philadelphia, 2007, Saunders.)

weight and volume. The sulci widen and the gyri thin, especially in the frontal and temporal lobes, and the ventricles enlarge to fill the space (Figure 17-15). Loss of acetylcholine and other neurotransmitters contributes to the decline of memory and attention and the decline of other cognitive functions associated with AD. Neuroinflammation is evident in the pathophysiology of AD but the exact mechanisms are still being determined.[38] Alterations in intracellular calcium levels are functionally linked to presenilin mutations, *apoE4* expression, amyloid plaques, tau tangles, and synaptic dysfunction. Aging and injury may result in changes that contribute to the development and progression of this disease. Such changes include oxidative stress and neuroinflammation, decreased oxygen and glucose transport, molecular changes in vascular smooth muscle and in the blood-brain barrier, and mitochondrial defects that alter cell metabolism and processing of proteins, including amyloid *(apoE4)*.[39-41]

CLINICAL MANIFESTATIONS. AD has a long preclinical and prodromal course while pathophysiologic changes can occur decades before the appearance of the clinical dementia syndrome. The disease progresses from mild short-term memory deficits and culminates in total loss of cognition and executive functions. Initial clinical manifestations are subtle and nonspecific and often attributed to forgetfulness, emotional causes, or other illness. The individual becomes progressively more forgetful over time, particularly in relation to recent events. Memory loss increases as the disorder advances, and the person becomes disoriented and confused. The ability to concentrate declines. Abstraction, problem solving, and judgment gradually deteriorate. A failure in mathematic calculation ability, language, and visuospatial orientation occurs. Dyspraxia may appear. The mental status changes induce behavioral changes, including irritability, agitation, and restlessness. Mood changes also result from the deterioration in cognition. The person may become anxious, depressed, hostile, emotionally labile, and prone to mood swings. Motor changes may occur if the posterior frontal lobes are involved. The individual exhibits rigidity (paratonia, gegenhalten), with flexion posturing, propulsion, and retropulsion. Weight loss can be significant (see Nutrition & Disease: Diet and Alzheimer Disease). Great variability in age of onset, intensity and sequence of symptoms, and location and extent of brain abnormalities occurs among individuals with AD. Table 17-15 presents the clinical findings in each stage of AD.

EVALUATION AND TREATMENT. The specific diagnosis of AD is made by postmortem examination.[42] The clinical history, cognitive testing, course of the illness, laboratory tests, and brain imaging are used for diagnostic evaluation. The course of the disorder is highly variable, usually developing over 5 years or more. Genetic susceptibility tests for *PSEN1, PSEN2,* and *APP* are used to screen for early-onset AD.[43]

There are no disease-arresting therapies available for AD. Cholinesterase inhibitors (ChE-Is) are used in mild to moderate AD to enhance cholinergic transmission. Drugs for moderate to severe AD block the activity of glutamate (an excitatory neurotransmitter and modulator of neuroplasticity) and work as an noncompetitive *N*-methyl-D-aspartate (NMDA) receptor (a glutamate receptor) antagonist.[44]

NUTRITION & DISEASE

Diet and Alzheimer Disease

Weight loss is a major concern for older adults with Alzheimer disease and it may precede onset of the classic motor symptoms. Weight loss may be a result of (1) increased incidence of infection, (2) increased energy output because of constant pacing, (3) olfactory and taste changes making food less appealing, (4) inadequate food intake, and (5) decreased independence and difficulty in self-feeding. Dementia may lead to memory loss, social isolation, depression, and poor food intake with resultant weight loss. Individuals may forget or refuse to eat, fail to communicate the need to eat, throw or hide food, eat spoiled food or nonfood substances, eat favorite foods to the exclusion of other foods, take a long time to eat, have difficulty in preparing foods, and be unable to feed themselves. Reduced lean body mass has been associated with brain atrophy and declining cognitive performance. Oral nutritional supplementation can improve nutritional status.

Data from Burns JM et al: *Arch Neurol* 67(4):428–433, 2010; Pivi GA et al: *Nutr J* 26(10):98, 2011; Soto ME et al: *J Alzheimers Dis* 28(3):647–654, 2012.

TABLE 17-15 **PROGRESSION OF ALZHEIMER DISEASE**

STAGE	MILD COGNITIVE IMPAIRMENT	EARLY STAGE	MIDDLE STAGE	LATE STAGE	END STAGE
Cognitive	Mild memory loss, particularly for recent event (episodic memory) and new information (semantic memory)	Measurable short-term memory loss; difficulty planning; disorientation to location	Significant forgetfulness; easy to get lost; may dress inappropriately; may have hallucinations	Little cognitive ability; language not clear; personality change; does not recognize family members; wandering; repetitive behavior	No significant cognitive function; loss of word speech
Functional	Possibly depression (vs. apathy); mild anxiety	Mild IADL problems	IADL-dependent; some ADL problems	ADL-dependent; incontinent; difficulty eating	Nonambulatory/bedbound; unable to eat

Adapted from National Conference of Gerontological Nurse Practitioners and the National Gerontological Nursing Association, *Counseling Points* 1(1):6, 2008.
ADL, Activities of daily living; *IADL,* instrumental activities of daily living.

Treatment of AD also is directed at decreasing impaired cognitive function by implementing compensation techniques (such as memory aids), maintaining cognitive functions that are not impaired, and retaining or improving the general state of hygiene, nutrition, and health. Environmental management, counseling, education, pharmacotherapy, and health promotion measures provide the foundation on which a comprehensive individualized treatment program is built.[45]

Frontotemporal Dementia

Frontotemporal dementia (FTD), previously known as **Pick disease,** is a rare, severe degenerative disease of the frontal and anterior frontal lobes that produces death of tissue and dementia. Age of onset is less than 60 years. Three different clinical presentations have been described: behavioral variant frontotemporal dementia (bvFTD), semantic dementia (SD), and progressive nonfluent aphasia (PNFA) (see What's New? The Frontotemporal Disorders). Each clinical presentation is associated with a distinct region of brain atrophy and patterns of cellular atrophy. There is an autosomal dominant pattern of inheritance in 30% to 50% of cases. The majority of cases involve mutations of genes encoding tau protein or progranulin (may be important for nerve repair). The disease is difficult to distinguish clinically and pathologically from Alzheimer disease.[46]

WHAT'S NEW?

The Frontotemporal Disorders

Although marked by progressive damage to the anterior temporal or frontal lobes of the brain, or both, specific subtypes of frontotemporal degeneration (FTD) have been identified with distinct clinical presentations associated with the brain area most affected. Behavioral variant FLTD (bvFTD, Pick disease, or frontal variant FTD) has a predominant behavioral presentation characterized by loss of empathy and increasingly inappropriate social behavior. The right frontal lobe is most affected by bvFTD. A predominant language presentation known as primary progressive aphasia (PPA) can manifest as a nonfluent/agrammatic PPA with the person talking less and the speech becoming hesitant or with a progressive deterioration in understanding language and recognizing objects. The left language areas are most affected in this subtype. A third variant is marked by deteriorating ability to retrieve (recall) words and is associated with left temporal areas. A predominant movement presentation occurs in corticobasal syndrome (CBS) characterized by decreased movement unilaterally and rigidity accompanied by a tremor initially and in progressive supranuclear palsy (PSP) characterized by gait and balance problems and inability to coordinate eye movements.

Data from Gorno-Tempini ML et al: *Neurology* 15:76(11):1006–1014, 2011; Sieben A et al: *Acta Neuropathol* 124(3):353–372, 2012.

Seizure Disorders

Seizure disorders represent a manifestation of disease and not a specific disease entity. A **seizure** is a sudden, transient disruption in brain electrical function caused by abnormal excessive hypersynchronous discharges of cortical neurons.[47] **Epilepsy** is the recurrence of seizures and a type of seizure disorder for which no underlying correctable cause for the seizure can be found. The term **convulsion** is sometimes applied to seizures and refers to the tonic-clonic (jerky, contract-relax) movement associated with some seizures. Seizures in children are presented in Chapter 20.

Diseases and Conditions Associated with Seizure Disorders

Any condition that changes the neuronal environment may produce seizure activity; therefore, in theory, anyone can have a seizure. The seizure threshold of some individuals, however, is genetically lower.

Diseases or other processes that involve the nervous system may cause a seizure disorder. The onset of seizures may point to the presence of an ongoing primary neurologic disease. Etiologic factors in seizures include: (1) cerebral lesions, (2) biochemical disorders, (3) cerebral trauma, and (4) epilepsy. Conditions that may produce a seizure are metabolic defects, congenital malformations, genetic predisposition, perinatal injury, postnatal trauma, myoclonic syndromes, infection, brain tumor, and vascular disease.

Seizures also may be precipitated by hypoglycemia; fatigue or lack of sleep; emotional or physical stress; fever; large amounts of water ingestion (hyponatremia); constipation; use of stimulant drugs; withdrawal from depressant drugs or alcohol; hyperventilation (respiratory alkalosis); and some environmental stimuli, such as blinking lights, a poorly adjusted television screen, loud noises, certain odors, or merely being startled. Immediately before or during menses women may have increased seizure activity.[48]

Types of Seizure

Seizures are classified in different ways—by clinical manifestations, site of origin, EEG correlates, or response to therapy.[49,50] Types of seizures are presented in Table 17-16. **Generalized seizures,** 30% of seizures, involve neurons bilaterally, often do not have a local (focal) onset, and usually originate from a subcortical or deeper brain focus. Generalized seizures result from cellular, biochemical, or structural abnormalities of a widespread nature.[47] With a generalized seizure, consciousness always is impaired or lost. **Focal seizures (partial seizures)**

TABLE 17-16 TYPES OF SEIZURES AND CLINICAL MANIFESTATIONS

TYPE	CLINICAL MANIFESTATIONS	SITE
I. Focal (partial) seizures	Seizures originating in one hemisphere	
A. Simple		
1. With motor symptoms		
a. Without jacksonian march (focal motor seizure—the motor movements do not extend into adjacent areas)	Motor activity is usually clonic Motor movement elicited by the seizure activity depends on the anatomic-physiologic portion of the irritated cortex, but motor seizures most often begin in the face and hands Focal seizures begin with slow, repetitive jerking of the body part, which increases in strength and rate over 5 to 15 seconds The seizure can cease spontaneously, with a gradual decrease in clonic movement	Primary motor area
b. With jacksonian march (jacksonian seizure—the seizure activity spreads in an orderly fashion to adjacent areas)	Seizure activity spreads to adjacent areas after the initial clonic movement increases; motor movements, for example, begin in the fingers of one side and spread to the hand, wrist, forearm, arm, face, and finally the lower extremity on the same side of the body After spreading, the jerking movements in all areas spontaneously stop	Primary motor area
c. Adversive seizure	Turning movement of hand and eyes to the side opposite the irritative focus occurs Often it is associated with contractions of the trunk and extremities It may remain local or develop into a generalized seizure	Frontal lobe anterior to the primary motor area
2. With special sensory or somatosensory symptoms (focal sensory seizure); less common than focal motor seizures; any age may be affected	Sensory experience is subjective and confined to the primary sensory modalities (somesthetic, visual, auditory-vestibular, or olfactory) If sensory seizure begins on the hand area of the sensory cortex, the person experiences numbness, tingling, or "pins and needles" phenomena. Other sensory experiences include burning, a crawling sensation, or a feeling of movement of the body part Areas most often affected include lips, fingers, and toes May remain local or develop into a generalized seizure	Sensory cortex Postcentral gyrus (parietal lobe) with involvement of the primary sensory area
B. Complex (temporal lobe or psychomotor seizure)		
1. Simple partial onset followed by impairment of consciousness—common seizures found in children and adults but in most persons occurs before 20 years of age	The person is able to interact with the environment with purposeful, although inappropriate, movements; although the body muscles stiffen, the person does not fall and may even continue the complex activity in which he or she was involved, such as driving (perseverative automatisms); the person may appear "wide eyed" A wide variety of sensory experiences precede the automatism and include illusions; formed hallucinations; primitive visceral, olfactory, and gustatory sensations; and affective and cognitive symptoms Most characteristic event of a temporal lobe seizure is the automatism; common examples of automatisms are lip smacking, chewing, facial grimacing, swallowing movements, and patting, picking, or rubbing oneself or one's clothing Temporal lobe seizures generally last 11 seconds to 8 minutes (average 2 minutes) and are followed by several minutes of postictal confusion	Temporal lobe and its connections Frontal lobes Other areas
2. Impaired consciousness at onset—with or without automatisms	See B1 above	
C. Secondarily generalized	Unconsciousness appears General symptoms are produced	
II. Generalized seizures	Seizures involve both hemispheres and without local onset	
A. Absence (petit mal seizures) 1. Typical 2. Atypical	Characterized by lapses in consciousness that rarely last longer than 10 seconds. Often associated with additional subtle signs and symptoms such as clonic movements, changes in postural tone, automatisms, and autonomic changes Immediate return to normal consciousness without a postictal period Hyperventilation will induce a typical absence seizure Lapses in consciousness occur almost always accompanied by motor signs, especially changes in tone and lasts from 10 to 25 seconds Often occurs on awakening and with drowsiness A postictal period of confusion may follow Hyperventilation does *not* induce an atypical absence seizure	Multifocal

Continued

TABLE 17-16 TYPES OF SEIZURES AND CLINICAL MANIFESTATIONS—cont'd

TYPE	CLINICAL MANIFESTATIONS	SITE
B. Myoclonus and myoclonic seizures	Characterized by sudden uncontrollable jerking movements of one or more extremities or the entire body Seizures usually occur in the morning Consciousness is thought to be preserved Person often is flung violently to the ground; injury is a real possibility Myoclonic seizures can occur in clusters	Multifocal
C. Clonic	Characterized by repetitive clonic jerks of constant amplitude and diminishing frequency	
D. Tonic (affects infants and children)	Loss of postural tone without evidence of clonicity, with flexion of the upper limbs and extension of the lower limbs	
E. Tonic-clonic (grand mal seizure) (affects children and adults)	Assumes an abnormal posture for seconds or minutes without losing consciousness A prodromal period of irritability and tension may precede a tonic-clonic seizure by several hours or days; however, usually seizures begin without warning Characteristically tonic-clonic seizures begin with a sudden loss of consciousness and brief flexion; the person falls to the ground and the body stiffens in an opisthotonos position with legs and, usually, arms extended; the jaw snaps shut; a shrill cry may be heard as a result of forceful exhalation of air through the closed vocal cords as the thoracic muscles initially contract; the bladder and, less often, the bowel may evacuate; during the tonic phase, the person is apneic with subsequent cyanosis; pupils are dilated and unresponsive to light The tonic phase lasts less than 1 minute (average 10-15 seconds) The clonic phase is characterized by flexion spasms of the whole body interrupted by muscular relaxation; muscular contractions are accompanied by strenuous hyperventilation; the face is contorted; the eyes roll, and there is excessive salivation with frothing from the mouth; profuse sweating and a rapid pulse rate are evident. The tongue is often bitten. The clonic jerking subsides in frequency and amplitude over a period of about 30 seconds The tonic-clonic seizure lasts 2-5 minutes After the clonic phase, the person is in a stupor or coma for about 5 minutes; the extremities are limp; breathing is quiet; and the pupils begin to respond to light When the person awakens, he or she may be confused and disoriented with complaints of headache, muscle aching, and fatigue There is no recollection of the attack Tonic-clonic seizures may occur at any time of day or night, whether the person is awake or asleep The frequency of recurrence may vary from hours to weeks, months, or years	Multifocal
F. Atonic (drop attack)	Characterized by sudden loss of postural muscle tone; the tone loss may be mild, resulting in a head nod, or more dramatic, including falls	Multifocal
III. Unclassified epileptic seizures		
A. Neonatal seizures	Occurs within first 28 days of life Myoclonic or tonic Presents as blinking, chewing, bicycling, or apnea	
B. Epileptic (infantile) spasms	Neck and trunk flexion and arm abduction with a jackknife pattern Extension may occur Epileptic spasms occur in clusters recurring every 5 to 40 seconds	

involve neurons only unilaterally, often have a local (focal) onset, and originate from discrete areas usually associated with structural abnormalities localized to the cortical brain tissue, thereby having a superficial focus. Consciousness may be maintained as long as the seizure activity is limited to one hemisphere in simple partial seizures, but partial seizures may become generalized to involve neurons of the other hemisphere and the deeper brain nuclei. This process is called **secondary generalization.** Consciousness is lost at the point of generalization. In complex partial seizures, consciousness is impaired; that is, the person is unable to respond normally to exogenous stimuli. Sixty percent of seizures are either complex partial seizures or seizures with secondary generalization.

PATHOPHYSIOLOGY. Seizures occur when there is disruption in the balance of excitation and inhibition of electrical impulses.[51] The primary abnormality may be a membrane defect leading to instability in resting potential, abnormalities of potassium conductance or calcium channels, defects of the gamma-aminobutyric acid (GABA) inhibitory system, or an abnormality in excitatory transmission enhancement, particularly of the *N*-methyl-D-aspartate type (NMDA). In animal models, a defect in the GABA inhibitory system is the mechanism causing generalized seizures. Three groups of physiologic mechanisms are involved in seizures and epilepsies: (1) mechanisms of seizure initiation and propagation (excitation and inhibition), (2) mechanisms of epileptogenesis, and (3) genetics.[52]

Seizure initiation is characterized by two simultaneous events in a group of neurons: (1) high-frequency bursts of action potentials and (2) hypersynchronization. The burst activity is produced by a relatively long-lasting depolarization of the neuron caused by an influx of extracellular calcium that opens the voltage-dependent sodium channel. The influx of sodium

generates repetitive action potentials.[47] The firing of involved neurons becomes increasingly greater in frequency and amplitude. With sufficient neuronal activation, recruitment of surrounding neurons occurs through a variety of mechanisms. The discharge spreads or propagates to adjacent normal neurons through corticocortical synapses. If uninhibited at this point, the cortical excitation spreads through interhemispheric tracts to the contralateral cortex and through projection pathways to the subcortical areas of the basal ganglia, thalamus, and brainstem. The excitation spread to the subcortical, thalamic, and brainstem areas corresponds to the **tonic phase** (phase of muscle contraction associated with increased muscle tone) and is associated with *loss of consciousness*. Autonomic clinical manifestations also may emerge at this point, and *apnea* may be present for a few seconds. The excitation is further projected downward to the spinal cord neurons through the corticospinal and reticulospinal pathways.

The **clonic phase** (phase of alternating contraction and relaxation of muscles) begins as inhibitory neurons in the cortex, anterior thalamus, and basal ganglia begin to inhibit the cortical excitation. This inhibition causes an interruption in the seizure discharge, producing an intermittent contract-relax pattern of muscle contractions. The intermittent clonic bursts gradually become more and more infrequent until they finally cease. At this point the epileptogenic neurons are exhausted and the neuronal membranes probably are hyperpolarized.

The maintenance of seizure activity demands a 250% increase in the concentration of adenosine triphosphate (ATP). Cerebral oxygen consumption is increased by 60%. Although cerebral blood flow also increases approximately 250% during seizure activity, available glucose and oxygen are readily depleted. With a severe seizure the brain tissue may require more ATP than can be produced by the tissues from the available oxygen and glucose. A deficiency of ATP, phosphocreatine, and glucose then occurs, and lactate accumulates in the brain tissues. Severe seizures thus may produce secondary hypoxia, acidosis, and lactate accumulation, all of which are imbalances that may result in progressive brain tissue injury and destruction. Cellular exhaustion and destruction are consequences of these events.

Epileptogenesis refers to the transformation of a normal neuronal network into one that is chronically hyperexcitable **(epileptogenic focus)**.[53] A delay of months to years often occurs between the initiating injury and the first seizure. Some forms of epileptogenesis involve structural changes in the neuronal network. Reorganization or "sprouting" of surviving neurons (plasticity) also has been found to affect the excitability of the network.

If a seizure focus is active for a prolonged period, a secondary focus, called a **mirror focus,** may develop in normal tissue. This process apparently is caused by the interhemispheric communication, inasmuch as the mirror focus is located in the contralateral cortical area. Seizure threshold in some individuals is genetically lower. Research is in progress to identify alterations in gene transcription that affect seizure threshold.[54,55]

Status epilepticus in adults is a state of continuous seizures lasting more than 5 minutes, or rapidly recurring seizures before the person has fully regained consciousness from the preceding seizure, or a single seizure lasting more than 30 minutes. Status epilepticus can arise from abnormal persistence of excessive excitation or ineffective recruitment of inhibition.[56] The person is still in a **postictal state** (a state that follows an epileptic seizure and returns to baseline) when the next seizure begins. Status epilepticus most often results from abrupt discontinuation of antiseizure medications but also may occur in untreated or inadequately treated persons with seizure disorders. The situation is a medical emergency because of the resulting cerebral hypoxia. Mental retardation, dementia, other brain damage, and even death are serious threats. Aspiration also is a great risk.

The term **epilepsy,** meaning "to be seized by a force from without," generally is applied to conditions in which there is no underlying correctable cause for the seizures. The seizure activity recurs without treatment because of a primary underlying brain abnormality. Epilepsy therefore is a general term for the primary condition that causes the symptoms of seizures.[57] It is now considered to be the result of the interaction of complex genetic mutations with environmental effects that cause abnormalities in brain wiring, an imbalance in the brain's neurotransmitters, or the development of abnormal nerve connections after injury.[58] Epilepsy is estimated to affect about 2.7 million people in the United States with 150,000 new cases of epilepsy reported in 2010.[59] Incidence is highest in early childhood and declines to plateau in adulthood. However, incidence rises again in older people to early childhood levels.

Epileptic syndromes are epileptic disorders characterized by specific clusters of signs and symptoms.[60] Two categories are based on clinical history, EEG manifestations, and etiology and include: (1) localization (focal) related (e.g., temporal lobe epilepsy) and (2) generalized. Localization-related epilepsies and syndromes are typified by seizures that originate from a localized cortical region and are characterized by seizures that have a focal or partial onset. Generalized epilepsies are characterized by seizures with initial activation of neurons within both cerebral hemispheres.

Epilepsy syndromes are further subdivided into idiopathic, symptomatic, or cryptogenic. **Idiopathic epilepsy** refers to syndromes that arise spontaneously without a known cause, presumably having a genetic basis. The genetic basis may be through a specific inherited trait in which the seizures are the principal expression of the genetic defect (e.g., childhood absence epilepsy). In two thirds of cases, the etiology of the epilepsy is not identified. **Symptomatic epilepsy** denotes epilepsies with an identified cause. One third of seizures can be classified as symptomatic (provoked or secondary). Some symptomatic epilepsies also have a genetic basis in which the inherited trait is expressed in a neurologic or systemic disorder that is associated with seizures (e.g., neurofibromatosis). The term **cryptogenic epilepsy** describes syndromes that are presumed to be symptomatic but have no known etiology, and occur in persons with or without abnormalities on neurologic examination. Box 17-2 presents the international classification of epilepsies, and Table 17-17 groups the etiology of recurrent seizures by age group.

CLINICAL MANIFESTATIONS. The clinical manifestations associated with seizure depend on the type of seizure (see Table 17-16). Two types of symptoms often signal an impending generalized tonic-clonic seizure: an **aura,** a partial seizure that immediately precedes the onset of a generalized tonic-clonic

BOX 17-2 INTERNATIONAL CLASSIFICATION OF THE EPILEPSIES

I. Localization related (focal, partial)
  A. Idiopathic
    1. Benign childhood epilepsy with centrotemporal spikes
    2. Childhood epilepsy with occipital paroxysms
    3. Primary reading epilepsy
  B. Symptomatic
    1. Temporal lobe epilepsy
    2. Frontal lobe epilepsy
    3. Parietal lobe epilepsy
    4. Occipital lobe epilepsy
    5. Chronic progressive epilepsia partialis continua of childhood
  C. Cryptogenic defined by:
    1. Seizure type
    2. Clinical features
    3. Etiology
    4. Anatomic localization
II. Generalized
  A. Idiopathic
    1. Benign neonatal familial convulsions
    2. Benign neonatal convulsions
    3. Benign myoclonic epilepsy in infancy
    4. Childhood absence epilepsy
    5. Juvenile absence epilepsy
    6. Juvenile myoclonic epilepsy
    7. Epilepsies with grand mal seizures on awakening
    8. Other generalized idiopathic epilepsies
  B. Cryptogenic or symptomatic
    1. West syndrome
    2. Lennox-Gastaut syndrome
    3. Epilepsy with myoclonic-astatic seizures
    4. Epilepsy with myoclonic absences
    5. Other symptomatic generalized epilepsies
  C. Symptomatic
    1. Nonspecific etiology
    2. Early myoclonic encephalopathy
    3. Early infantile epileptic encephalopathy with suppression bursts
III. Undetermined epilepsies
  A. Generalized and focal features
    1. Neonatal seizures
    2. Severe myoclonic epilepsy in infancy
    3. Epilepsy with continuous spike wave during slow-wave sleep
    4. Acquired epileptic aphasia
IV. Special syndromes
  A. Situation-related seizures
    1. Febrile convulsions
    2. Isolated seizures or isolated status epilepticus
    3. Seizures occurring only when there is an acute or toxic event attributable to factors such as alcohol, drugs, eclampsia, nonketotic hyperglycemia

From the Commission on Classification and Terminology of the International League Against Epilepsy: *Epilepsia* 30:389–399, 1989. Used with permission of International League Against Epilepsy.

TABLE 17-17 CAUSES OF RECURRENT SEIZURES IN DIFFERENT AGE GROUPS

AGE AT ONSET	PROBABLE CAUSE
Neonates (<1 month)	Acute CNS infection (e.g., sepsis, meningitis, encephalitis) Cortical malformation Drug withdrawal or toxicity Genetic disorders Intracranial hemorrhage and trauma Kernicterus Metabolic disturbances (e.g., hypoglycemia, hypocalcemia, hypomagnesemia, pyridoxine deficiency) Perinatal hypoxic and ischemic encephalopathy
Infants and children (1 month to 12 yr)	Degenerative disorders (e.g., tuberous sclerosis, neurofibromatosis, Tay-Sachs disease) Febrile seizures Genetic disorders (e.g., metabolic, degenerative, primary epilepsy syndromes) Idiopathic Infantile spasms Trauma
Children (5-11 yr)	Early onset and childhood absence seizures Meningoencephalitis
Adolescents (12-18 yr)	Acute CNS infection (e.g., sepsis, meningitis, encephalitis) Brain tumor Genetic disorders Idiopathic Illicit drug use (e.g., cocaine, amphetamines) Trauma
Young adults (18-35 yr)	Alcohol or drug withdrawal (e.g., barbiturates, benzodiazepines) Brain tumor Idiopathic Illicit drug use (e.g., cocaine, amphetamines) Trauma
Older adults (>35 yr)	Alcohol or drug withdrawal (e.g., barbiturates, benzodiazepines) Brain tumor Cerebrovascular disease (e.g., stroke, aneurysm, arteriovenous malformations) CNS degenerative diseases (e.g., Alzheimer disease, multiple sclerosis) Idiopathic Metabolic disorders (e.g., uremia, hepatic failure, electrolyte abnormalities, hypoglycemia)

TABLE 17-18 TERMINOLOGY USED TO DESCRIBE A SEIZURE

TERM	DEFINITION
Aura	A partial seizure experienced as a peculiar sensation preceding the onset of a generalized seizure or complex partial seizure that may take the form of gustatory, visual, or auditory experience; a feeling of dizziness or numbness; or just "a funny feeling"
Prodroma	Early clinical manifestations, such as malaise, headache, or a sense of depression, that may occur hours to a few days before the onset of a seizure
Tonic phase	A state of muscle contraction in which there is excessive muscle tone
Clonic phase	A state of alternating contraction and relaxation of muscles
Postictal state	The period immediately following the cessation of seizure activity

seizure; and a **prodroma,** an early manifestation that may occur hours to days before a seizure (Table 17-18). Both manifestations may become familiar to the person experiencing recurrent generalized seizures and so may help in preventing injuries during the seizure.

EVALUATION AND TREATMENT. Health history is the most critical aspect in diagnosing a seizure disorder and establishing the cause and onset. The health history is supplemented by the physical examination and laboratory tests of blood and urine (blood glucose, serum calcium, blood urea nitrogen, urine sodium, and creatinine clearance measurements) to identify any systemic diseases known to have seizures as a clinical manifestation. Brain imaging and cerebrospinal fluid (CSF) examination are useful for identifying any neurologic diseases associated with seizures. The EEG is useful in assessing the type of seizure and may help determine its focus. Combined EEG and functional magnetic resonance imaging (MRI) are useful in identifying neural networks involved in epileptic activity.[61]

Treatment for a seizure disorder is first to correct or control its cause, if possible. If this is not possible, the major means of management is the judicious administration of antiseizure medications. The therapeutic goal is complete suppression of seizure activity without intolerable side effects of the drug or drug resistance. Dietary treatments (e.g., ketogenic diet) are effective for some individuals with epilepsy.[62] Surgical interventions can improve seizure control and quality of life in people with drug-resistant epilepsy.[63] Vagus nerve stimulation can reduce seizure frequency in persons with drug-resistant partial seizures.[64] Educational programs may reduce seizure frequency and improve psychologic functioning but it is not known if behavioral and psychologic treatments are beneficial.[65]

ALTERATIONS IN CEREBRAL HEMODYNAMICS

An injured brain reacts with structural, chemical, and pathophysiologic changes called secondary brain injuries (see Chapter 18). The primary injury is the original trauma and the secondary injury is a consequence of ischemia often related to cerebral hemorrhage and edema. Critical features of these injuries include alterations in cerebral blood flow, intracranial pressure, and oxygen delivery. Several relevant features of cerebral hemodynamics relate to cerebral oxygenation (Box 17-3).

BOX 17-3 CEREBRAL HEMODYNAMICS

Cerebral blood volume (CBV) is the amount of blood in the intracranial vault at a given time (normally about 10%). Most of this CBV is in the low-pressure venous system. CBV is determined by autoregulatory mechanisms that control **cerebral blood flow** (CBF). CBF is the flow of blood through the brain and is normally maintained at a rate that matches local oxygen need and removal of metabolic wastes. CBF is sensitive to concentrations of carbon dioxide, hydrogen ion, and oxygen. CBF decreases 3% for every 1-mmHg decrease in CO_2 pressure attributable to vasoconstriction. CBF increases at a Pao_2 of less than 50 mmHg; CBF is stable (maintained) at a Pao_2 of greater than 80 mmHg.

CBF to the brain is maintained at a rate that matches local metabolic needs of the brain, about 750 to 900 ml/minute (15% to 20% of the cardiac output). Blood flow to neuronal cell bodies of gray matter is about three to four times greater than that to white matter because of the increased metabolic activity. CBF is calculated as follows: CBF + CPP **(cerebral perfusion pressure)**/CVR (cardiovascular resistance). CPP is the net pressure gradient required to perfuse the cells of the brain. CPP is calculated as follows: CPP = mean arterial pressure (MAP) – intracranial pressure (ICP). Normal CPP is 60 to 100 mmHg. The CPP determines the CBF. As the CPP decreases to 70 to 80 mmHg in the injured brain, vasodilation occurs, which increases the CBV, also increasing the ICP. An increased ICP will decrease CPP.

Cerebral oxygen saturation is measured in the internal jugular vein (Sjo_2) at the jugular bulb and reflects the amount of oxygen still bound as the blood leaves the cranial vault. Cerebral extraction of oxygen (CEo_2) is calculated using the formula $Sao_2 - Sjo_2/Sao_2 \times 100$. Normal CEo_2 is 20% to 24%; normal Sjo_2 is 55% to 70%. When oxygen demand exceeds oxygen supply, extraction increases, increasing the Sjo_2. A CEo_2 less than 24% or an Sjo_2 greater than 75% indicates cerebral hyperemia. Acid-base balance and temperature influence oxyhemoglobin dissociation (see Figure 34-16).

Data from Arshi B, Mack WJ, Emanuel B: *Neural Res Int* 2013:987934, 2013; Brady KM et al: *Anesth Analg* 108(4):1278–1283, 2009; Verweij BH, Amelink GJ, Muizelaar JP: *Prog Brain Res* 161:111–124, 2007.
CO_2, Carbon dioxide; *PaO_2*, arterial oxygen pressure; *SaO_2*, oxygen saturation in arterial blood; *SjO_2*, oxygen saturation in the jugular vein.

Alterations in cerebral blood flow may be related to three injury states: (1) cerebral oligemia (inadequate cerebral perfusion), (2) cerebral perfusion pressure (CPP) in the normal range (60 to 100 mmHg) but with an elevated intracranial pressure (ICP), and (3) cerebral hyperemia (excessive cerebral blood volume). In the treatment algorithms, oxygen saturation measured in the internal jugular vein (Sjo_2) is categorized as less than 55%, greater than 55% but less than 70%, or greater than 75%. After Sjo_2 is categorized, the ICP must be added to the equation as less than 20 mmHg or greater than 20 mmHg. Depending on the Sjo_2 and ICP values, treatment algorithms are implemented that address not only ICP but also CPP. The therapeutic goal is to balance ICP and Sjo_2. Target values for relevant clinical parameters are presented in Table 17-19.

Increased Intracranial Pressure

Intracranial pressure normally is 5 to 15 mmHg, or 60 to 180 mm H_2O. **Increased intracranial pressure (IICP)** may result

from an increase in intracranial content (as occurs with tumor growth), edema, excess CSF, or hemorrhage. It necessitates an equal reduction in volume of the other cranial contents. The most readily displaced content is CSF. If intracranial pressure remains high after CSF displacement out of the cranial vault, cerebral blood volume and blood flow are altered.

In *stage 1 of intracranial hypertension,* vasoconstriction and external compression of the venous system occur in an attempt to further decrease the intracranial pressure. Thus, during the first stage of intracranial hypertension, ICP may not change because of the effective compensatory mechanisms and there may be few symptoms (Figure 17-16). Small increases in volume, however, cause an increase in pressure, and the pressure may take longer to return to baseline. This can be detected with ICP monitoring.

In *stage 2 of intracranial hypertension,* there is continued expansion of intracranial contents. The resulting increase in ICP may exceed the brain's compensatory capacity to adjust. The pressure begins to compromise neuronal oxygenation, and systemic arterial vasoconstriction occurs in an attempt to elevate the systemic blood pressure sufficiently to overcome the IICP. Clinical manifestations at this stage are usually subtle and transient, including episodes of confusion, restlessness, drowsiness, and slight pupillary and breathing changes (see Figure 17-16).

In *stage 3 of intracranial hypertension,* the ICP begins to approach arterial pressure, the brain tissues begin to experience hypoxia and hypercapnia, and the individual's condition rapidly deteriorates. Clinical manifestations include decreasing levels of arousal or central neurogenic hyperventilation, widened pulse pressure, bradycardia, and pupils that become small and sluggish (see Figure 17-16).

Dramatic sustained rises in ICP are not seen until all compensatory mechanisms have been exhausted. Then dramatic rises in ICP occur over a very short period. **Autoregulation,** the compensatory alteration in the diameter of the intracranial blood vessels designed to maintain a constant blood flow during changes in cerebral perfusion pressure, is lost with progressively increased ICP. Accumulating carbon dioxide may still cause vasodilation locally, but without autoregulation this vasodilation causes the hydrostatic (blood) pressure in the vessels to drop and blood volume to increase. The brain volume is thus further enhanced, and ICP continues to rise. Small increases in volume cause dramatic increases in ICP, and the pressure takes much longer to return to baseline. As the ICP begins to approach systemic blood pressure, cerebral perfusion pressure falls and cerebral perfusion slows dramatically. The brain tissues experience severe hypoxia, hypercapnea, and acidosis.

TABLE 17-19 THERAPEUTIC MANAGEMENT GOALS FOR INDIVIDUALS WITH ALTERED CEREBRAL HEMODYNAMICS

CLINICAL PARAMETER	TARGET VALUE
Central perfusion pressure	>70 mmHg
Intracranial pressure	<20 mmHg
Arterial CO_2 pressure (Pa_{CO_2})	35 mmHg
Mean arterial pressure	90 mmHg
Temperature	34-36° C (93.2-96.8° F)
Pulmonary capillary wedge pressure	10-15 mmHg

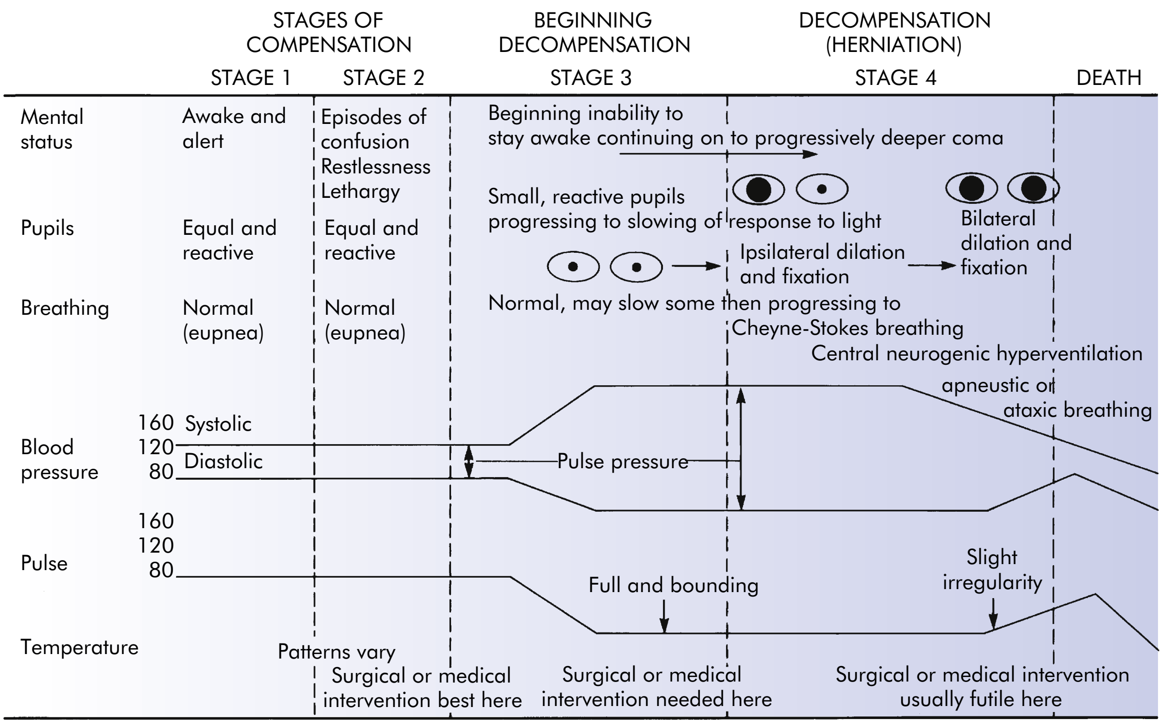

FIGURE 17-16 Clinical Correlates of Compensated and Uncompensated Phases of Intracranial Hypertension. (From Beare PG, Myers JL: *Principles and practice of adult health nursing,* ed 3, St Louis, 1998, Mosby.)

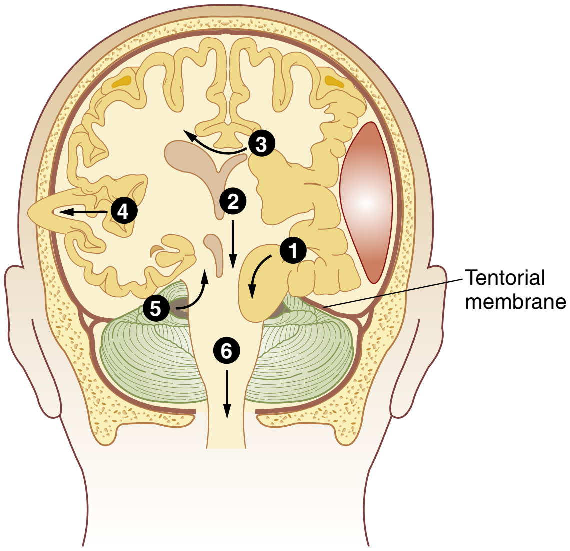

FIGURE 17-17 Brain Herniation. Herniations can occur both above and below the tentorial membrane. *Supratentorial:* **1,** uncal (transtentorial); **2,** central; **3,** cingulate; **4,** transcalvarial (external herniation through an opening in the skull). *Infratentorial:* **5,** upward herniation of cerebellum; **6,** cerebellar tonsillar moves down through foramen magnum.

In *stage 4 of intracranial hypertension,* brain tissue shifts (herniates) from the compartment of greater pressure to a compartment of lesser pressure and IICP in one compartment of the cranial vault is not evenly distributed throughout the other vault compartments (see Figures 17-16 and 17-17). With this shift in brain tissue, the herniating brain tissue's blood supply is compromised, causing further ischemia and hypoxia in the herniating tissues. The volume of content within the lower pressure compartment increases, exerting pressure on the brain tissue that normally occupies that compartment, and impairing its blood supply. Small hemorrhages often develop in the involved brain tissue. Obstructive hydrocephalus may develop. The herniation process markedly and rapidly increases intracranial pressure. Mean systolic arterial pressure soon equals ICP and cerebral blood flow ceases at this point. The types of **herniation syndromes** are outlined in Box 17-4.

Cerebral Edema

Cerebral edema is an increase in the fluid content of brain tissue, a net accumulation of water within the brain (Figures 17-18 and 17-19). Cerebral edema causes an increase in extracellular or intracellular tissue volume after brain insult from trauma, infection, hemorrhage, tumor, ischemia, infarct, or hypoxia. The harmful effects of cerebral edema are caused by the distortion of blood vessels, the displacement of brain tissues, and the eventual herniation of brain tissue from one brain compartment to another.

Three types of cerebral edema are (1) vasogenic edema, (2) cytotoxic (metabolic) edema, and (3) interstitial edema. **Vasogenic edema** is clinically the most important type. It is caused by the increased permeability of the capillary endothelium of the brain after injury to the vascular structure. The result

BOX 17-4 BRAIN HERNIATION SYNDROMES

Supratentorial Herniation

1. *Uncal herniation.* This occurs when the uncus or hippocampal gyrus, or both, shifts from the middle fossa through the tentorial notch into the posterior fossa, compressing the ipsilateral third cranial nerve, the contralateral third cranial nerve, and the mesencephalon. Uncal herniation generally is caused by an expanding mass in the lateral region of the middle fossa. The classic manifestations of uncal herniation are a decreasing level of consciousness, pupils that become sluggish before fixing and dilating (first the ipsilateral, then the contralateral pupil), Cheyne-Stokes respirations (which later shift to central neurogenic hyperventilation), and the appearance of decorticate and then decerebrate posturing.
2. *Central herniation.* This is the straight downward shift of the diencephalon through the tentorial notch. It may be caused by injuries or masses located around the outer perimeter of the frontal, parietal, or occipital lobes; extracerebral injuries around the central apex (top) of the cranium; bilaterally positioned injuries or masses; and unilateral cingulate gyrus herniation. The individual rapidly becomes unconscious; moves from Cheyne-Stokes respirations to apnea; develops small, reactive pupils and then dilated, fixed pupils; and passes from decortication to decerebration.
3. *Cingulate gyrus herniation.* This occurs when the cingulate gyrus shifts under the falx cerebri. Little is known about its clinical manifestations.
4. *Transcalvarial herniation.* The brain shifts through a skull fracture or a surgical opening in the skull. This type of external herniation may occur during a craniectomy—surgery in which a flap of skull is removed, preventing the piece of skull from being replaced.

Infratentorial Herniation

The most common syndrome is *cerebellar tonsillar.* The cerebellar tonsil shifts through the foramen magnum because of increased pressure within the posterior fossa. The clinical manifestations are an arched stiff neck, paresthesias in the shoulder area, decreased consciousness, respiratory abnormalities, and pulse rate variations. Occasionally the force produces an *upward transtentorial* herniation of a cerebellar tonsil or the lower brainstem. There is increased ICP but no specific set of clinical manifestations associated with infratentorial herniation (see Figure 17-17).

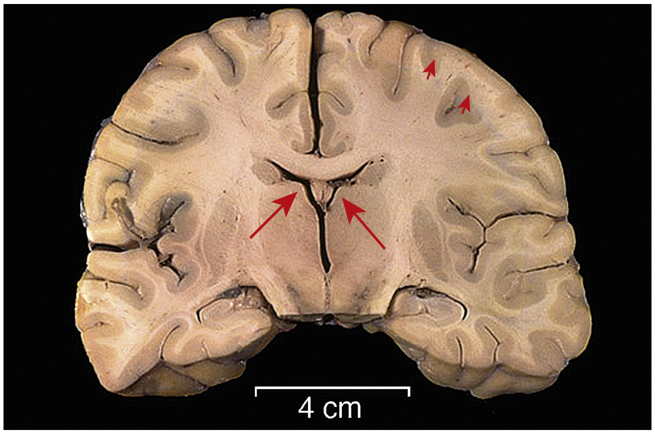

FIGURE 17-18 Cerebral Edema. This coronal section of cerebrum demonstrates marked compression in the lateral ventricles *(long arrows)* and flattening of gyri *(short arrows)* from extensive bilateral cerebral edema. Edema increases intracranial pressure, leading to herniation. (From Klatt EC: *Robbins and Cotran atlas of pathology,* ed 2, Philadelphia, 2010, Saunders.)

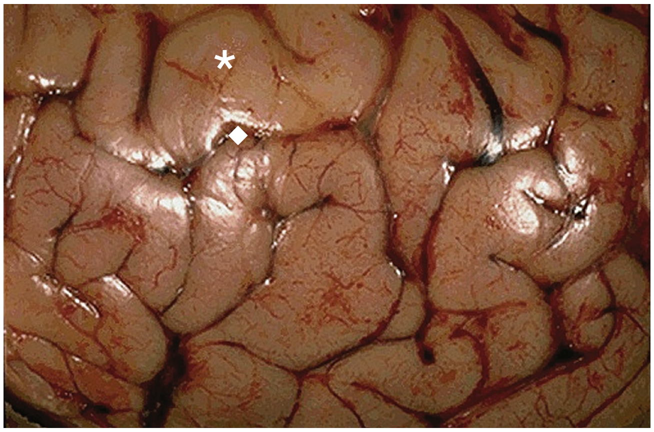

FIGURE 17-19 Cerebral Edema, Gross. The surface of the meninges of the brain with cerebral edema shows widened, flattened gyri (*) with narrowed sulci (◇). (From Klatt EC: *Robbins and Cotran atlas of pathology,* ed 2, Philadelphia, 2010, Saunders.)

is a disruption in the blood-brain barrier (selective permeability of brain capillaries). Plasma proteins leak into the extracellular spaces, drawing water to them, and the water content of the brain parenchyma increases. Vasogenic edema begins in the area of injury and spreads with preferential accumulation in the white matter of the ipsilateral side because the parallel myelinated fibers separate more easily. Edema then promotes more edema because of ischemia from increasing pressure.

Clinical manifestations of vasogenic edema include focal neurologic deficits, disturbances of consciousness, and a severe increase in intracranial pressure. Vasogenic edema resolves by slow diffusion.

In **cytotoxic (metabolic) edema,** toxic factors directly affect the cellular elements of the brain parenchyma (neuronal, glial, and endothelial cells), causing failure of the active transport systems. The blood-brain barrier is not disrupted. The cells lose their potassium and gain larger amounts of sodium. Water follows by osmosis into the cell so that the cells swell. Cytotoxic edema occurs principally in the gray matter and may increase vasogenic edema.

Interstitial edema is seen most often with noncommunicating hydrocephalus (see following section and Chapter 20). The edema is caused by transependymal movement of CSF from the ventricles into the extracellular spaces of the brain tissues. The brain fluid volume thus is increased predominantly around the ventricles. The hydrostatic pressure within the white matter increases, and the size of the white matter is reduced because of the rapid disappearance of myelin lipids.

Hydrocephalus

The term **hydrocephalus** refers to various conditions characterized by an excess of fluid within the cerebral ventricles, subarachnoid space, or both (see Figures 15-15 and 15-16). Hydrocephalus occurs because of interference with CSF flow caused by increased fluid production, obstruction within the ventricular system, or defective reabsorption of the fluid. A papilloma (i.e., epithelial tumor) may, in rare instances, cause overproduction of CSF (Figure 17-20).

Types of Hydrocephalus

Noncommunicating hydrocephalus (obstructive) *(internal or intraventricular hydrocephalus)* is caused by obstruction within the ventricular system. Impaired absorption of CSF from the subarachnoid space occurs when an obstructive process disrupts the flow of CSF through the subarachnoid space. The fluid is prevented from reaching the convex portion of the cerebrum, where the arachnoid granulations are located.

Communicating hydrocephalus (nonobstructive) *(extraventricular)* results from impaired absorption of CSF in the absence of obstruction between the ventricles and subarachnoid space. The most common causes of communicating hydrocephalus are subarachnoid hemorrhage, developmental malformation, head injury, neoplasm, inflammation (i.e., meningitis), high venous pressure in the sagittal sinus, and increased CSF secretion by the choroid plexus.

Hydrocephalus ex vacuo is a form of communicating hydrocephalus that arises from cerebral atrophy. CSF fills the unoccupied space. The amount of CSF is increased, but the fluid is not under pressure.

Normal-pressure hydrocephalus (low-pressure, adult, or **occult hydrocephalus)** is a form of communicating hydrocephalus that occurs mostly in late middle age. The ventricles are enlarged and the cerebrospinal fluid pressure is minimally elevated. This form of hydrocephalus is idiopathic or occurs secondarily as a complication of head injury or subarachnoid hemorrhage.

Acute hydrocephalus may develop in several hours in persons who have sustained head injuries. Acute hydrocephalus contributes significantly to increased ICP.

PATHOPHYSIOLOGY. The obstruction of CSF flow associated with hydrocephalus produces dilation of the ventricles proximal to the obstruction. Obstructed CSF is under pressure, causing atrophy of the cerebral cortex and degeneration of the white matter tracts. There is selective preservation of gray matter. When excess CSF fills a defect caused by atrophy, a degenerative disorder, or a surgical excision, this fluid is not under pressure; therefore, atrophy and degenerative changes are not induced.

CLINICAL MANIFESTATIONS. Most cases of hydrocephalus develop gradually and insidiously over time. Acute hydrocephalus presents with signs of rapidly developing increased intracranial pressure. The person deteriorates rapidly into a deep coma if not promptly treated. Normal-pressure hydrocephalus has a long-term presentation and develops slowly over time. A triad of symptoms, including declining memory with loss of cognitive function (frontal lobe and subcortical dementia); unsteady, broad-based gait; and urinary urgency and incontinence from detrusor overactivity, are common and make diagnosis difficult to differentiate from other causes of dementia. Additional clinical manifestations are apathy, inattentiveness, and indifference to self, family, and the environment.[66,67]

EVALUATION AND TREATMENT. The diagnosis is made on the basis of clinical history and physical examination, evaluation of CSF pressure and volume, and results of brain imaging. Hydrocephalus can be treated by surgery to resect cysts, neoplasms, or hematomas or by ventricular bypass into the normal intracranial channel or into an extracranial compartment using a shunt.

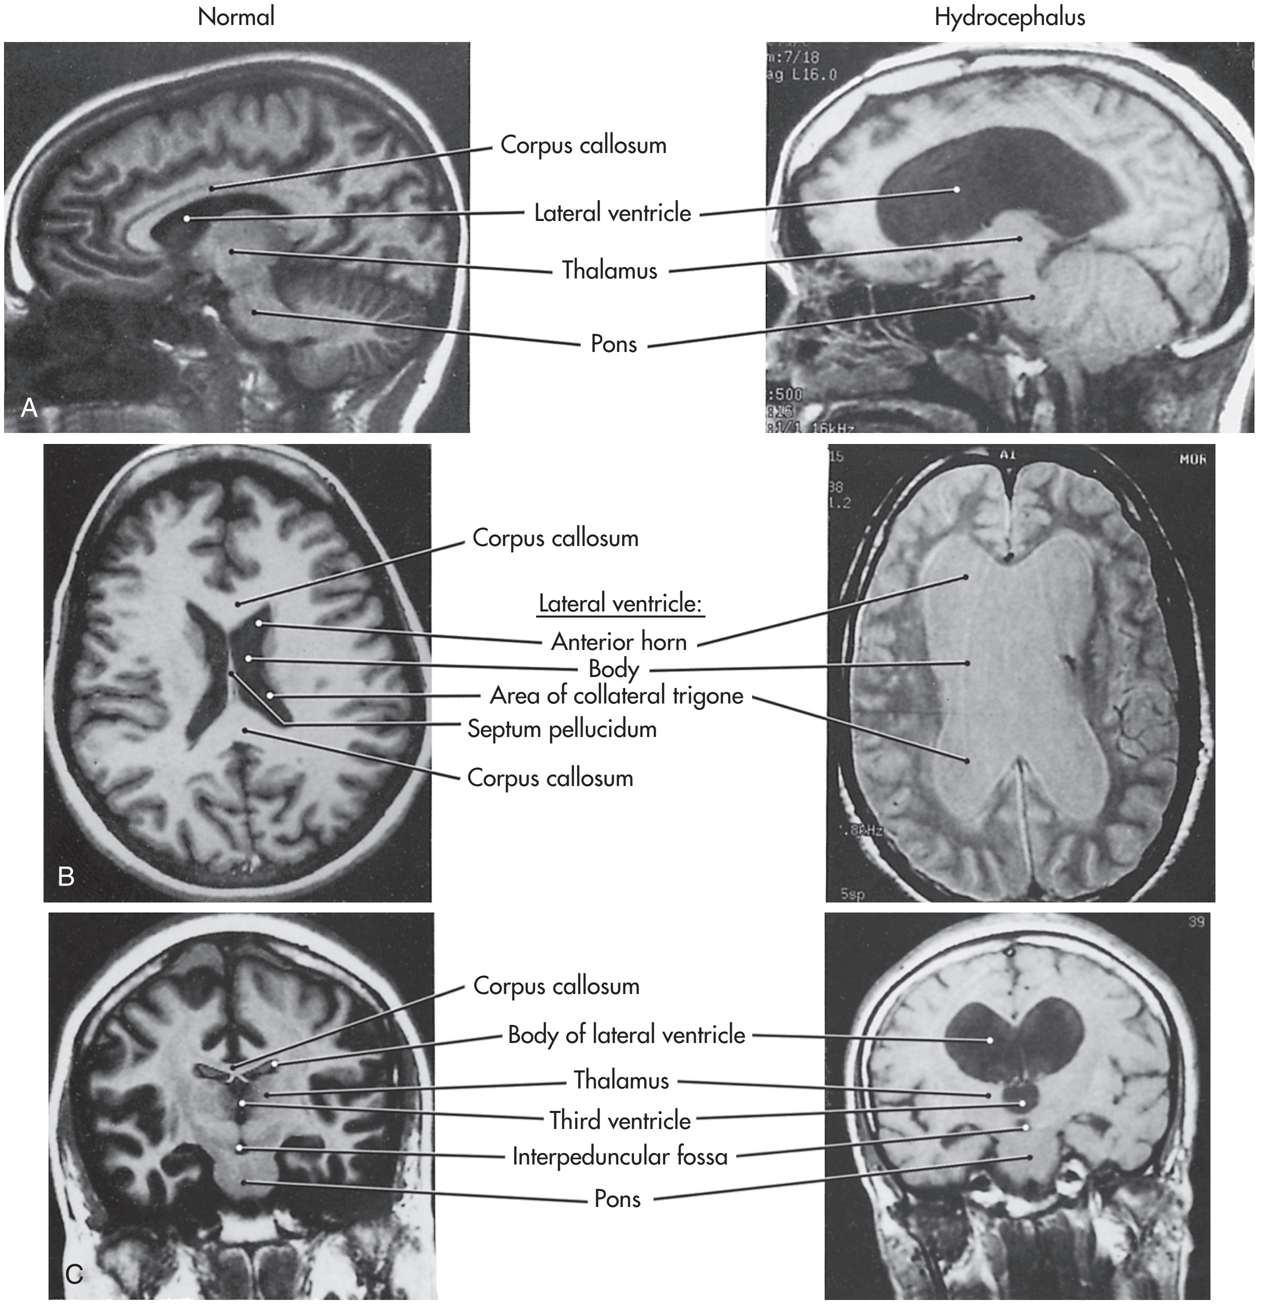

FIGURE 17-20 Comparison of Normal and Hydrocephalic Brains. **A,** Sagittal; **B,** axial; and **C,** coronal planes as seen in magnetic resonance imaging (MRI). (From Haines DE, editor: *Fundamental neuroscience for basic and clinical applications,* ed 4, Philadelphia, 2013, Saunders.)

Excision or coagulation of the choroid plexus is needed occasionally when a papilloma is present.

ALTERATIONS IN NEUROMOTOR FUNCTION

Movements are complex patterns of activity controlled by the cerebral cortex, the pyramidal system, the extrapyramidal system, and the muscle motor units. Dysfunction in any of these areas can cause motor dysfunction. General motor dysfunctions are associated with changes in muscle tone, movement, and complex motor performance.[68,69]

Alterations in Muscle Tone

Normal muscle tone involves a slight resistance to passive movement. The resistance is smooth, constant, and even throughout the range of motion. Abnormalities of muscle tone are presented in Table 17-20.

Hypotonia

In **hypotonia (decreased muscle tone),** passive movement of a muscle occurs with little or no resistance to stretching. Hypotonia is a symptom of alterations in nervous control of muscles. It is thought to be caused by decreased muscle spindle

TABLE 17-20 **ALTERATIONS IN MUSCLE TONE**

ALTERATIONS	CAUSE	CHARACTERISTICS
Hypotonia	Thought to be caused by decreased muscle spindle activity as a result of decreased excitability of neurons Occurs typically when nerve impulses necessary for muscle tone are lost	Passive movement of a muscle mass with little or no resistance Difficult to detect; extremity is floppy and allows excessive movement when displaced Muscles may be rapidly moved without resistance
Flaccidity		Associated with limp, atrophied muscles and paralysis
Hypertonia	Results when the lower motor unit reflex arc continues to function but is not mediated or regulated by higher centers	Increased muscle resistance to passive movement May be associated with paralysis May be accompanied by muscle hypertrophy (see Figure 17-24)
Spasticity	Exact mechanism unclear; appears to arise from an increased excitability of the alpha motor neurons to any input because of absence of the descending inhibition of the pyramidal systems	A gradual increase in tone causing increased resistance until tone suddenly is reduced, which results in clasp-knife phenomenon Velocity dependent (may be absent with slow speed of displacement) Selective distribution (predominates in flexors of upper extremities and extensors of lower extremities and in pronators compared with supinators)
Gegenhalten (paratonia)	Exact mechanism unclear: associated with frontal lobe injury	Resistance to passive movement, which varies in direct proportion to force applied
Dystonia	Loss of CNS inhibitory function with sustained muscular contraction	Sustained involuntary twisting and repetitive movements or abnormal posture
Rigidity	Occurs as a result of constant, involuntary contraction of muscle	Muscle resistance to passive movement of a rigid limb that is uniform in both flexion and extension throughout the motion Not velocity dependent Activated by contraction of muscles in contralateral extremities Uniform through range in displacement
Plastic or lead-pipe	Associated with basal ganglion damage	Increased muscular tone relatively independent of degree of force used in passive movement; does not vary throughout the passive movement
Cogwheel	Associated with basal ganglion damage	The uniform resistance may be interrupted by a series of brief jerks resulting in movements much like a ratchet, "cogwheel" phenomenon
Gamma	Loss of excitation of extensor inhibitory areas by the cerebral cortex, decreasing the inhibition of alpha and gamma motor neurons	Characterized by extensor posturing (decerebrate rigidity)
Alpha	Loss of cerebellum input to lateral vestibular nuclei	Impaired relaxation characterized by extensor rigidity of skeletal muscle after the contraction
Myotonia		Impaired relaxation of skeletal muscle after the contraction

activity secondary to decreased excitability of neurons. Hypotonia caused by pure pyramidal tract damage (a rare occurrence) produces hypotonia and weakness. Hypotonia contributes to the ataxia and intention tremor in cerebellar damage and manifests with minimal weakness and normal or slightly exaggerated reflexes. Hypotonia, often described as flaccidity (a state in which the muscle may be moved rapidly without resistance), occurs when nerve impulses necessary for muscle tone are lost, such as in spinal cord injury or cerebrovascular accident.

Individuals with hypotonia report that they tire easily (asthenia) or are weak, signs that can be observed during their activity attempts. They may have difficulty rising from a sitting position, sitting down without using arm support, or walking up and down stairs, as well as an inability to stand on their toes. Because of their weakness, accident proneness during locomotion and self-care activities is common. Inasmuch as the joints become hyperflexible in hypotonic states, people with hypotonia may be able to assume positions that require extreme joint mobility. The joints may appear loose, and the knee jerks are pendulous.

The muscle mass atrophies because of decreased input entering the motor unit. Muscle cells gradually are replaced by connective tissue and fat. The muscles are flabby on palpation and are flat in appearance. Fasciculations may be present in some cases.

Hypertonia

In **hypertonia (increased muscle tone),** passive movement of a muscle occurs with resistance to stretch and is caused by upper motor neuron damage. Four types of hypertonia are described: spasticity, gegenhalten (paratonia), dystonia, and rigidity.

Spasticity results from hyperexcitability of the stretch reflexes (overactivation of the alpha motor neurons) and is associated with damage to the motor, premotor, and supplementary motor areas, as well as lateral corticospinal tract damage (Figure 17-21). Spasticity is accompanied by increased deep tendon reflexes (hyperreflexia) and the spread of reflexes (clonus).

Gegenhalten (paratonia) is resistance to passive movement that increases with velocity of movement. **Dystonia** is increased involuntary muscle contraction, manifested as sustained, involuntary twisting movements. It is caused by slow muscle contraction and may be caused by a failure in appropriate reciprocal inhibition of the muscles (Figures 17-22 and 17-23).

FIGURE 17-21 **Left-Sided Hemifacial Spasm.** (From Perkin GD: *Mosby's color atlas and text of neurology,* London, 1998, Mosby-Wolfe.)

FIGURE 17-22 **Dystonic Posturing of the Hand and Foot.** (From Perkin GD: *Mosby's color atlas and text of neurology,* London, 1998, Mosby-Wolfe.)

Injury to the putamen or its outflow tracts also is associated with hemidystonia.

Rigidity produced by tonic reflex activity mediated by gamma motor neurons may be continuous or intermittent. The involved muscles are firm and tense; the increase in muscle movement is even and uniform throughout the range of passive movement. Four types of rigidity are described: plastic, or lead-pipe; cogwheel; gamma; and alpha (see Table 17-20).

Individuals with hypertonia may tire easily (asthenia) or be weak. Passive movement and active movement are equally affected, except in gegenhalten, in which more active than passive movement is possible. As a result of hypertonia and weakness, accident proneness during locomotion and self-care activities is common.

The muscles may atrophy because of decreased use. However, hypertrophy occasionally may occur in some diseases. Hypertrophy results from overstimulation of muscle fibers. Overstimulation occurs when the motor unit reflex arc remains intact and functioning but is not inhibited by higher centers. The loss of inhibition and the constant state of excitation cause continual muscle contraction, resulting in enlargement of the muscle mass. The muscles are firm on palpation (Figure 17-24).

FIGURE 17-23 **Spasmodic Torticollis.** A characteristic head posture. (From Perkin GD et al: *Atlas of clinical neurology,* ed 3, Philadelphia, 2011, Saunders.)

Alterations in Movement

Movement requires a change in the contractile state of muscles. Abnormal movements may occur when a variety of CNS dysfunctions alter muscular innervation. The neurotransmitter *dopamine* has a role in motor function. Some movement disorders (e.g., the akinesias) result from too little dopaminergic activity, whereas others (e.g., chorea, ballism, tardive dyskinesia) result from too much dopaminergic activity. Still others are not related primarily to dopamine function. Movement disorders are not associated necessarily with mass, strength, or tone but are neurologic dysfunctions with either an excess of movement or a lack of voluntary movement. Muscle strength is quantitatively evaluated on a scale of 0 to 4+ or 0 to 5, in which 4+ or 5 is normal and 0 indicates an inability to move against gravity (Table 17-21).

Hyperkinesia (excessive movements), *dyskinesias* (unnatural movements), and *abnormal involuntary movements* represent excess movement. Huntington disease is the hallmark of excess movement. *Hypokinesia* (decreased amplitude of movement), *bradykinesia* (decreased speed of movement), and *akinesia*

FIGURE 17-24 Pseudohypertrophy of the Calf Muscles. (From Perkin GD et al: *Atlas of clinical neurology,* ed 3, Philadelphia, 2011, Saunders)

TABLE 17-21 UK MEDICAL RESEARCH COUNCIL CLASSIFICATION OF MUSCLE POWER

GRADE	DEFINITION
0	Total paralysis—no muscle contraction
1	Flicker of contraction—no joint movement
2	Movement with gravity eliminated
3	Movement against gravity but not resistance
4	Movement against resistance but incomplete
5	Normal power against resistance

Data from Vanhoutte EK et al: *Brain* 135(Pt 5):1639–1649, 2012.
UK, United Kingdom.

(absence of voluntary movement) are terms that represent lack of voluntary movement. Parkinson disease is the hallmark of lack of movement.

Hyperkinesia

Hyperkinesia (excessive movement) represents the second broad category of abnormal movements. Within this category are a number of specific hyperkinesia syndromes (Table 17-22). Also included in the general category of hyperkinesias are dyskinesias, that is, abnormal involuntary movements.

Paroxysmal dyskinesias are abnormal, involuntary movements that occur as spasms. The type of dyskinesia varies depending on the specific disorder.

Tardive (slow onset) **dyskinesia** is the involuntary movement of the face, trunk, and extremities. Although the condition occurs occasionally in individuals with Parkinson disease, it usually occurs as a side effect of prolonged use of first- or second-generation antipsychotic drugs.[70] The antipsychotic drugs cause denervation hypersensitivity, thereby mimicking the effect of excessive dopamine. The most common symptom of tardive dyskinesia is rapid, repetitive, stereotypic movements. The most characteristic movements of tardive dyskinesia include continual chewing with intermittent protrusions of the tongue, lip smacking, and facial grimacing. Stereotypic movements are believed to be a form of excessive dopaminergic activity.

WHAT'S NEW?

Tourette Syndrome

There is growing evidence that Tourette syndrome (TS) occurs worldwide and, has common features across all races and cultures. No specific genetic mutations have been found. The hallmark of TS is the presence of multiple motor and vocal tics. The tics may be simple, involving only an individual muscle group (for example, eye blinking or a grunt), or complex, requiring coordinated movement of muscle groups (for example, head banging or repeating of another person's words). Sensory tics involve unpleasant sensations in the face, head, and neck areas. Onset of TS is typically between the ages of 2 and 15 years, is more common in males, and is probably underdiagnosed. The tics lessen in adulthood. The syndrome has a complex, multifactorial etiology with as yet to be determined genetic, environmental, immune, and hormonal factors. The pathophysiology of TS is unclear and currently under study. There is evidence of basal ganglia dysfunction and, in some cases, altered dopaminergic neurotransmission. TS is often diagnosed in association with anxiety, depression, attention-deficit/hyperactivity disorder (ADHD), and obsessive-compulsive disorder.

Data from Bloch M, State M, Pittenger C: *Curr Opin Neurol* 24(2):119–125, 2011; Deng H, Gao K, Jankovic J: *Nat Rev Neurol* 8(4):203–213, 2012; Jankovic J, Kurlan R: *Mov Disord* 26(6):1149–1156, 2011; State MW: *Curr Opin Genet Dev* 21(3):302–309, 2011.

Other movement disorders under this category are (1) complex repetitive movements, including automatism, stereotype, complex tics (e.g., Tourette syndrome [see What's New? Tourette Syndrome]), compulsions, perseverations, and mannerisms; (2) positivism (excessive reactions to certain stimuli); and (3) paroxysmal excessive activity, including cataplexy and excessive startle reaction.

Huntington Disease

Huntington disease (HD), also known as *chorea,* is a relatively rare, autosomal dominant disease with high penetrance. The onset of HD is usually between 25 and 45 years of age, when the trait may already have been passed to the person's children. The disorder has a prevalence rate of approximately 2 to 8 per 100,000 persons and occurs in all races.[71]

PATHOPHYSIOLOGY. The genetic defect of HD is on the short arm of chromosome 4. There is an abnormally long polyglutamine tract in the huntingtin (htt) protein that is toxic to neurons and is caused by a cytosine-adenine-guanine (CAG) trinucleotide repeat expansion (40 to 70 repeats instead of 9 to 34). Age of symptom onset is related to the length of the repeat sequences and mechanisms of toxicity. Repeat lengths greater than 60 cause the juvenile form of the disease.[72]

The principal pathologic feature of HD is severe degeneration of the basal ganglia, particularly the caudate and putamen nuclei and the frontal cerebral cortex. The degeneration of the basal ganglia leaves enlarged lateral ventricles (Figure 17-25). Expression of the *huntingtin* gene produces tangles of protein that collect in brain cells and chains of glutamine on the abnormal molecules that adhere to each other.[73] The mechanism of neuronal death is unknown. The excitotoxic theory of striatal and cortical degeneration proposes that the mutated huntingtin protein produces excitotoxic pathways meditated by glutamate function that also induce concomitant dysregulation of

TABLE 17-22 **TYPES OF HYPERKINESIA SYNDROMES**

TYPE	CHARACTERISTICS	CAUSES
Chorea*	Nonrepetitive muscular contractions, usually of the extremities of the face; random pattern of irregular, involuntary rapid contractions of groups of muscles; disappears with sleep, decreases with resting; increases with emotional stress and attempted voluntary movement	Associated with excess concentration of or a supersensitivity to dopamine within basal ganglia
Athetosis*	Disorder of distal-muscle postural fixation; slow, twisting, sinuous, irregular movements most obvious in the distal extremities, more rhythmic than choreiform movements and always much slower; movements accompany characteristic hand posture; slowly fluctuating grimaces	Occurs most commonly as a result of injury to the putamen of the basal ganglion; exact pathophysiologic mechanism is not known
Ballism	Disorder of proximal-muscle postural fixation with wild flinging movement of the limbs; movement is severe and stereotyped, usually lateral; does not lessen with sleep; ballism is most common on one side of the body, a condition termed hemiballism	Results from injury (vascular disease) to the subthalamic nucleus (one of the nuclei that comprise the basal ganglia); thought to be caused by reduced inhibitory influence in the nucleus, a release phenomenon; hemiballism results from injury to the contralateral subthalamic nucleus
Hyperactivity	State of prolonged, generalized, increased activity that is largely involuntary but may be subject to some voluntary control; not highly stereotyped but rather manifests as continual changes in total body posture or in excessive performance of some simple activity, such as pacing under inappropriate circumstances	May be caused by frontal and reticular activating system injury
Wandering	Tendency to wander without regard for environment	"Release" phenomenon; associated with bilateral injury to globus pallidus or putamen
Akathisia	Special type of hyperactivity; mild compulsion to move (usually more localized to legs); severe frenzied motion possible; movements are partly voluntary and may be transiently suppressed; carrying out the movement brings a sense of relief; a frequent complication of antipsychotic drugs	Dopaminergic transmission may be involved
Tremor at Rest	Rhythmic, oscillating movement affecting one or more body parts	Caused by regular contraction of opposing groups of muscles
Parkinsonian tremor	Regular, rhythmic, slow flexion-extension contraction; involves principally the metacarpophalangeal and wrist joints; alternating movements between thumb and index finger described as "pill rolling"; disappears during voluntary movement	Loss of inhibitory influence of dopamine in the basal ganglia, causing instability of basal ganglia feedback circuit within the cerebral cortex
Postural Tremor		
Asterixis (tremor of hepatic encephalopathy)	Irregular flapping movement of the hands accentuated by outstretching arms	Caused by transient inhibition of muscles that maintain posture; thought to be related to accumulation of products normally detoxified by the liver
Metabolic	Rapid, rhythmic tremor affecting fingers, lips, and tongue; accentuated by extending the body part; enhanced physiologic tremor	Occurs in conditions associated with disturbed metabolism or toxicity, as in thyrotoxicosis (hyperthyroidism), alcoholism, and chronic use of barbiturates, amphetamines, lithium, amitriptyline (Elavil); exact mechanism responsible unknown
Essential (familial)	Tremor of fingers, hands, and feet; absent at rest but accentuated by extension of body part, prolonged muscular activity, and stress	Not associated with any other neurologic abnormalities; cause unknown
Intentional Tremor		
Cerebellar	Tremor initiated by movement, maximal toward end of movement	Occurs in disease of the dentate nucleus (one of the deep cerebellar nuclei responsible for efferent output) and the superior cerebellar peduncle (a stalklike structure connected to the pons); caused by errors in feedback from the periphery and errors in preprogramming goal-directed movement
Rubral	Rhythmic tremor of limbs that originates proximally by movement	Results from lesions involving the dentatorubrothalamic tract (a spinothalamic tract connecting the red nucleus in the reticular formation and the dentate nucleus in the cerebellum)
Myoclonus	Series of shocklike, nonpatterned contractions of a portion of a muscle, entire muscle, or group of muscles that cause throwing movements of a limb; usually appear at random but frequently triggered by sudden startle; do not disappear during sleep	Associated with an irritable nervous system and spontaneous discharge of neurons; structures associated with myoclonus include the cerebral cortex, cerebellum, reticular formation, and spinal cord

*Choreoathetosis involves chorea and athetosis; precise pathophysiology unknown.

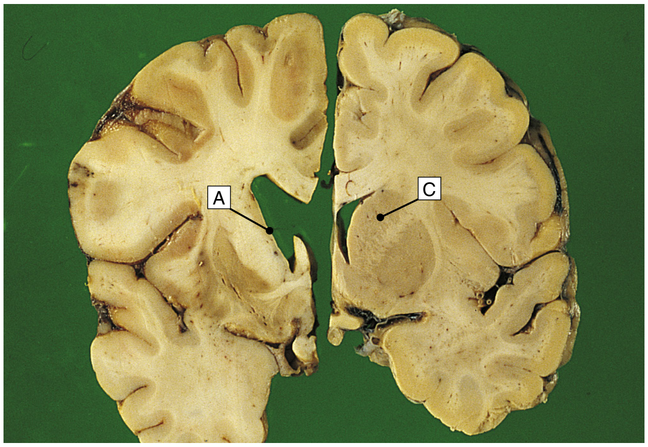

FIGURE 17-25 Huntington Disease. On the right is a normal brain with a normal caudate *(C);* on the left is a brain from an individual with Huntington disease showing severe atrophy of the caudate *(A)* and an enlarged lateral ventricle. (From Stevens A, Lowe J, Scott I: *Core pathology,* ed 3, London, 2009, Mosby.)

dopaminergic function. The huntingtin protein also may alter mitochondrial function, which in turn activates apoptotic pathways and causes neuronal death. Neurotrophic factors also may be depleted, leading to loss of neurons.[73-75]

Early in the disease, selective loss of the striatal GABA/dopamine-enkephalin pathway to the lateral aspect of the pallidum occurs. The striatum of the basal ganglia normally contains a preponderance of GABAergic (GABA-secreting) neurons, including the pathway between the basal ganglia and substantia nigra (pallidonigral pathway–express dopamine D_1-receptors, dynorphin, and substance P). Basal ganglia and nigral depletion of GABA, an inhibitory neurotransmitter, is the principal biochemical alteration in HD. Degeneration of the GABAergic pallidonigral pathway causes GABA depletion in the substantia nigra with decreased inhibitory GABA activity on dopaminergic neurons in the substantia nigra and a relative excess of dopaminergic activity in the basal ganglia feedback circuit within the cerebral cortex. A relative excess of dopaminergic activity in this circuit, as in HD, is manifested by hypotonia and hyperkinesia (involuntary, fragmentary movements such as chorea). Loss of excitatory glutamate may liberate the pathway from the thalamus to the premotor cortex, impairing modulation of movement later in the course of the disease. Producing energy for brain activity is difficult and there is resultant buildup of lactic acid.

CLINICAL MANIFESTATIONS. The classic manifestations of HD are abnormal movements that occur without conscious effort, emotional lability, and progressive dysfunction of cognitive processes (dementia). Any one of these features may mark the onset of the disease. Cognitive impairment may precede motor symptoms by up to 15 years.[76] Chorea is the most common type of abnormal movement and begins in the face and arms, eventually affecting the entire body. It can be combined with athetosis (twisting and writhing). Symptoms of frontal lobe dysfunction include executive attention deficits and short-term memory loss (working memory); reduced capacity to plan, organize, and sequence, as well as bradyphrenia (slow thinking); and apathy. Restlessness, disinhibition, and irritability are common. Affectively, euphoria or depression or both may be present. Progression of the disease is fatal.

EVALUATION AND TREATMENT. The diagnosis of HD is based on family history, clinical presentation of the disorder, and genetic testing. No known treatment is effective in halting the degeneration or progression of symptoms. Chorea is treated with dopamine receptor–blocking or dopamine receptor–depleting agents. Medication and nonmedical care for depression and aggressive behavior may be required. Efforts are in progress to identify biomarkers for early diagnosis and to monitor disease progression.[77,78]

Hypokinesia

Hypokinesia (decreased movement) is loss of voluntary movement despite preserved consciousness and normal peripheral nerve and muscle function. Types of hypokinesia include akinesia, bradykinesia, and loss of associated movement.

Akinesia. **Akinesia** is an absence, poverty, or lack of control of associated and voluntary muscle movements. There is a disturbance in the time it takes to perform a movement. Akinesia is related to dysfunction of the extrapyramidal system, as in parkinsonism. Pathogenesis is related to either a deficiency of dopamine or a defect of the postsynaptic dopamine receptors, which occurs in parkinsonism (see Parkinson disease below).

Bradykinesia. **Bradykinesia** is slowness of voluntary movements. There is a disturbance in the time it takes to perform a movement. In bradykinesia all voluntary movements become slow, labored, and deliberate. Bradykinesia consists of: (1) difficulty in initiating movements, (2) difficulty in continuing movements smoothly, and (3) difficulty in performing synchronous (at the same time) and consecutive tasks. Difficulty in initiating movements ranges from slight hesitancy to severe **freezing** (transient, helpless immobility). Each intended movement requires effort. Difficulty in continuing motions smoothly causes jerky, irregular, rapid movements, which then decrease in rate and amplitude until they stop. The individual is scarcely aware of the cessation. Difficulty in performing synchronous and consecutive tasks means that each motor act is performed separately. The individual is unable to integrate two acts or to change from one motor pattern to the next with a single smooth motion.

Loss of Associated Movement. In hypokinesia the normal, habitually associated movements that provide skill, grace, and balance to voluntary movements are lost. Decreased associated movements accompanying emotional expression cause an expressionless face, a statue-like posture, absence of speech inflection, and absence of spontaneous gestures. Decreased associated movements accompanying locomotion cause reduction in arm and shoulder movements, in hip swinging, and in rotary motion of the cervical spine.

Parkinson Disease

Parkinson disease (PD) is a complex motor disorder accompanied by systemic nonmotor and neurologic symptoms. The main disease feature is degeneration of the basal ganglia (corpus striatum, globus pallidus, subthalamic nucleus, and substantia nigra) involving the dopaminergic (dopamine-secreting) nigrostriatal pathway. Nigrostriatal disorders produce a

BOX 17-5 PRIMARY AND SECONDARY CAUSES OF PARKINSONISM

Primary Parkinsonism

Sporadic (idiopathic); most common form
Genetic: autosomal dominant; autosomal recessive
Phenotype may be influenced by gene-environment interactions

Secondary Parkinsonism

- Neurodegenerative disorders (sporadic or genetic)
  - Disorders associated with alpha-synuclein pathology
    - Multiple system atrophies (glial and neuronal inclusions)
      - Nigrostriatal degeneration
      - Olivopontocerebellar atrophy
      - Shy-Drager syndrome
      - Motor neuron disease with PD features
    - Dementia with Lewy bodies (cortical and brainstem neuronal inclusions)
  - Disorders associated with primary tau pathology ("tauopathies")
    - Progressive supranuclear palsy
    - Corticobasal degeneration
    - Frontotemporal dementia
  - Disorders associated with primary amyloid pathology ("amyloidopathies")
    - Alzheimer disease with parkinsonism
- Genetically mediated disorders with occasional parkinsonian features
  - Wilson disease
  - Hallervorden-Spatz disease
  - Chédiak-Higashi syndrome
  - SCA-3 spinocerebellar ataxia
  - X-linked dystonia-parkinsonism *(DYT3)*
  - Fragile X permutation associated with ataxia-tremor-parkinsonism syndrome
  - Huntington disease (Westphal variant)
  - Prion disease
- Miscellaneous acquired conditions
  - Vascular parkinsonism: atherosclerosis, amyloid angiopathy
  - Normal pressure hydrocephalus
  - Catatonia
  - Cerebral palsy
- Repeated head trauma ("dementia pugilistica" with parkinsonian features)
- Infectious and postinfectious diseases
  - Postencephalitic PD
  - Creutzfeldt-Jakob disease
  - Neurosyphilis
- Metabolic conditions
  - Hypoparathyroidism or pseudohypoparathyroidism with basal ganglia calcifications
  - Non-wilsonian hepatolenticular degeneration
- Multiple sclerosis
- Neoplastic disease
- Drugs
  - Neuroleptics (typical antipsychotics)
  - Selected atypical antipsychotics
  - Antiemetics (e.g., compazine, metoclopramide)
  - Dopamine-depleting agents (reserpine, tetrabenazine)
  - α-Methyldopa
  - Lithium carbonate
  - Valproic acid
  - Fluoxetine
- Toxins
  - 1-Methyl-1,2,4,6-tetrahydropyridine (MPTP)
  - Manganese
  - Cyanide
  - Methanol
  - Carbon monoxide
  - Carbon disulfide
  - Hexane

Data from Delong MR, Juncos IL: Parkinson's disease and other extrapyramidal movement disorders. In Fauci AS et al, editors: *Harrison's principles of internal medicine,* ed 17, p 2553, New York, 2008, McGraw-Hill; Lang A: Parkinsonism. In Goldman L, Ausiello D, editors: *Cecil medicine,* ed 23, p 2726, Philadelphia, 2008, Saunders.

syndrome of abnormal movement called **parkinsonism (Parkinson syndrome, parkinsonian syndrome).**

Etiologic classification of parkinsonism includes primary parkinsonism and secondary parkinsonism (Box 17-5). The onset of PD occurs after 40 years of age, with mean onset of 60 years of age.[79] PD is one of the most prevalent of the primary CNS disorders and a leading cause of neurologic disability in individuals older than 60 years. Approximately 60,000 people in the United States are diagnosed each year and an estimated 10 million people worldwide are living with PD. Men are 150% more likely to have PD than women.[80] The familial form represents about 10% of PD; however, the majority of cases are sporadic or idiopathic.

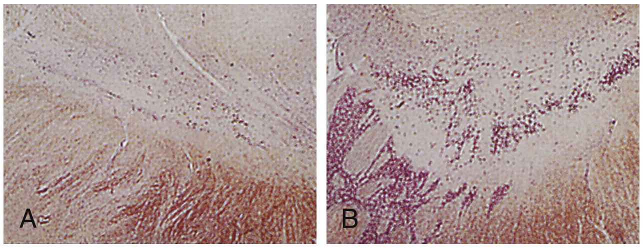

FIGURE 17-26 **Atrophic Substantia Nigra (A) Compared with Normal Control (B).** (From Perkin GD et al: *Atlas of clinical neurology,* ed 3, Philadelphia, 2011, Saunders.)

PATHOPHYSIOLOGY. The pathogenesis of primary PD is unknown. Several PD genes have been identified, the most significant of which are listed in Table 17-13 (p. 547). The hallmark pathologic features of PD are loss of dopaminergic pigmented neurons in the substantia nigra (SN) pars compacta with dopaminergic deficiency in the putamen portion of the striatum (the striatum includes the putamen and caudate nucleus) (Figure 17-26). Dopamine loss in other brain areas including the brainstem, thalamus, and cortex also occurs.[81] Degeneration of the dopaminergic nigrostriatal pathway to the basal ganglia results in underactivity of the direct motor pathway (normally facilitates movement) (Figure 17-27) and overactivity of the indirect motor loop (normally inhibits movement). This results in inhibition of the motor cortex manifested with *bradykinesia* and *rigidity*. The subthalamic nucleus (STN) overactivity also influences the limbic system,[79] accounting for emotional signs and symptoms. Neuronal loss within the cerebral cortex is found in half of individuals with PD. Mechanisms of cell dysfunction and death

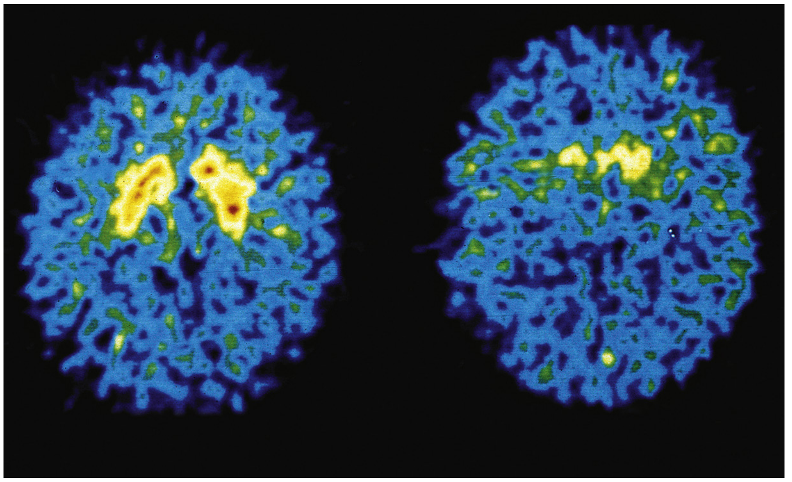

FIGURE 17-27 Reduced Fluorodopa in Parkinson Disease. Positron-emission tomography scan showing reduced fluorodopa uptake in the basal ganglia consistent with neurodegeneration *(right)* compared with a normal control *(left)*. (From Perkin GD et al: *Atlas of clinical neurology,* ed 3, Philadelphia, 2011, Saunders.)

include mitochondrial dysfunction, oxidative stress, altered protein handling, and inflammatory changes with autophagy and apoptosis.[82]

Lewy bodies, fibrillar intracellular eosinophilic inclusions, and high concentrations of alpha-synuclein, ubiquitin, tau protein, tuberculin, and other proteins are found in the substantia nigra (SN), locus ceruleus (LC), and other areas of the brain. They are a marker for neuronal degeneration.[83] Degeneration of the LC, which contains noradrenergic neurons, also occurs in PD. Norepinephrine is thought to be neuroprotective and loss of LC neurons may be associated with a worsening of disease progression and the behavioral symptoms of PD.[84] Molecular events thought to be associated with the neurodegeneration of PD include mitochondrial dysfunction, oxidative stress, abnormal folding and accumulation of alpha-synuclein, abnormal phosphorylation, and dysfunction of the ubiquitin proteasome system (regulates intracellular protein processing)[85,86] (Figure 17-28).

CLINICAL MANIFESTATIONS. Onset of symptoms is insidious and symptoms appear after a 70% to 80% loss of pigmented nigral neurons and a 60% to 90% loss of striatal dopamine.[87] The classic motor manifestations of PD are resting tremor, bradykinesia/akinesia (poverty of movement), rigidity (muscle stiffness), and postural abnormalities. These manifestations may develop alone or in combination; however, as the disease progresses, all four are usually present to at least some degree. There is no true paralysis. A modified Hoehn and Yahr scale[88] can be used to assess progression of symptoms:

0 No visible disease
1 Unilateral involvement, may have tremor of one limb
2 Bilateral involvement, balance intact
3 Bilateral involvement, slowing of body movement, mild to moderate postural instability, and gait difficulty
4 Bilateral involvement with severe postural instability, rigidity, and bradykinesia present
5 Bilateral involvement with inability to walk, confinement to wheelchair, cachexia present

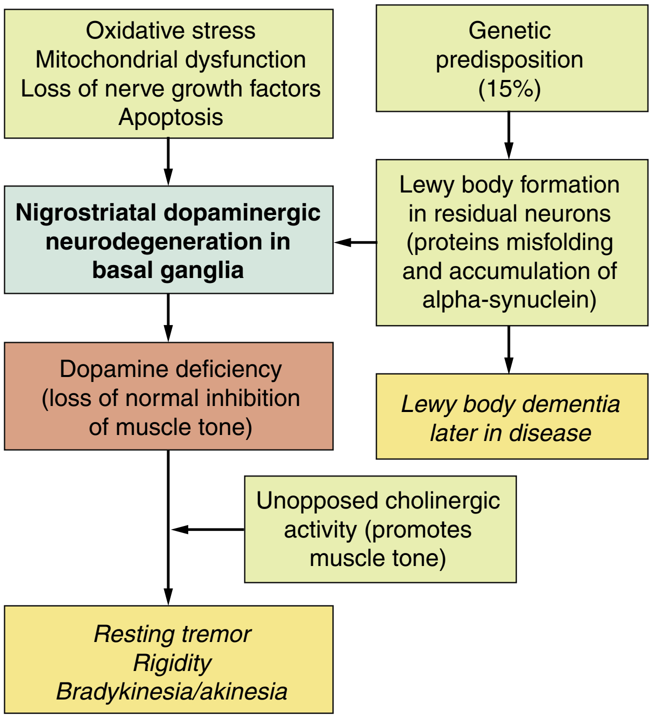

FIGURE 17-28 Pathophysiology of Parkinson Disease.

In early stages of the disease, reflex, sensory, and mental status are usually normal. Nonmotor symptoms associated with PD include hyposmia, fatigue, pain, autonomic dysfunction, sleep fragmentation, depression, and dementia with or without psychosis.[89]

Parkinsonian tremor, the most conspicuous and most variable symptom, is usually the first motor symptom to appear. It is a tremor at rest, disappearing briefly during the course of a voluntary movement and reappearing when the limb is held in a stationary position. Intensity and amplitude of the tremor vary. The arm is more affected than the leg. Most individuals with PD have this tremor and tremors are increased by stress and anxiety.

Parkinsonian tremor appears to result from instability of feedback from the basal ganglia to the cerebral cortex caused by loss of the inhibitory influence of dopamine in the basal ganglia. Increased oscillation in the normal feedback cycles of the motor outflow feedback circuit when the muscles are at rest produces the tremor. When the individual performs voluntary movements, the tremor becomes temporarily blocked, presumably because other motor control signals arriving in the thalamus override the abnormal basal ganglia signals. As the disorder worsens, tremor may lessen as rigidity supervenes. The postural tremor is associated with damage to the cerebellofugal pathway to the red nucleus, a pathway that subserves communication from muscle spindles to the thalamus and motor cortex.

Parkinsonian rigidity is an increased resistance to the passive movement of a joint that impedes active and passive movement. The first symptoms of rigidity may be painful muscle cramps in the toes or hands. More commonly the limb feels stiff, heavy, tired, or aching. **Plastic rigidity** is constant throughout the entire range of motion and is felt as lead-pipe resistance during passive movement. **Cogwheel rigidity,** brief palpable jerks, is accompanied by tremor. The mechanism underlying rigidity is unclear, but there is increased resting muscle activity of antagonistic muscle groups with enhancement of the long-latency component of the stretch reflex.[79]

Parkinsonian bradykinesia is poverty of associated and voluntary movements. It is the most prevalent and crippling symptom and often is overlooked in the early stages. The pathophysiology underlying the bradykinesia is an overactive subthalamic nucleus (STN) that inhibits the motor thalamus and motor cortex.[79] It is associated with dopamine deficiency and failure of the mechanism programming movement patterns manifested as a defect in the voluntary production of smooth motions at different speeds.[90]

All striated muscles—extremity, trunk, ocular, facial—are affected eventually, including muscles of mastication (chewing), deglutition (swallowing), and articulation. Micrographia (small handwriting) is present. Extreme underactivity in the individual with PD makes the person appear stiff, even when resistance to passive movement cannot be felt. Bradykinesia is a separate phenomenon from rigidity and may be severe even in the presence of rigidity. Individuals state that they feel "wooden" (as though moving against resistance) and complain of rapid, severe fatigue.

Hypokinesia, or decreased frequency or absence of associated movements, is one of the earliest symptoms. Individuals with PD sit and lie motionless for long periods without the little shifts an unaffected person makes to prevent discomfort and stiffness. Bradykinesia, or slowness of voluntary movements, is characterized by difficulty initiating, continuing, or synchronizing movements. Both associated and voluntary movements are interspersed by freezing (an inability to continue movement). Freezing may be precipitated by (1) increasing the effort to move, (2) turning, and (3) initiating certain types of tactile and visual contact.

Postural Abnormalities. Three types of postural abnormalities occur in individuals with PD: (1) disorders of postural fixation, (2) disorders of equilibrium, and (3) disorders of righting. The disorder of postural fixation associated with PD is involuntary flexion of the head and neck. The individual is unable to maintain an upright position of the trunk while standing or walking. Postural abnormalities of the hands and feet also occur. Postural abnormalities are caused by a loss of normal postural reflexes, muscular rigidity, axial dystonia, weakness caused by myopathy, and impaired proprioception.[91]

FIGURE 17-29 Stooped Posture of Parkinson Disease. (From Perkin GD et al: *Atlas of clinical neurology,* ed 3, Philadelphia, 2011, Saunders.)

Disorders of equilibrium result from loss of postural stability. The person with PD is unable to make the appropriate postural adjustment to tilting or falling and falls like a post when starting to tilt. The festinating gait (short, accelerating steps) of the person with PD is an attempt to maintain an upright position while walking (Figure 17-29). Individuals also are unable to right themselves when changing from a reclining or crouching position to a standing position and when rolling over from a supine to a lateral or prone position.

Autonomic and Neuroendocrine Symptoms. Autonomic and neuroendocrine dysfunctions in PD produce nonmotor symptoms that are distressing but not incapacitating. The basal ganglia influence hypothalamic function (autonomic and neuroendocrine) through pathways connecting the hypothalamus with the basal ganglia and cerebral cortex. Common autonomic symptoms in PD include inappropriate diaphoresis, gastric retention, constipation, and urinary retention. Cardiac sympathetic denervation is common and causes neurogenic orthostatic hypotension. A symptom attributed to neuroendocrine dysfunction is seborrhea. Hypothalamic hypersecretion of hormone-releasing factors acting on the anterior pituitary causes

hypersecretion of androgenotropic hormones, producing sebum hypersecretion by sebaceous glands. The resulting seborrhea is characterized by oily skin with seborrheic dermatitis along the hairline and in chin-nasal creases.[92]

Cognitive-Affective Symptoms and Dementia. Approximately 30% to 40% of people with PD have a depression that is now believed to be an inherent part of the pathologic state of the disease (an endogenous depression), not a response to the situation.[93,94] Mild cognitive impairment not associated with either dementia or depression is associated with dopaminergic dysmodulation. *Bradyphrenia* (slowness of thinking) also is present. These disorders may appear early in the course of the disease and may progress to dementia. Bradyphrenia is caused by disruption of the caudal basal ganglion connections and outflows. The clinical manifestations are slowness of thinking, poverty of thought (diminished imagination and insight), and difficulty formulating thoughts (decreased ability to conceptualize, plan, decide, or improvise).[95]

Of individuals treated on an outpatient basis for PD, 30% have a dementia, and 80% of those with PD requiring institutional care have dementia as well.[96] Dementia is more common in individuals older than 70 years. Pathologically, in those with dementia, findings include loss of cholinergic cells in the basal nucleus of Meynert (nucleus basalis); neuronal loss, senile plaques, and neurofibrillary tangles in the neocortex; and amyloid changes in small blood vessels. Lewy bodies (alpha-synuclein inclusions) are distributed diffusely in many neurons, making this a Lewy body dementia.[97] The individual evidences disorientation; confusion; memory loss; distractibility; and difficulty with concept formation, abstraction, calculations, thinking, and judgment. Although the symptoms fluctuate, they progressively worsen. Anxiety disorders, impulse-control disorders, and punding (a disorder of stereotypical motor behavior in which there is intense fascination with repetitive handling and examining of mechanical objects) are recognized features of PD.

Other nonmotor symptoms are common in PD including sensory dysfunction with anosmia, ageusia, pain, paresthesias, fatigue and weight loss, sweating, urinary and gastrointestinal dysfunction, and eye tremor.[98,99] Sleep disorders are common including disturbances in the sleep-wake cycle, excessive daytime sleepiness, obstructive sleep apnea, and restless leg syndrome.[100]

Influence of Symptoms. Early in the disease, people often experience a sleep benefit; that is, symptoms decrease with sleep. Symptoms also fluctuate in an on-off pattern. Stress influences symptoms adversely, but the underlying mechanism is unclear. The person's mental status may be further compromised by the side effects of the medication taken to control symptoms.

The combination of all the parkinsonian symptoms gives the individual a characteristic appearance: a wide-eyed, unblinking, staring expression with the facial muscles smoothed out and almost immobile. Saliva frequently drools from the corners of the slightly open mouth. The skin of the face is frequently greasy. The gait is pathognomonic: the individual walks with slow, short, shuffling steps; the arms are flexed, abducted, and held stiffly at the side; and the trunk is bent slightly forward. The person may break into a run spontaneously or when pushed forward or backward. Because of the disorder of postural fixation, the tendency is to fall to the side. Postural instability, sleep disorders, and difficulty concentrating are some of the most depressing symptoms for people with PD.[101]

EVALUATION AND TREATMENT. The diagnosis of primary PD is made on the basis of the four cardinal symptoms: (1) resting tremor, (2) cogwheel rigidity, (3) akinesia, and (4) postural instability. This group of symptoms has the acronym TRAP.[102] The exclusion of other causes of parkinsonism and a combination of imaging techniques, clinical evaluations, biochemical markers, and genetic tests support the diagnosis of PD.[103,104] Early nonmotor symptoms of PD can precede motor symptoms and their identification may assist early diagnosis and guide disease-modifying strategies.[103,105] Median time between diagnosis and death is between 7 and 15 years. Disease progression varies with age of disease onset, comorbidities, quality of care, and among different populations.[106,107]

The aim of drug therapy is to restore striatal dopamine levels using oral drugs such as levodopa (L-dopa), a precursor of dopamine (dopamine does not cross the blood-brain barrier), dopamine agonists that directly stimulate dopamine receptors, anticholinergic drugs, antihistamines, and amantadine; L-dopa is effective in reducing symptoms in early PD but can cause motor fluctuations, "off" periods, and dyskinesia in the long term. Monoamine oxidase B inhibitors, which inhibit the breakdown of endogenous dopamine, may improve symptoms, reduce motor fluctuations, and delay the need for L-dopa but can cause adverse effects. Adding catechol-*O*-methyltransferase (COMT) inhibitor prolongs the half-life of dopamine (COMT metabolizes dopamine in the synapse). Dopamine agonists to L-dopa or a dopamine agonist alone may reduce "off" time or improve symptoms but can also increase disability.[108] Surgery may be considered in later stages of PD. Thalamotomy and pallidotomy are surgical options. Deep brain stimulation is an approach to controlling medically resistant motor symptoms and L-dopa–related peak dose dyskinesia.[109] Gene- and cell-based therapies hold promise for future treatment.[110] Dysphagia and general immobility are special problems of the individual with PD requiring preventive, symptomatic, supportive, and rehabilitative management, such as physiotherapy and speech therapy.[99] Nursing interventions, occupational therapy (OT), physical therapy (PT), and speech, language, and swallowing therapy are effective and safe for improving functional status.

Upper and Lower Motor Neuron Syndromes

Paresis and paralysis are symptoms of upper and lower motor neuron syndromes (Table 17-23).

Paresis (weakness) is impairment of motor function, that is, partial paralysis with incomplete loss of muscle power. **Paralysis** is loss of motor function, that is, inability of a muscle group to overcome gravity. The characteristics of paresis or paralysis are related to involvement of either the upper or the lower motor neurons.

Upper Motor Neuron Syndromes. **Upper motor neuron paresis/paralysis** is known also as *spastic paresis/paralysis* and different terms are used to describe the specific disorders. **Hemiparesis** or **hemiplegia** is paresis or paralysis, respectively,

TABLE 17-23 UPPER AND LOWER MOTOR NEURON SIGNS AND SYMPTOMS

UPPER MOTOR NEURON (PYRAMIDAL CELLS [MOTOR CORTEX])	LOWER MOTOR NEURON (VENTRAL HORN [SPINAL CORD], MOTOR NUCLEI [BRAINSTEM])
Muscle groups are affected	Individual muscles may be affected
Mild weakness	Mild weakness
Minimal disuse muscle atrophy	Marked muscle atrophy
No fasciculations	Fasciculations
Increased muscle stretch reflexes (clasp-knife spasticity; resistance to passive flexion that releases abruptly to allow easy flexion)	Decreased muscle stretch reflexes
Clonus may be present	Clonus not present
Hypertonia, spasticity	Hypotonia, flaccidity
Pathologic reflexes (Babinski and Hoffmann signs, loss of abdominal reflexes)	Hyporeflexia
Often initial impairment of only skilled movements	No Babinski sign
	Asymmetric and may involve one limb only in beginning to become generalized as disease progresses

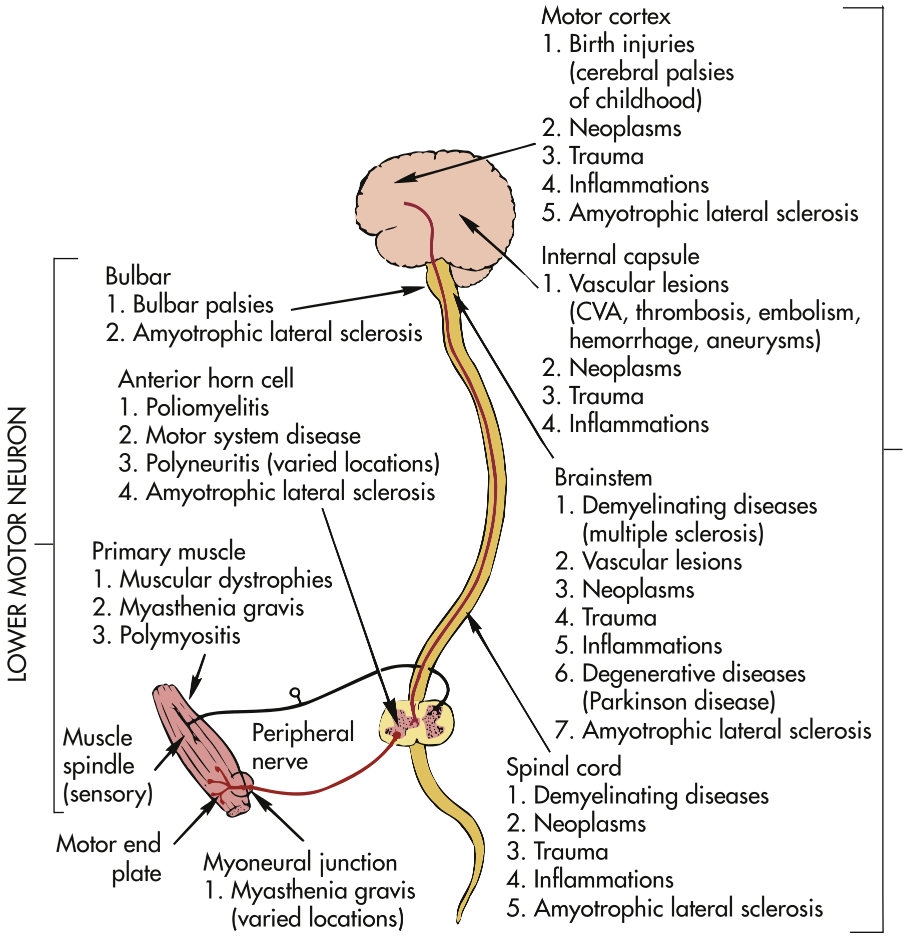

FIGURE 17-30 **Disturbances in Motor Function.** Disturbances in motor function are classified pathologically along upper and lower motor neuron structures. It should be noted that neoplasms occur at more than one site in an upper motor neuron *(above right)*. A few pathologic conditions, such as amyotrophic lateral sclerosis, involve upper and lower motor neuron structures. Other lesion sites include myoneural junctions and primary muscles, making it possible to classify conditions as neuromuscular and muscular, respectively. *CVA,* Cerebrovascular accident.

of the upper and lower extremities on one side. **Diplegia** is the paralysis of both upper and lower extremities as a result of cerebral hemisphere injuries. **Paraparesis** or **paraplegia** refers to weakness or paralysis, respectively, of the lower extremities. **Quadriparesis** or **quadriplegia** refers to paresis or paralysis of all four extremities. Paraparesis or paraplegia and quadriparesis or quadriplegia may be caused by dysfunction of the spinal cord. Upper cord damage results in quadriparesis or quadriplegia, and lower cord damage preserves upper extremity function and causes paraparesis or paraplegia (spinal cord injury is discussed in Chapter 18).

Upper motor neuron paresis/paralysis is associated with a pyramidal motor syndrome. The **pyramidal motor syndrome** is a series of motor dysfunctions that result from interruption of the pyramidal system (Figures 17-30 and 17-31). The

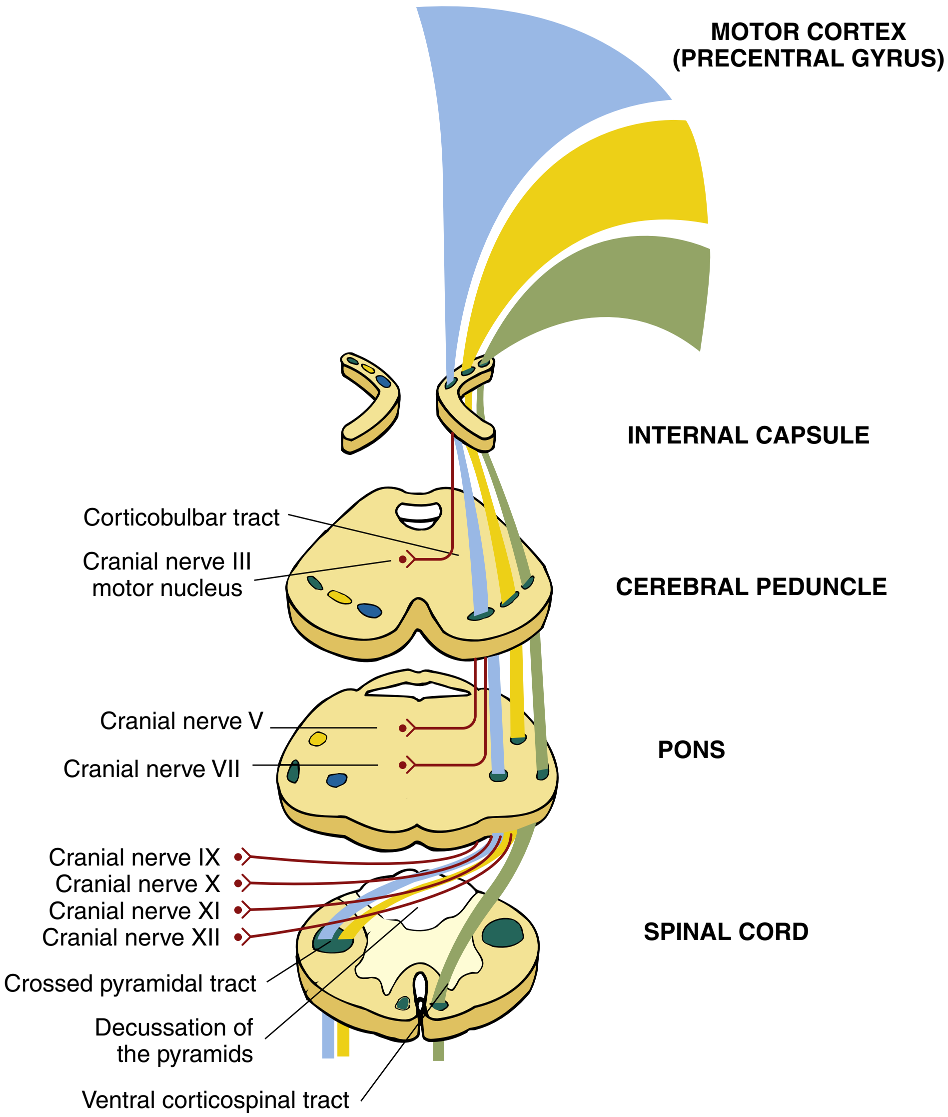

FIGURE 17-31 Structures of the Upper Motor Neuron, or Pyramidal, System. Pyramidal system fibers are shown to originate primarily in the cells in the precentral gyrus of the motor cortex; to converge at the internal capsule; to descend to form the central third of the cerebral peduncle; to descend farther through the pons, where small fibers supply cranial nerve motor nuclei along the way; to form pyramids at the medulla, where most of the fibers decussate; and then to continue to descend in the lateral column of the white matter of the spinal cord. A few fibers descend without crossing at the medulla level.

injury may be in the cerebral cortex, the subcortical white matter, the internal capsule, the brainstem, or the spinal cord. The clinical manifestations reflect overactivity and include excessive movements, such as clonus and spasms, occurring regularly as a result of loss of higher motor control. The distribution of clinical manifestations varies, depending on the location of the lesion, although certain features are constant. There is great variation depending on the suddenness of onset and the age of the individual.

Spinal shock is the complete cessation of spinal cord function below the lesion. When the pyramidal system is destroyed below the level of the pons, spinal shock occurs. It is characterized by complete flaccid paralysis, absence of reflexes, and marked disturbances of bowel and bladder function. The reasons for spinal shock are not fully understood, but a major factor is the sudden destruction of the efferent pathways. If destruction occurs more slowly, spinal shock may not develop (see Chapter 18).

If the pyramidal system is interrupted above the level of the pons, the hand and arm muscles are greatly affected. Paralysis rarely involves all the muscles on one side of the body, however, even when the hemiplegia results from complete damage to the internal capsule. Bilateral movements, such as those of the eye, jaw, and larynx, are affected only slightly, if at all. Predominantly the limbs are affected. Because of their bilateral control, trunk muscles are much less influenced.

Paralysis associated with a pyramidal motor syndrome rarely remains flaccid for a prolonged time. After a few days or weeks, a gradual return of spinal reflexes marks the end of spinal shock. Reflexes then become hyperactive, and muscle tone is increased significantly, particularly in antigravity muscles. Spasticity is common, although rigidity occasionally occurs. Most often,

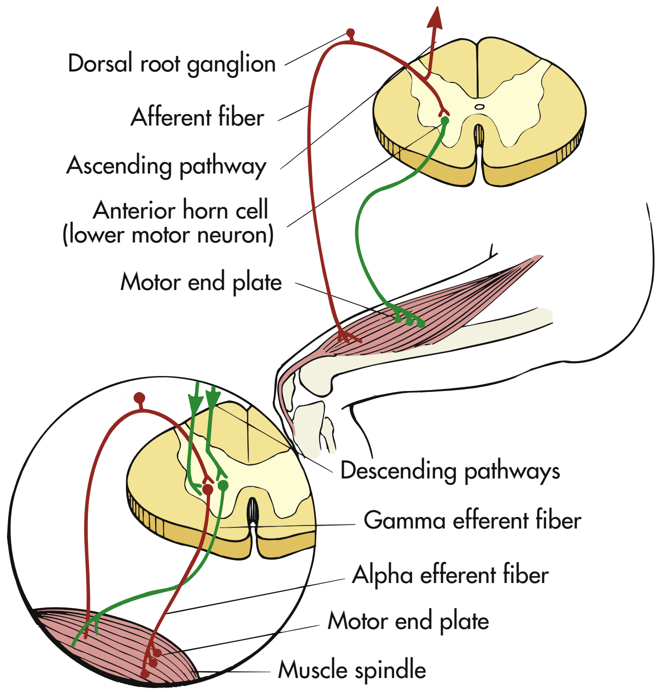

FIGURE 17-32 **Component Structure of a Lower Motor Neuron, Including Motor (Efferent) and Sensory (Afferent) Elements.** *Top,* Anterior horn cell (in anterior gray column of spinal cord and its axon), terminating in motor end plate as it innervates extrafusal muscle fibers in the quadriceps muscle. *Detailed enlargement:* Sensory and motor elements of the gamma loop system. The gamma efferent fiber is shown innervating the polar, or end, region of the muscle spindle (sensory receptor of skeletal muscle). Contraction of muscle spindle fibers stretches the central portion of the spindle and causes the afferent spindle fiber to transmit the impulse centrally to the cord. Muscle spindle afferent fibers in turn synapse on the anterior horn cell and are transmitted by way of gamma efferent fibers to skeletal (extrafusal) muscle, causing it to contract. Muscle spindle discharge is interrupted by active contraction of extrafusal muscle fibers.

passive range of motion causes the "clasp-knife" phenomenon, probably because of the activation of the two varieties of stretch receptors: (1) the muscle spindles and (2) the Golgi tendon organ. (Muscle function is discussed in Chapter 43.) With pyramidal motor syndrome, predominantly the flexors of the arms and the extensors of the legs are affected.

Lower Motor Neuron Syndromes. Lower (primary, alpha) motor neurons are the large motor neurons in the anterior (ventral) horn of the spinal cord and the motor nuclei of the brainstem. The axons from these nerve cell bodies bring nerve impulses from upper motor neurons to the skeletal muscles through the anterior spinal roots or cranial nerves (Figure 17-32). **Lower motor neuron syndromes** impair voluntary and involuntary movement. The degree of paralysis or paresis is proportional to the number of lower motor neurons affected. If only a portion of the motor units that supply a muscle is affected, only partial paralysis or paresis results. If all the motor units are affected, a complete paralysis results. Other clinical manifestations also are proportional to the degree of dysfunction, but the precise manifestations depend on the location of the dysfunction in the motor unit and in the CNS.

Small motor (gamma) neurons, which function to maintain muscle tone and protect the muscle from injury, also are necessary for normal motor movement. These neurons depend on input from the muscle spindle (arriving through an afferent limb rising to the cord). Dysfunction in this motor system impairs tone and reduces the tendon reflexes, causing hyporeflexia. The muscle is lax and soft, with a decrease in normal tone, or hypotonia, which impairs voluntary and involuntary motor movements. The muscles become susceptible to damage from hyperextensibility because the normal protective mechanisms that prevent muscle fiber injury are impaired. The degree of tone loss and the loss of tendon reflexes are proportional to the dysfunction in these reflex motor units.

Generally in a pathologic process the large and small motor neuron systems are equally affected. Therefore, the paresis and paralysis caused by a disorder of the lower motor neurons are called **flaccid paresis/flaccid paralysis** because the muscle has reduced or absent tone and is accompanied by hyporeflexia or **areflexia** (loss of tendon reflexes).

A few **gamma neuropathies** (small motor neuron disorders) affect only the gamma motor system of the spinal cord. A manifestation of these disorders is a marked reduction in the deep tendon reflexes, which are strikingly out of proportion to the degree of muscle weakness present.

Denervated muscles (i.e., muscles that have lost their nervous system input) undergo atrophy over weeks to months, mostly from disuse. Denervated muscles also demonstrate fasciculations, which are seen as muscle rippling or quivering under the skin. Occasionally denervated muscles cramp. Fibrillation (isolated contraction of a single muscle fiber) also may occur, although this manifestation is not visible clinically.

Motor Neuron Diseases

Motor neuron diseases result from progressive degeneration of upper or lower motor neurons in the spinal cord, brainstem, or cortex. Amyotrophic lateral sclerosis and paralytic poliomyelitis (now almost nonexistent because of the polio vaccine) are examples of these diseases.

Several pathologic processes may generate motor neuron diseases, which can be sporadic or inherited. A virally induced or postinfectious or postvaccination inflammatory process may injure or destroy anterior horn cells or cranial nerve cell bodies. Most of these inflammatory processes are mild and are followed by rapid cellular recovery (see What's New? Bell Palsy).

In motor neuron disease, muscle strength, muscle tone, and muscle bulk are affected in the muscles innervated by the involved motor neurons. The paresis and paralysis associated with anterior horn cell injury are segmental, but because each muscle is supplied by two or more roots, the segmental character of the weakness may be difficult to recognize. When cranial nerve motor nuclei are affected (these lack nerve roots and have only small rootlets near the point of exit from the brainstem), the distribution of the motor weakness follows that of the peripheral nerve. The weakness may involve distal muscles, proximal muscles, and the muscles of midline structures. Hypotonia and hyporeflexia or areflexia are present.

The atrophy associated with motor neuron disease is segmental when the anterior horn cells of the spinal cord are involved and follows the distribution of the peripheral nerve

WHAT'S NEW?

Bell Palsy

The etiology of Bell palsy (facial nerve palsy) remains unknown. There is usually an inflammatory reaction compressing the facial nerve in the fallopian canal, particularly in the narrowest labyrinthine segment, followed by demyelinating neural change. The most distressing symptoms are unilateral facial weakness and inability to smile or whistle. Bell palsy may be caused by reactivation of herpesviruses in cranial nerve VII (facial) geniculate ganglia. Herpes simplex type 1 has been detected in up to 78% of cases and herpes zoster in 30% of cases. Severe pain with facial palsy and a vesicular rash in the ear or mouth suggest herpes zoster infection. Ramsay Hunt syndrome (herpes zoster oticus) is rare but complete recovery is less than 50%. Recovery from Bell palsy is usually complete. Both disorders may be treated with antivirals, corticosteroids, or both. Treatment should be individualized according to severity of symptoms.

Data from Arbusow V et al: *J Med Virol* 82(11):1917–1920, 2010; Gronseth GS, Paduga R: *Neurology* 79(22):2209–2213, 2012; Linder TE, Abdelkafy W, Cavero-Vanek S: *Otol Neurotol* 31(2):319–327, 2010; Santos Rde F, Brasileiro BF: *Gen Dent* 59(4):266–271, 2011.

when the motor nuclei of the cranial nerves are affected. The atrophy may be in distal, proximal, or midline muscles. Fasciculations are particularly associated with primary motor neuron injury, and muscle cramps are common. Mild fatigue is a common complaint. If the pathologic process is limited to the primary motor neuron, no sensory changes are evident.

Because degenerative disorders can cause loss of nerve cells in the anterior horn or motor nuclei, the surviving cells are small and shrunken and filled with lipofuscin. Lost neurons are replaced by astrocytes. The roots or rootlets are thin, and the muscles show denervation and atrophy.

Several brainstem syndromes involve damage to one or more of the cranial nerve nuclei. These are called cranial nerve palsy (Table 17-24) and may be caused by vascular occlusion, tumor, aneurysm, tuberculosis, or hemorrhage.

The anterior horn cells and the motor nuclei of the cranial nerves may be affected secondarily in many severe pathologic processes that primarily involve the peripheral nerves. The condition may extend proximally to affect the nerve roots or rootlets and the motor neurons themselves, a process commonly seen, for example, in Guillain-Barré syndrome (see Chapter 18). If sufficient numbers of motor neurons are destroyed, permanent loss of motor function results because regeneration of the damaged axons requires a living neuronal cell body.

A group of degenerative disorders principally cause progressive motor cell atrophy. One of these is **progressive spinal muscular atrophy,** in which the degenerated anterior horn cells of the spinal cord are the affected motor neurons. This disorder occurs in adults and closely resembles the familial progressive muscular atrophies that occur in infants and children and that are considered inherited metabolic disorders (see Chapter 45). If the motor nuclei of the cranial nerves are affected instead of the anterior horn cells, the disorder is labeled **progressive bulbar palsy,** so named because the myelencephalon (medulla and upper cranial nerves) originally was called the *bulb* and a degenerative process causes a progressively more serious condition. When any lower motor neuron syndrome involves the cranial nerves that arise from the bulb (i.e., cranial nerves IX, X, and XII), the dysfunction is called a **bulbar palsy.**

The clinical manifestations of bulbar palsy include paresis or paralysis of the jaw, face, pharynx, and tongue musculature. Articulation is affected, especially articulation of the lingual *(r, n, l)*, labial *(b, m, p, f)*, dental *(d, t)*, and palatal *(k, g)* consonants. Modulation is impaired, making the voice rasping or nasal. Pharyngeal reflexes are diminished or lost. Palate and vocal cord movement during phonation is impaired, and chewing and swallowing are affected. The facial muscles are weak, and the face appears to droop. The jaw jerk reflex is decreased. Atrophy eventually becomes apparent, as do fasciculations. All these manifestations become progressively worse, leading to aspiration, malnutrition, possible dehydration, and an inability to communicate verbally.

TABLE 17-24 EXAMPLES OF CRANIAL NERVE PALSIES

TYPE OF NUCLEAR PALSY	CAUSES	ASSOCIATED CLINICAL MANIFESTATIONS
Ocular	Upper brainstem tumor Cerebrovascular disease in the vertebrobasilar system Aneurysm Intramedullary bleeding	Other cranial nerve signs Contralateral spastic hemiparesis/hemiplegia Contralateral hyperreflexia Contralateral extensor plantar reflex
Facial	Pontine tumor Cerebrovascular disease in the vertebrobasilar system	Paresis/paralysis of both upper and lower facial muscles for both voluntary movement and emotionally induced movement
Vagal	Intramedullary tumor	Ipsilateral loss of pain and temperature sensations of the face
	Cerebrovascular disease in the vertebrobasilar system	Contralateral spastic arm and leg paresis/hemiplegia Ipsilateral cerebellar signs
Hypoglossal	Intramedullary tumor	Contralateral loss of position sense and vibration in the arm and leg
	Cerebrovascular disease in the vertebrobasilar system	Contralateral spastic hemiparesis/hemiplegia

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) (sporadic motor system disease, sporadic motor neuron disease, motor neuron disease, Lou Gehrig disease) is a worldwide degenerative disorder diffusely involving lower and upper motor neurons. Progressive muscle weakness leads to respiratory failure and death, usually 2 to 5 years from symptom onset. There are no racial, ethnic, or socioeconomic boundaries. The prevalence rate is about 6 to 8 cases per 100,000. ALS may begin at any time from the fourth decade of life; its peak occurrence is in the early fifties. Male/female ratio is 1:4 to 2:5, equalizing at about age 70 years.[111]

The term *amyotrophic* (without muscle nutrition or progressive muscle wasting) refers to the predominant lower motor

neuron component of the syndrome. Lateral sclerosis, or scarring of the corticospinal tract in the lateral column of the spinal cord, refers to the upper motor neuron component of the syndrome. ALS differs from other motor neuron disorders in that upper and lower motor neurons are both involved.

Most cases of ALS are sporadic. In familial ALS (5% to 10% of cases), mutations have been found in 12 different genes with the superoxide dismutase *(SOD1)* gene on chromosome 21 the most common.[112] The defective *SOD1* gene leads to an autosomal dominant pattern with age-dependent penetrance and accounts for 15% to 20% of the cases of familial ALS. Mutated TAR DNA-binding protein 43 *(TDP-43)* is a major constituent of the ubiquitinated protein inclusions in ALS, and provides a possible link between the genetic mutation and cellular pathology of motor neuron injury.[113]

PATHOPHYSIOLOGY. The pathogenesis of ALS is not clear. Apoptotic factors, abnormal synthesis of filament units, defects in axonal transport, glutamate excitotoxicity, oxidative stress, growth factors, mitochondrial dysfunction, and neuroinflammation are under study for a possible contribution to the pathogenesis.[114] The principal pathologic feature of ALS is lower and upper motor neuron degeneration. The number of large motor neurons in the spinal cord, brainstem, and cerebral cortex (premotor and motor areas) is reduced, with ongoing degeneration in the remaining motor neurons. The nuclei of cranial nerves III, IV, and VI usually are not involved. Death of the motor neuron results in axonal degeneration and secondary demyelination with glial proliferation and sclerosis (scarring) along the corticospinal tract. Inclusion bodies containing the protein *ubiquitin* are found in surviving neurons. However, there also is widespread neural degeneration of nonmotor neurons in the spinal cord and motor cortices, as well as in the premotor, sensory, and temporal cortices.[115] Altered astrocytes and microglial functions are suspected to exist. Lower motor neuron degeneration denervates motor units. Adjacent, still-viable lower motor neurons attempt to compensate by a process of distal intramuscular sprouting, reinnervation, and enlargement of motor units.

CLINICAL MANIFESTATIONS. The initial onset of ALS can be subtle with cramping or weakness that affects a limb, incoordination, slurring of speech, and difficulty swallowing. Muscle weakness in ALS exhibits the following characteristics:

1. Paresis usually begins in a single muscle group.
2. Corresponding muscle groups are asymmetrically affected in a mottled distribution.
3. Gradual involvement occurs in all striated muscles, except extraocular and heart muscles, and progresses to paralysis with no remissions.
4. Flaccid and spastic paresis may coexist in a single muscle group; flaccid paresis may mask spasticity, which is usually mild.
5. Urethral and anal sphincter weakness is uncommon.

The lower motor neuron syndrome of flaccid paresis consists of weakness of individual muscles, progressing to paralysis, associated with hypotonia and primary muscle atrophy (i.e., atrophy caused by denervation). Hypotonia is manifested by (1) decreased resistance to passive movement, (2) hypoactive or absent deep tendon reflexes, (3) absent abdominal and cremasteric reflexes, and (4) absent Babinski sign. Primary atrophy is manifested by (1) severe, irreversible muscular wasting; (2) fasciculations; (3) metabolically related changes in the skin and appendages; and (4) specific electromyographic (EMG) findings. Fasciculations, along with fibrillations, are prominent features of ALS. Metabolic changes include: (1) thinning of the skin, (2) thickening of the nails, (3) loss of body hair, and (4) decreased perspiration.

The upper motor neuron syndrome of spastic paresis consists of weakness of movement patterns, progressing to paralysis, associated with spasticity and, in some cases, atrophy secondary to disuse. Spasticity is manifested by (1) clasp-knife phenomenon, evident with passive movement; (2) hyperactive deep tendon reflexes and clonus with severe spasticity; (3) absent abdominal and cremasteric reflexes; and (4) presence of Babinski sign. The coexistence of a dementia has been demonstrated to be higher than previously thought.

EVALUATION AND TREATMENT. The diagnosis of ALS is based predominantly on medical history and physical examination.[116] Nerve conduction studies are important to exclude other diagnoses. There must be upper and lower motor neuron symptoms not attributable to other causes. Riluzole (Rilutek), an antiglutamate, is the standard treatment for ALS and prolongs life for months. Treatment also is directed at relief of symptoms, prevention of complications, maintenance of maximal function, and maintenance of optimal quality of life. Special problems requiring preventive and symptomatic management are communication difficulties caused by dysmasesis and dysphonia, salivation problems with either thick saliva or excessively thin saliva (sialorrhea), and dyspnea caused by diaphragmatic and intercostal weakness. Ventilatory issues become prominent. Supportive and rehabilitation management is directed toward preventing complications of immobility. Psychologic support of the affected individual and the family is extremely important in this disorder. ALS is fatal from respiratory failure usually within 3 years of diagnosis. A small percentage of individuals live 5 to 10 years or longer.[117]

Extrapyramidal Motor Syndromes

Because the extrapyramidal system encompasses all the motor pathways except the pyramidal system, two types of motor dysfunction comprise the **extrapyramidal motor syndromes:** (1) the basal ganglia motor syndromes and (2) the cerebellar motor syndromes. Unlike pyramidal motor syndromes, both extrapyramidal motor syndromes result in movement or posture disturbance without significant paralysis, along with other distinctive symptoms (Table 17-25).

Basal ganglia motor syndromes are movement disorders that involve either a paucity or an excess of movements. Stress and nervous tension typically worsen the symptoms, whereas relaxation improves motor performance. Akinesia may occur despite normal strength. Involuntary movements, such as tremor, chorea, ballism, athetosis, and dystonia, also may occur and probably are caused by the loss of the normal modulating effects of the corpus striatum and other parts of the basal ganglia.

Basal ganglia motor syndromes also are characterized by alterations in muscle tone and posture. Rigidity, together with the cogwheel phenomenon, is present in all muscle groups but is most prominent in those that maintain flexed position. Postural

TABLE 17-25 PYRAMIDAL VS. EXTRAPYRAMIDAL MOTOR SYNDROMES

MANIFESTATIONS	PYRAMIDAL MOTOR SYNDROME	EXTRAPYRAMIDAL MOTOR SYNDROME
Unilateral movement	Paralysis of voluntary movement	Little or no paralysis of voluntary movement
Tendon reflexes	Increased tendon reflexes	Normal or slightly increased tendon reflexes
Babinski sign	Present	Absent
Involuntary movements	Absence of involuntary movements	Presence of tremor, chorea, athetosis, or dystonia
Muscle tone	Spasticity in muscles (e.g., clasp-knife phenomenon)	Plastic (equal throughout movement) rigidity or intermittent (generalized but predominantly in flexors of limbs and trunk) rigidity (cogwheel rigidity)
	Hypertonia present in flexors of arms and extensors of legs	Hypotonia, weakness and gait disturbance in cerebellar disease

abnormalities result from the loss of normal postural reflexes. Dysfunctional equilibrium results from the loss of postural stability.

Cerebellar motor syndromes involve the cerebellum and may result in (1) acute loss of muscle tone; (2) difficulty with coordination of voluntary movements (ataxia); (3) minor degrees of muscle weakness, tendency toward fatigue, and impairment of associated movements; and (4) disorders of equilibrium, posture, and gait. Cerebellar effects are chiefly ipsilateral (primarily affecting the same side of the body), so damage to the right cerebellum generally causes symptoms on the right side of the body. Predominant symptoms depend on the area of damage within the cerebellum. The four cerebellar syndromes are the rostral vermis, caudal vermis, cerebellar hemisphere, and pancerebellum[118] (Table 17-26).

Diagnosis of a cerebellar motor syndrome is based on the symptoms, but these may vary because of the individual's attempts at compensation. Further, the nervous system often can operate well despite destruction of parts of the cerebellum, although the mechanisms responsible for this retained function are not fully understood.

Alterations in Complex Motor Performance

The alterations in complex motor performance include disorders of posture (stance), disorders of gait, and disorders of expression.

Disorders of Posture (Stance)

An inequality of tone in muscle groups because of a loss of normal postural reflexes results in a posturing of limbs. Many reflex systems govern tone and posture, but the most important factor in posture control is the stretch reflex, in which stretching of extensor (antigravity) muscles causes increased extensor tone and inhibited flexor tone. Four types of disorders of posture are described: (1) dystonic posture, (2) decerebrate posture, (3) basal ganglion posture, and (4) senile posture. Equilibrium and balance are disrupted when postural disorders are present.

Dystonia is the maintenance of an abnormal posture through muscular contractions. When muscular contractions are sustained for several seconds, they are called **dystonic movements,** such as in choreoathetoid movements associated with high levels of L-dopa. When contractions last for longer periods, they are called **dystonic postures,** such as in torticollis. Dystonic postures may last for weeks, causing permanent fixed contractures. Dystonia has been associated with basal ganglia abnormality, but the exact pathophysiologic mechanisms are unknown (Box 17-6). One particularly relevant dystonic posture already discussed in this chapter is decorticate posture (striatal posture or upper motor neuron dysfunction posture), which may be unilateral or bilateral in occurrence. **Decorticate posture** (also referred to as **antigravity posture** or **hemiplegic posture**) is characterized by upper extremities that are flexed

TABLE 17-26 CEREBELLAR MOTOR SYNDROMES

ANATOMIC LOCATION OF DYSFUNCTION	CHARACTERISTICS
Rostral vermis (so-called *anterior lobe*)	Ataxia of stance and gait with varying degrees of instability of the trunk and ataxia of legs; anteroposterior body sway; presence of Romberg sign
Caudal vermis (including flocculonodular lobe)	Truncal, postural, and gait ataxia; omnidirectional body sway; Romberg negative; tendency to fall; saccadic slow pursuit, nystagmus; inability to suppress vestibulo-ocular reflex (doll's eyes)
Cerebellar hemisphere (neocerebellar syndrome)	Severe disturbance in ipsilateral limb movements; hypotonia in acute situation; dysmetria (extremity overshooting its target); decomposition of movement; kinetic tremor, past-pointing; deviation of gait; dysarthria
Pancerebellum	Ataxia of trunk and bilateral limbs; ataxia of gait and stance; dysarthria; oculomotor disturbance

Data from Timmann D, Diener HC: Coordination and ataxia. In Goetz GC, editor: *Textbook of clinical neurology,* St Louis, 2007, Saunders.

BOX 17-6 BOTULINUM TOXIN THERAPEUTIC EFFECTIVENESS IN DYSTONIA

Botulinum toxin, both A and B, is effective in relieving cervical dystonia (spasmodic torticollis) symptoms in adults and is the mainstay of modern treatment for focal dystonia. The effectiveness of other drugs (benodiazepines, gamma-aminobutyric acid [GABA] inhibitors, atypical anticonvulsants, dopaminergic agonists and antagonists), as well as the effect of surgical interventions or physical therapies, is not empirically known.

Data from Nijmeijer SW et al: *Parkinsonism Relat Disord* 18(6):731–736, 2012; Truong D: *Neurol Sc* 316(1-2):9–14, 2012; Colosimo C, Tiple D, Berardelli A: *Neurotox Res* 22(4):265–273, 2012.

at the elbows and held close to the body and by lower extremities that are externally rotated and extended (see Figure 17-6). Decorticate posture is believed to occur when the brainstem, which facilitates the antigravity position, is not inhibited by the motor function of the cerebral cortex. Upper motor neuron posture is more commonly described as the arm flexed at the elbow, with a wristdrop; the leg inadequately bent at the knee, with the hip excessively circumabducted; and the presence of a footdrop.

Decerebrate posture refers to increased tone in extensor muscles and trunk muscles, with active tonic neck reflexes. When the head is in a neutral position, all four limbs are rigidly extended (see Figure 17-6). The decerebrate posture is caused by severe injury to the brain and brainstem, resulting in overstimulation of the postural righting and vestibular reflexes.

Basal ganglion posture refers to a stooped, hyperflexed posture with a narrow-based, short-stepped gait. This posture abnormality results from the loss of normal postural reflexes and not from defects in proprioceptive, labyrinthine, or visual function. Dysfunctional equilibrium results from the loss of postural stability, and thus the individual is unable to make the appropriate postural adjustment to tilting or loss of balance and consequently falls. Dysfunctional righting is the inability to right oneself when changing from a lying or crouching to a standing position or when rolling from the supine to the lateral or prone position. Dysfunctional postural fixation is the involuntary flexion of the head and neck, causing the person difficulty in maintaining an upright trunk position while standing or walking. Basal ganglion dysfunction accounts for this posture.

Senile posture is characterized by an increasingly flexed posture similar to that caused by basal ganglion dysfunction. The posture is associated with frontal lobe dysfunction, but the primary pathophysiology is not well described.

Disorders of Gait

Four predominant types of gait disorder are: (1) upper motor neuron dysfunction gait, (2) cerebellar (ataxic) gait, (3) basal ganglion gait, and (4) senile (frontal lobe, pseudoparkinsonian) gait. As with posture, equilibrium and balance are affected with gait disturbances.

Several upper motor neuron gaits exist. In the presence of mild upper motor neuron dysfunction, a footdrop may appear only with fatigue. The individual may complain of hip and leg pain. A **spastic gait,** which is associated with unilateral injury, is manifested by a shuffling gait with the leg extended and held stiff, causing a scraping over the floor surface. An impaired leg swing around the body rather than an appropriate lifting and placing of the leg is noted. The foot may drag on the ground, and the person tends to fall to the affected side. A **scissors gait** is associated with bilateral injury and spasticity. The legs are abducted, causing them to touch each other. As the person walks, the legs are still swung around the body but then cross in front of each other because of adduction. Injury to the pyramidal system accounts for these gaits.

A **cerebellar gait** manifests as a wide-based gait with the feet apart and often turned outward or inward for greater stability. The pelvis is held stiff, and it seems to be independent of the trunk. The individual staggers when walking. Cerebellar dysfunction accounts for this particular gait.

A **basal ganglion gait** and a **senile gait** are both broad-based gaits. The person walks with small steps and a decreased arm swing. The head and body are flexed and the arms are semiflexed and abducted, whereas the legs are flexed and rigid in more advanced states. Basal ganglion and frontal lobe dysfunction, respectively, account for these two gaits.

Disorders of Expression

Disorders of expression involve the motor aspects of communication and include (1) hypermimesis, (2) hypomimesis, and (3) dyspraxias and apraxias. **Hypermimesis** is a disinhibition phenomenon that most commonly manifests as pathologic laughter or crying. Pathologic laughter is associated with right hemisphere injury, and pathologic crying is associated with left hemisphere injury. The exact pathophysiology is not known. **Hypomimesis** manifests as aprosody, or the loss of voice modulation (pitch, speed, emphasis, emotion). Receptive aprosody involves an inability to *understand* emotion in speech and facial expression, whereas expressive aprosody involves the inability to *express* emotion in speech and facial expression. Aprosody is associated with right hemisphere damage.

Dyspraxia is the partial inability and **apraxia** is the complete inability to perform purposeful or skilled motor acts in the absence of paralysis, sensory loss, abnormal posture and tone, abnormal involuntary movement, incoordination, or inattentiveness. These are disorders of learned skilled movements.[119] Dyspraxia and apraxia are associated with left hemisphere vascular disorders, trauma, tumor, degenerative disorders, infections, and metabolic disorders. The medial premotor cortex, including the supplementary motor area (SMA), appears to play a role in skilled movements as does the convexity premotor areas[119] (Table 17-27).

True dyspraxias occur when the connecting pathways between the left and right cortical areas are interrupted, causing language-motor and motor representation disconnections between the hemispheres. Dyspraxias may result from any pathologic process that disrupts the cortical areas necessary for the conceptualization and execution of a complex motor act or the communication pathways within the left hemisphere or between the hemispheres.

TABLE 17-27 DYSPRAXIAS AND APRAXIAS

TYPES	DESCRIPTION	LOCATION
Ideomotor apraxia	Impairment in selecting, sequencing, and spatial orientation of movements involved in gestures (spatial and temporal production errors)	Left parietal cortex (angular gyrus) or supramarginal gyrus
Posterior form	Difficulty performing in response to command and imitation; cannot discriminate well between poorly performed and well-performed acts	Left parietal cortex (angular gyrus or supramarginal gyrus) lesion
Anterior form	Performs poorly to command and imitation but comprehends and discriminates pantomime	Lesions anterior to the supramarginal gyrus, which disconnects visual kinesthetic motor engrams from premotor and motor areas
Conduction apraxia	Greater impairment in performance when imitating movements than when pantomiming to command; comprehends pantomime and gesture but cannot perform the movements	Location unknown at this time
Disassociation apraxia	Inability to gesture normally to command and required verbal mediation; has good performance with imitation and actual tools and objects	Callosal abnormalities but not all locations known
Ideational apraxia	Inability to carry out an ideational plan or a series of acts in the proper sequence	Location unclear at this time
Conceptual apraxia	Cannot recall type of action associated with specific tools, utensils, or objects (content and tool selection errors; may be unable to recall which tool is associated with a specific object or may have impaired mechanical knowledge)	Bilateral frontal and parietal dysfunction

SUMMARY REVIEW

Alterations in Cognitive Systems

1. Full consciousness is an awareness of oneself and the environment and includes an ability to respond to external stimuli with a wide variety of responses.
2. Consciousness has two components: arousal (state of awakeness) and awareness (content of thought).
3. Alterations in level of arousal may be caused by structural, metabolic, or psychogenic disorders.
4. Levels of consciousness can diminish in stages from alert and oriented to confusion and coma.
5. An alteration in breathing pattern and level of coma reflects the level of hemispheric and brainstem dysfunction.
6. Pupillary changes reflect changes in level of brainstem function, drug action, and response to hypoxia and ischemia.
7. Abnormal eye movements, including nystagmus and divergent gaze, reflect alterations in brainstem function.
8. Level of brain function manifests by changes in generalized motor responses or the presence of no responses.
9. Loss of cortical inhibition associated with decreased consciousness includes abnormal flexor and extensor movements.
10. Brain death represents irreversible total brain damage including an inability to maintain cardiac, respiratory, and other vital functions.
11. Arousal returns in the vegetative state and minimally conscious state, but content of thought is absent or markedly reduced, respectively.
12. Alterations in awareness encompass all cognitive functions including awareness, selective attention, and memory.
13. With a deficit in selective attention, mediated by the brainstem, the parietal lobe structures, and the pulvinar nucleus of the thalamus, the individual cannot focus on selective stimuli and thus neglects those stimuli, causing a neglect syndrome.
14. In dysmnesia and amnesia, some memories are not retrieved and new memories cannot be stored.
15. Frontal areas mediate vigilance, detection, and working memory. With a vigilance deficit, the person cannot maintain search and scanning activities. With a detection deficit, the person is unmotivated and unable to use feedback.
16. Some specific disorders of awareness (content of thought) are data processing deficits: agnosias, dysphasias, acute confusional states, and dementias, including AD.
17. Agnosias are a defect of recognition and may be tactile, visual, or auditory. They are caused by dysfunction in the primary sensory area or the interpretive areas of the cerebral cortex.
18. Dysphasia is an impairment of comprehension or production of language. Dysphasia may be expressive or sensory.
19. Aphasia is loss of language comprehension or production.
20. Wernicke dysphasia is a disturbance in understanding all language—verbal and reading comprehension.
21. Conductive dysphasias result from disruption of temporal lobe fibers, with a failure to repeat words but an ability to initiate speech, writing, and reading aloud.
22. Anomic dysphasia is an inability to name objects, people, or qualities.
23. Transcortical dysphasias involve an ability to repeat and recite.
24. Broca aphasia is an expressive dysphasia of speech and writing but with retention of comprehension.
25. Global aphasia involves anterior and posterior speech areas, with expressive and receptive aphasia.
26. Acute confusional states are characterized chiefly by defects in attention and coherence of thoughts and actions and, in the case of delirium, an intense autonomic nervous system hyperactivity.
27. Dementia is impairment of intellectual function, memory, and language with alteration in behavior and can be caused by trauma, vascular disease, infection, and progressive neurodegeneration.

SUMMARY REVIEW—cont'd

28. AD is the most common chronic, irreversible dementia.
29. Seizures represent abnormal, excessive hypersynchronous discharges of cerebral neurons with transient alterations in brain function. Seizures may be generalized or focal. There are three categories of epileptic syndrome: location-related, generalized, and cryptogenic (undetermined).

Alterations in Cerebral Hemodynamics

1. Cerebral oxygenation is a critical management issue.
2. Cerebral perfusion pressure determines cerebral blood flow.
3. An injured brain may experience cerebral oligemia, normal cerebral blood flow but with increased intracranial pressure, or cerebral hyperemia.
4. Increased intracranial pressure may result from edema, excess CSF, hemorrhage, or tumor growth. When intracranial pressure approaches arterial pressure, hypoxia and hypercapnia produce brain damage.
5. Cerebral edema is an increase in the fluid content of the brain resulting from infection, hemorrhage, tumor, ischemia, infarct, or hypoxia.
6. The shifting or herniation of brain tissue from one compartment to another disrupts the blood flow of both compartments and damages brain tissue.
7. Supratentorial herniation involves temporal lobe and hippocampal gyrus shifting from the middle fossa to the posterior fossa; transtentorial herniation with a downward shift of the diencephalon through the tentorial notch; and shifting of the cingulate gyrus herniation under the falx.
8. The most common infratentorial herniation is a shift of the cerebellar tonsils through the foramen magnum.
9. Hydrocephalus comprises a variety of disorders characterized by an excess of fluid within the cranial vault, subarachnoid space, or both. Hydrocephalus occurs because of interference with CSF flow caused by increased fluid production or obstruction within the ventricular system or by defective reabsorption of the fluid.

Alterations in Neuromotor Function

1. Motor dysfunction may be characterized as alterations of motor tone, movement, and complex motor performance.
2. Hypotonia and hypertonia are the main categories of altered muscle tone.
3. Four types of hypertonia exist: spasticity, gegenhalten, dystonia, and rigidity.
4. Alteration in muscle movement includes hyperkinesia (excessive movement), hypokinesia (slow movement), and dyskinesias (abnormal voluntary movement).
5. Included in the category of hyperkinesia are chorea, athetosis, ballism, akathisia, tremor, and myoclonus.
6. HD (chorea) is a rare hereditary irreversible disease involving the basal ganglia and frontal cerebral cortex with a depletion of neurons that secrete GABA (an inhibitory neurotransmitter) that causes involuntary, fragmentary movements accompanied by emotional lability and progressive dementia.
7. Types of hypokinesia include akinesia, bradykinesia, and loss of associated movements.
8. PD is a common degenerative disorder of the basal ganglia (corpus striatum) involving degeneration of the dopamine-secreting nigrostriatal pathway resulting in overactivity by the subthalamic nucleus, causing tremor, rigidity, and bradykinesia. Involvement of the limbic system causes emotional lability. Progressive dementia may be associated with an advanced stage of the disease.
9. Two subtypes of paresis and paralysis are described: upper motor neuron and lower motor neuron.
10. An upper motor neuron syndrome is characterized by spastic paresis or paralysis, hypertonia, and hyperreflexia.
11. Interruption of the pyramidal tract below the pons results in spinal shock.
12. Lower motor neuron syndromes manifest with impaired voluntary and involuntary movements and flaccid paralysis.
13. Partial paralysis occurs with only partial loss of alpha motor neurons, and total paralysis is complete loss of alpha motor neurons. Loss of gamma motor neurons impairs muscle tone and decreases deep tendon reflexes.
14. Motor neuron diseases result from progressive degeneration of upper or lower motor neurons in the spinal cord, brainstem, or cortex.
15. Nuclear palsies involve damage to the cranial nerve nuclei.
16. Bulbar palsies involve cranial nerves IX, X, and XII.
17. ALS is a motor neuron disease. The pathogenesis of ALS is not fully known; however, lower and upper motor neuron degeneration occurs as well as degeneration of the nonmotor neurons in the cortices and spinal cord. Clinical manifestations of ALS may include weakness in all muscles that may begin in a single muscle group, slurring of speech, and difficulty swallowing. Flaccid paresis progressing to paralysis is characteristic of the lower motor neuron syndrome.
18. Extrapyramidal motor syndromes include basal ganglia and cerebellar motor syndromes.
19. Basal ganglia disorders manifest with alterations in muscle tone and posture, including rigidity, involuntary movements, and loss of postural reflexes.
20. Cerebellar motor syndromes result in loss of muscle tone, difficulty with coordination, and disorders of equilibrium and gait.
21. Alterations in complex motor performance include disorders of posture (stance), disorders of gait, and disorders of expression.
22. Disorders of posture include dystonic posture, decerebrate posture, basal ganglion posture, and senile posture.
23. Disorders of gait include upper motor neuron gaits, cerebellar gait, basal ganglion gait, and senile gait.
24. Disorders of expression include hypermimesis, hypomimesis, and dyspraxia or apraxia.
25. Dyspraxia is the partial inability and apraxia is the complete inability to perform purposeful or skilled motor acts.

CHAPTER OUTLINE

Alterations in central nervous system (CNS) structure and function are caused by traumatic injury, vascular disorders, tumor growth, infectious and inflammatory processes, metabolic derangements (including those arising from nutritional deficiencies and drugs/chemicals), and degenerative processes. Alterations in peripheral nervous system function involve the nerve roots (radiculopathies), a nerve plexus, the nerves themselves (neuropathies), or the neuromuscular junction.

CENTRAL NERVOUS SYSTEM DISORDERS

Traumatic Brain and Spinal Cord Injury

Traumatic Brain Injury

Traumatic brain injury (TBI) is an alteration in brain function or other evidence of brain pathology caused by an external force.[1] An estimated 1.7 million people sustain TBI in the United States each year with approximately 53,000 deaths. Those at highest risk for TBI are children 4 years and younger, adolescents 15 to 19 years, and adults 65 years and older. Males have the highest incidence in every age group.[2] TBI is highest among American Indian/Alaska Natives and blacks and in lower- and median-income families. TBIs are caused by falls (35%), motor vehicle–related injuries (17%), and a strike or blow to the head from or against an object (e.g., workplace or sports-related injuries [16.5%], assaults [10%], and other and unknown causes [21%]).[3]

TBI survival is improving because of advancements in safety measures (e.g., passive seat restraints, air bags, protective head gear), reduced transport time to hospitals or trauma centers, and improved on-scene and follow-up medical management. Prevention and management of secondary and tertiary brain injuries also have improved outcomes. TBI is capable of producing physical, intellectual, emotional, social, and vocational changes.

TABLE 18-1 SEVERITY OF BLUNT TRAUMA, TRAUMA STATE INDUCED, AND ONSET AND PERSISTENCE OF CLINICAL MANIFESTATIONS

SEVERITY OF TRAUMA	TRAUMA STATE INDUCED: FOCAL INJURY	TRAUMA STATE INDUCED: DIFFUSE AXONAL INJURY (DAI)	ONSET OF CLINICAL MANIFESTATIONS	PERSISTENCE OF DAI CLINICAL MANIFESTATIONS
Mild blunt trauma		Mild concussion	Immediate	Hours to days
Moderate blunt trauma		Classic cerebral concussion	Immediate	Up to 6 months or longer
	Paraplegia (associated with injury to top of head)		Immediate	
	Blindness (associated with occipital injury)		Immediate	
	Delayed development of unresponsiveness (vasomotor or vasovagal syncopal episode)		Delayed	
Severe blunt trauma		Mild DAI	Immediate	Recovery in days to weeks
		Moderate DAI	Immediate	Residual manifestation
		Severe DAI	Immediate	Permanent severe disability
	Acute epidural hemorrhage		Immediate to delayed (2-3 hours)	
	Acute contusional swelling		Delayed onset (few hours after injury)	
	Acute subdural hematoma		Delayed onset (few hours to 1 week after injury)	
	*Subacute subdural hematoma**		Delayed onset (1 to few weeks)	
	Subdural hygroma (fluid accumulation)		Delayed onset	
	*Traumatic cerebral hemorrhage**		Delayed onset (as late as 1 week after injury)	

*May be seen after moderate head injury, especially in elderly people.

Traumatic brain injury can be caused by closed (blunt) trauma and open (penetrating) trauma. **Closed (blunt) trauma** is more common and involves either the head striking a hard surface or a rapidly moving object striking the head. The dura mater remains intact, and brain tissues are not exposed to the environment. Most closed (blunt) trauma is mild (75% to 90%) and causes mild concussion and classic cerebral concussion (see pp. 587-588 and Table 18-1). **Open (penetrating) trauma** occurs when a break in (penetration of) the dura mater results in exposure of the cranial contents to the environment.

The Glasgow Coma Scale (GCS) is used to assess severity of injury.[4] The hallmark of a severe TBI is loss of consciousness for 6 hours or more. TBI classifications using the GCS are: (1) mild TBI with GCS score of 13 to 15, associated with mild concussion; (2) moderate TBI with GCS score of 9 to 12, associated with structural injury such as hemorrhage or contusion; and (3) severe TBI with GCS score of 3 to 8, associated with cognitive and/or physical disability or death. Age and admission GCS score are important diagnostic factors in TBI.[5] Mild TBI is characterized by five features: a GCS score between 13 and 15, a brief period of unconsciousness or dazed consciousness, posttraumatic amnesia, negative neuroimaging studies, and recovery within weeks to months without sequelae or the need for specific medical intervention.

Three mechanisms produce brain damage: primary, secondary, and tertiary injury. Primary injury is caused by the impact and involves neural injury, primary glial injury, vascular responses, and shearing and rotational forces. Secondary injury is an indirect consequence of the primary injury and includes a cascade of cellular and molecular brain events (Figure 18-1). Tertiary injury can develop days or months later as a consequence of systemic complications, such as pneumonia, fever, infections, and immobility, which contribute to further brain injury or delays in repair.

Primary Brain Injury. Primary brain injuries can be classified as focal, affecting one area of the brain, or diffuse (diffuse axonal injury [DAI]), involving more than one area of the brain (see Table 18-1). Both types of injury can be associated with the same initiating event and can occur with brain trauma or stroke syndromes (see Figure 18-1). Focal brain injury accounts for more than two thirds of head injury deaths; DAI accounts for less than one third. However, more severely disabled survivors, including those in an unresponsive state or reduced level of consciousness, have DAI.

Focal Brain Injury. **Focal brain injuries** are specific, grossly observable brain lesions that occur in a precise location (e.g., cortical contusions, epidural hemorrhage, subdural hematoma, intracerebral hematoma). Focal brain injuries can occur

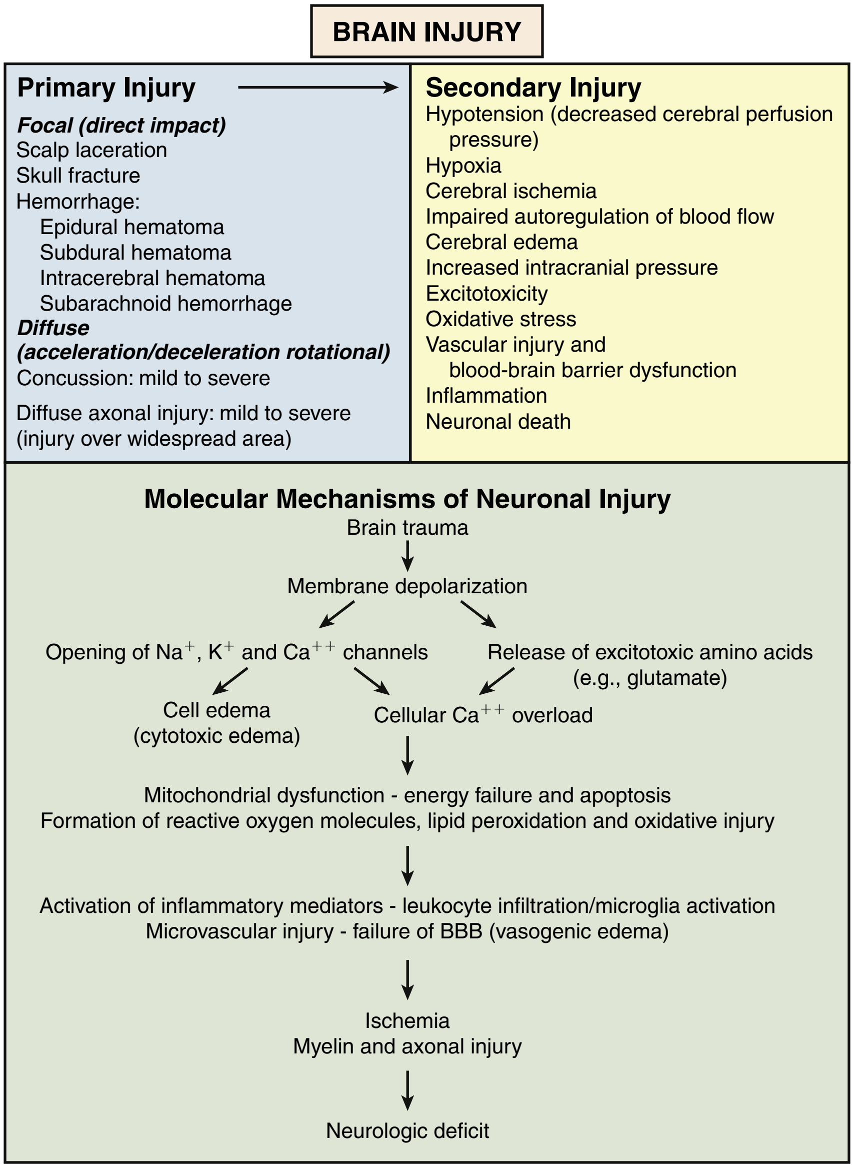

FIGURE 18-1 Pathophysiology of Brain Injury. *BBB,* Blood-brain barrier.

with both blunt and open brain trauma and can be associated with skull fractures.

Focal brain injury results from compression of the skull at the point of impact and rebound effects. The focal injury may be a **coup injury** (directly below the point of impact) or **contrecoup** (on the pole opposite the site of impact) (Figure 18-2). Objects (e.g., baseball bat, weapon) striking the front of the head usually produce only coup injuries (contusions and fractures) because the inner skull in the occipital area is smooth. Objects striking the back of the head usually result in both coup and contrecoup injuries because of the irregularity of the inner surface of the frontal bones. Objects striking the side of the head may produce coup or contrecoup injuries. The force of impact (translational acceleration) typically produces localized brain contusions. Injury to the vault, other vessels, and supporting structures can produce epidural hemorrhage and subdural and intracerebral hematomas.

Contusions (blood leaking from an injured vessel) (Figure 18-3) are found most commonly in the frontal lobes, particularly at the poles and along the inferior orbital surfaces; in the temporal lobes, especially at the anterior poles and along the inferior surface; and at the frontotemporal junction. Contusion severity varies with the amount of impact energy transmitted by the skull to underlying brain tissue. The smaller the area of impact, the greater the severity of injury because the force is concentrated into a smaller area. Brain edema forms around and in damaged neural tissues, contributing to increasing intracranial pressure (ICP). Within the contused areas are infarction and necrosis, multiple hemorrhages, and edema. The tissue has a pulpy quality. The maximum effects of injury related to contusion, bleeding, and edema peak 18 to 36 hours after severe head injury.

Contusions cause changes in attention, memory, executive attentional function (motivation, goal selection or formation, planning, self-monitoring, and use of feedback), affect, emotion, and behavior. Less commonly, contusions occur in the parietal and occipital lobes. Focal cerebral contusions are

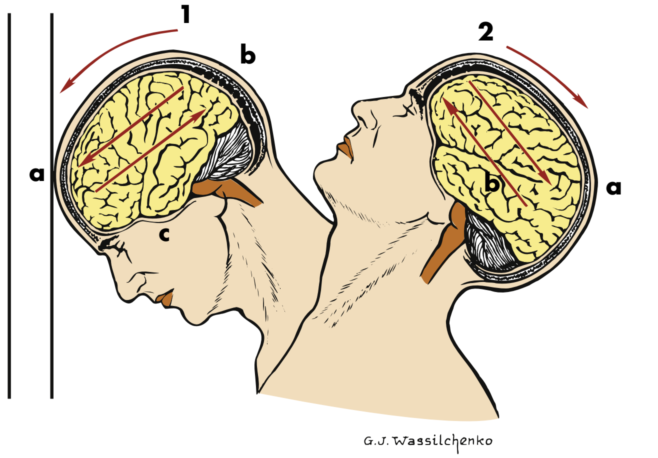

FIGURE 18-2 Coup and Contrecoup Brain Injury Following Blunt Trauma. **1,** Coup injury: impact against object; ***a,*** site of impact and direct trauma to brain; ***b,*** shearing of subdural veins; ***c,*** trauma to base of brain. **2,** Contrecoup injury: impact within skull; ***a,*** site of impact from brain hitting opposite side of skull; ***b,*** shearing forces through brain. These injuries occur in one continuous motion—the head strikes the wall (coup) and then rebounds (contrecoup). (Modified from Rudy EB: *Advanced neurological and neurosurgical nursing,* St Louis, 1984, Mosby.)

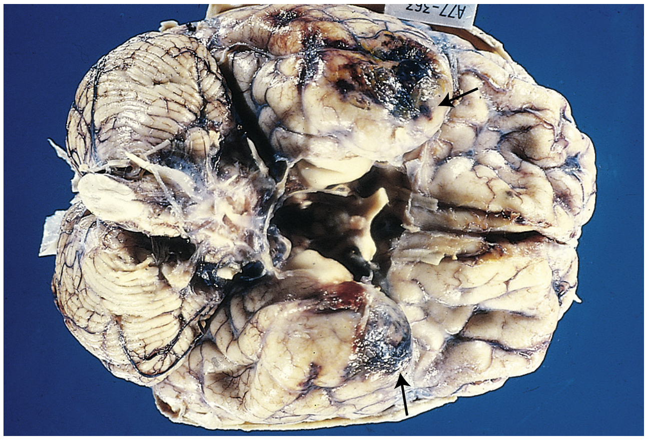

FIGURE 18-3 Cerebral Contusions. The temporal poles are discolored by areas of hemorrhage *(arrows).* Such lesions represent "bruises" on the surface of the brain caused by violent contact between the delicate brain parenchyma and the hard inner surface of the skull. (From Kumar V, Cotran RS, Robbins SL: *Robbins basic pathology,* ed 7, Philadelphia, 2003, Saunders.)

superficial, involving just the gyri. Hemorrhagic contusions may coalesce into a large, confluent intracranial hematoma.

The clinical manifestations of a *contusion* may include immediate loss of consciousness (generally accepted to last no longer than 5 minutes); loss of reflexes, which results in the individual falling to the ground; transient cessation of respiration; brief period of bradycardia; and decrease in blood pressure (lasting 30 seconds to a few minutes). A momentary increase in cerebrospinal fluid (CSF) pressure and changes on electrocardiogram (ECG) and electroencephalogram (EEG) recordings have been demonstrated to occur on impact. Vital signs may stabilize to normal values in a few seconds. Reflexes return next and the person begins to regain consciousness. Returning to being fully awake and alert can vary from minutes to days. Regaining

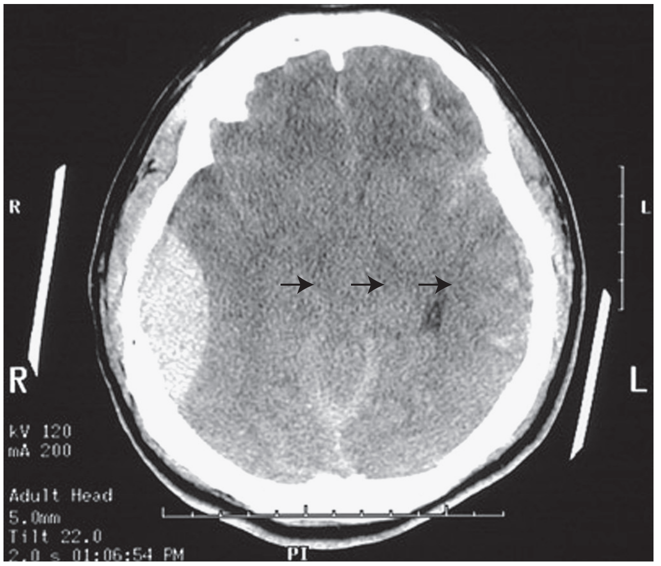

FIGURE 18-4 Epidural Hematoma, CT Image. Note the large right epidural hematoma with a lens-shaped outline as the smooth dura becomes indented against the underlying cortex on the right lateral aspect of the cerebrum. The epidural hematoma is confined within an area bounded by cranial sutures where the dura is firmly adherent to the skull. Note the mass effect with effacement of the lateral ventricles and the shift of midline to the left *(arrows).* In this case the individual fell from a height and struck the right side of his head, severing the middle meningeal artery. This epidural hematoma collected within hours. *CT,* Computed tomography. (From Klatt EC: *Robbins and Cotran atlas of pathology,* Philadelphia, 2006, Saunders.)

a full level of consciousness may be extremely slow and residual deficits may persist. In some persons, full level of consciousness never returns.

Evaluation is based on history, level of consciousness using the Glasgow Coma Scale, imaging studies (e.g., computed tomography [CT], magnetic resonance imaging [MRI], and positron-emission tomography [PET]), and assessment of vital parameters (e.g., ICP and EEG). Large contusions and lacerations with hemorrhage may be excised surgically.[6] Otherwise, treatment is directed at controlling ICP and managing symptoms.

Extradural hematomas (bleeding between the dura mater and the skull [i.e., epidural hematomas or epidural hemorrhages]) represent 1% to 2% of major head injuries and occur in all age groups, but most commonly in those 20 to 40 years of age. Extradural hematomas are caused most commonly by motor vehicle accidents (MVAs) and occasionally by falls and sporting accidents. A temporal fracture causes 90% of temporal lobe extradural hematomas. Direct frontal lobe trauma is associated with frontal extradural hematomas. Posterior extradural hematomas are associated with a fracture across the transverse sinus from an occipital blow.

An artery is the source of bleeding in 85% of extradural hematomas (Figure 18-4); 15% result from injury to the meningeal vein or dural sinus. Ninety percent of individuals also have a skull fracture. The temporal fossa is the most common site of extradural hematoma caused by injury to the middle meningeal artery or vein. The resulting shift of the temporal lobe medially precipitates uncal and hippocampal gyrus herniation

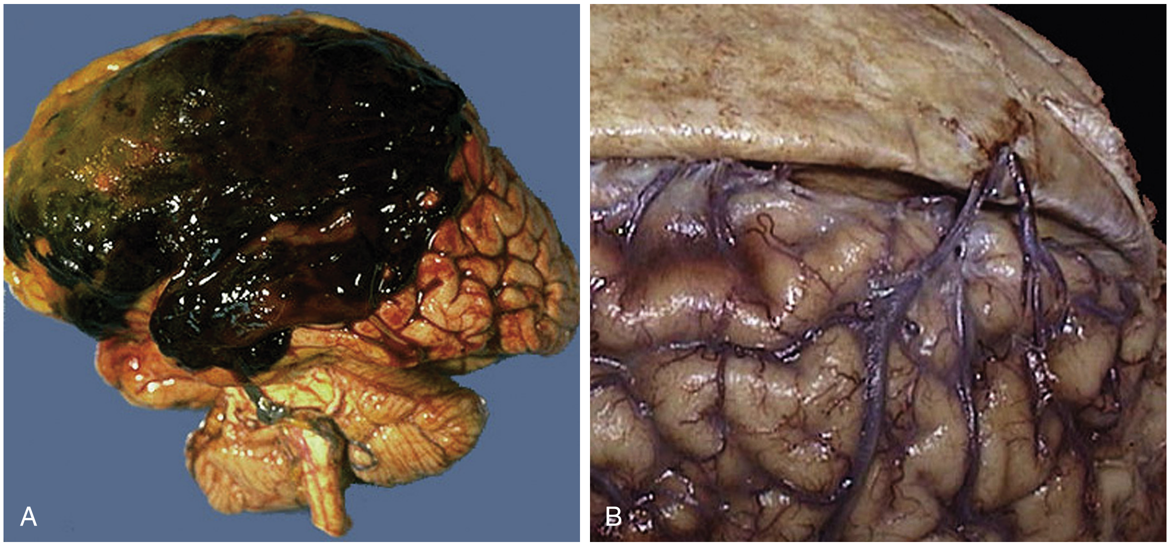

FIGURE 18-5 Subdural Hematoma, Gross, and Bridging Veins, Gross. A large subdural hematoma **(A)** is seen in the frontoparietal region. A subdural hematoma forms after head trauma that severs the bridging veins from dura to brain, shown in the right panel **(B),** where the dura has been reflected to reveal the normal appearance of the bridging veins that extend across to the superior aspect of the cerebral hemispheres. Older adults and the very young are at greater risk because their cerebral veins are more vulnerable to injury. Because the bleeding is venous, blood collects over hours to weeks, with variable onset of symptoms. Because the blood collects beneath the dura, a subdural hematoma can be seen to cross the region of cranial sutures. (From Klatt EC: *Robbins and Cotran atlas of pathology,* Philadelphia, 2006, Saunders.)

through the tentorial notch. Extradural hemorrhages are found occasionally in the subfrontal area (especially in the young and older adult populations), caused by injury to the anterior meningeal artery or a venous sinus, and in the occipital-suboccipital area, which results in herniation of the posterior fossa contents through the foramen magnum. CT and MRI show a lens-shaped mass over the surface of the cortex.

Individuals with classic *temporal extradural hematomas* (i.e., over the temporal lobe) experience loss of consciousness at the time of injury, followed by a lucid period that lasts from a few hours to a few days in one third of individuals (if bleeding from a vein). As the hematoma accumulates, a headache of increasing severity, vomiting, drowsiness, confusion, seizure, and hemiparesis may develop. Level of consciousness may dwindle rapidly as temporal lobe herniation begins. Clinical manifestations of temporal lobe herniation also include ipsilateral pupillary dilation and contralateral hemiparesis.

The diagnosis of an extradural hematoma is usually made by CT or MRI. In some instances, diagnosis is made by history and clinical findings, because time for a CT or MRI is not available. The prognosis is usually good if intervention is initiated before bilateral dilation of the pupils. Surgical therapy is evacuation of the hematoma through burr holes, followed by ligation of the bleeding vessel or vessels. Extradural hematomas are almost always medical emergencies.

Subdural hematomas arise in 10% to 20% of TBIs. MVAs are the most common cause of subdural hematomas; 50% of subdural hematomas are associated with skull fractures. Falls, especially in older adults or in those with long-term alcohol abuse, are associated with chronic subdural hematomas.

Acute subdural hematomas rapidly develop (within 48 hours) and usually are located at the top of the skull (the cerebral convexities). On CT they appear as a high-density mass. *Bilateral hematomas* occur in 15% to 20% of persons. *Subacute subdural hematomas* develop more slowly, often over 48 hours to 2 weeks. On CT they appear as a mixed-density mass. Chronic subdural hematomas (commonly found in older adults and those who abuse alcohol and have some degree of brain atrophy with a subsequent increase in the extradural space) develop over weeks to months. Tearing of the bridging veins is the major cause of rapidly developing and subacutely developing subdural hematomas, although torn cortical veins or venous sinuses and contused tissue may be the source. These subdural hematomas act as expanding masses, giving rise to increased ICP that eventually compresses the bleeding vessels (Figures 18-5 and 18-6). The displacement of brain tissue can result in a herniation syndrome.

In *acute, rapidly developing subdural hematomas* the expanding clots directly compress the brain, giving rise to the clinical manifestations. As the ICP rises the bleeding veins are compressed and thus bleeding is self-limiting, although cerebral compression and displacement of brain tissue can cause temporal lobe herniation.

An *acute subdural hematoma* classically begins with headache, drowsiness, restlessness or agitation, slowed cognition, and confusion. These symptoms worsen over time and progress to loss of consciousness, respiratory pattern changes, and pupillary dilation (the symptoms of temporal lobe herniation). These manifestations are more pronounced than focal manifestations such as dysphasia, dyspraxia, or hemiparesis. Other clinical manifestations may include homonymous hemianopsia (defective vision in either the right or the left field), dysconjugate gaze, and gaze palsies.

The pathogenesis of a *chronic subdural hematoma* is different. The existing subdural space gradually fills with blood.

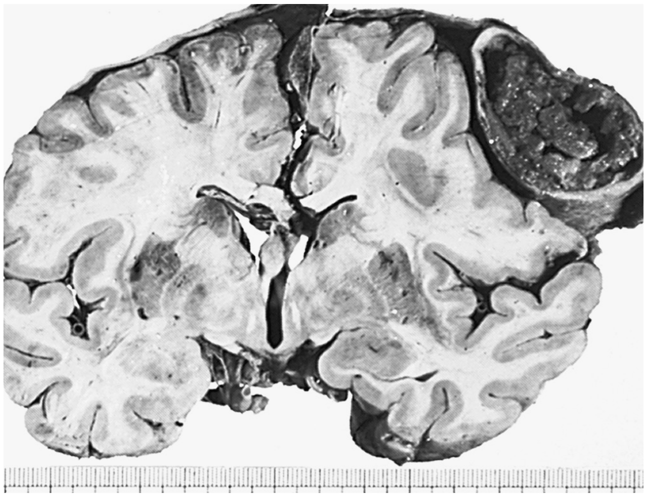

FIGURE 18-6 Chronic Subdural Hematoma. Compression of underlying brain and lateral ventricle. (From Kissane JM, editor: *Anderson's pathology,* ed 9, St Louis, 1993, Mosby.)

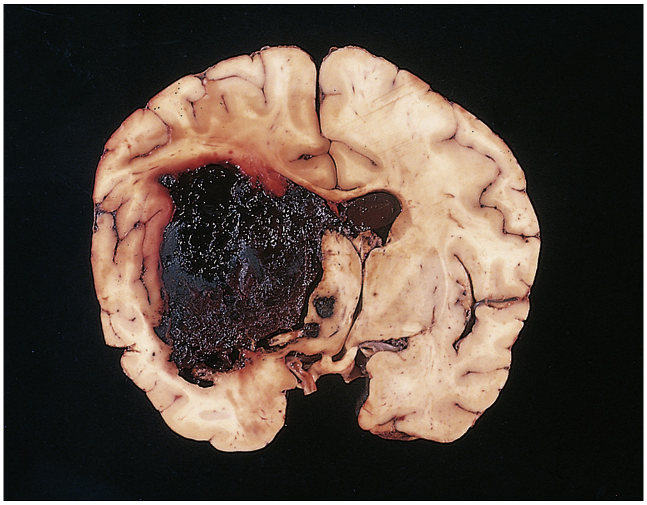

FIGURE 18-7 Acute Intracerebral Hemorrhage. A fresh hematoma has disrupted and expanded the left cerebral hemisphere, causing the midline structures to shift to the right. Uncontrolled hypertension is an important cause of this catastrophic lesion. (From Kumar V, Cotran RS, Robbins SL: *Robbins basic pathology,* ed 7, Philadelphia, 2003, Saunders.)

A vascular membrane forms around the hematoma in approximately 2 weeks. Further enlargement takes place in some persons, but the mechanism of this enlargement is unclear.

Presenting manifestations of *chronic subdural hematomas* vary. Of those affected, 80% have chronic headaches and tenderness over the hematoma on percussion. Most appear to have a progressive dementia accompanied by generalized rigidity (paratonia).

Whereas most acute and subacute subdural hematomas are treated with clot evacuation through a burr hole, chronic subdural hematomas (and some that are subacute) require a craniotomy to evacuate the gelatinous blood. The membrane around a chronic subdural hematoma is then dissected away from the dura mater and arachnoid membranes. A technique for percutaneous drainage for chronic subdural hematomas has proved successful.

Intracerebral hematomas occur in 2% to 3% of head injuries and are usually associated with MVAs and falls from some distance. Intracerebral hematomas may be single or multiple, and they are associated with contusions. Although most commonly located in the frontal and temporal lobes, intracerebral hematomas may occur in the hemispheric deep white matter. Small blood vessels are traumatized by penetrating injury or shearing forces. The intracerebral hematoma then acts as an expanding mass, resulting in increased ICP and compression of brain tissues with resultant edema and ischemia (Figure 18-7). Delayed intracerebral hematomas may appear 3 to 10 days after the head injury.

A decreasing level of consciousness is associated with an *intracerebral hematoma*. Coma or a confusional state from other injuries, however, can make the cause of this increasing unresponsiveness difficult to detect. Contralateral hemiplegia also may occur. As the ICP rises, clinical manifestations of temporal lobe herniation may appear. In delayed intracerebral hematoma, the presentation is similar to that of hypertensive brain hemorrhage: sudden, rapidly progressive decreased level of consciousness with pupillary dilation; breathing pattern changes; hemiplegia; and bilateral positive Babinski reflexes.

Evacuation of a singular intracerebral hematoma has only occasionally been helpful, mostly for subcortical white matter hematomas. Otherwise, treatment is directed at reducing the ICP to maintain cerebral perfusion pressure and allowing the hematoma to reabsorb slowly. Secondary brain injury is common (see p. 588).

Open brain trauma produces both focal and diffuse injuries and includes compound skull fractures and missile injuries (e.g., bullets, rocks, shell fragments, knives, and blunt instruments). A compound fracture opens a communication between the cranial contents and the environment and should be investigated whenever there are lacerations of the scalp, tympanic membrane, a sinus, an eye, or mucous membranes. Such fractures may involve the cranial vault or the base of the skull (basilar skull fracture). A basilar skull fracture can involve the temporal, sphenoid, and occipital bones. The cranial nerves may be damaged and the meninges torn, causing leakage of cerebrospinal fluid from the ear and nose, or both. Severity of brain damage is related to the severity of skull fracture. Infection is a significant complication. Injury incurred from bone fragments is mainly a tangential injury (injury caused by direct contact) and occasionally a penetrating injury. Bone fragments may lacerate or contuse brain tissues or blood vessels.

The mechanisms of open brain trauma are crush injury (laceration and crushing of tissue touched by the missile) and stretch injury (damage of blood vessels and nerves not directly contacted, occurring as a result of stretching). *Crush injury* is the laceration and crushing of whatever tissue the missile touches, with the amount of crush related to the degree of fragmentation, deformity, size, and shape. The tangential injury is injury to the coverings of the brain (scalp and brain lacerations) and also may include skull fractures and meningeal and cerebral lacerations. When driven into the brain substance, projectiles and debris from scalp and skull injury produce a penetrating brain injury. Occasionally projectiles are so forceful that they exit the

cranial vault in addition to entering it, producing a through-and-through injury (e.g., high-velocity bullets). Primary damage is localized along the path of the penetrating object, and direct tissue disruption along the projectile tract results.

Stretch injury involves blood vessels and nerves that are damaged without direct contact as a result of the amount of tissue stretched secondary to shape, deformation, and striking velocity. Air compressed in front of a bullet exerts an explosive effect on entry, producing extreme distant tissue damage and an immediate primary increase in ICP; a cavity many times greater than the size of the bullet is produced because the brain tissue is propelled away from the tract. The cavity and pressure produce contrecoup injuries. The intracranial volume is increased directly by the projectile and the debris. The temporary cavity collapses back onto itself, leaving a smaller, permanent cavity. Intracranial bleeding occurs into the permanent cavity and may cause the cavity to expand. Edema in and around the injured brain tissue rapidly develops; edema and bleeding contribute markedly to increased ICP. This second rise in ICP to 60 to 100 mmHg may last 2 to 5 minutes. Because of acute ischemic damage to the tract, necrosis of tissue begins. Within hours after bullet-induced injury, tissue within 1 cm adjacent to the tract disintegrates. Demyelination of white matter affected by hemorrhage and edema occurs by the second day. Clinical manifestations such as unconsciousness, flaccidity, or decerebrate posture (see Chapter 17) are associated with high mortality.

Most victims lose consciousness with open-head injury. The depth of the coma and the length of the unresponsive state are related to the location of injury, extent of damage, and amount of bleeding. The diagnosis of a compound fracture is made through physical examination, skull radiographs, or both. The diagnosis of a basilar skull fracture is made on the basis of clinical findings. Skull radiographs often do not demonstrate the fracture, although intracranial air or air in the sinuses on radiograph, CT, or MRI is indirect evidence of a basilar skull fracture.

A compound linear fracture is débrided nonsurgically in cooperative adults and surgically in children and uncooperative adults. Cranioplasty with insertion of bone or an artificial graft may be necessary but often is delayed until antibiotics have been given. Antibiotics are administered after surgery. Open-head injury often requires surgery to débride the traumatized tissues to prevent infection and to remove blood clots to help reduce the ICP. ICP also is managed with dehydrating agents, osmotic diuretics, or a combination of these drugs. Broad-spectrum antibiotics are administered to prevent infection. Use of prophylactic antibiotics is controversial because studies have failed to demonstrate that they reduce the rate of infection.[7] Bed rest and close observation for meningitis and other complications are prescribed for a basilar skull fracture.

Diffuse Brain Injury. **Diffuse brain injury (diffuse axonal injury [DAI])** involves widespread areas of the brain. Damage to delicate axonal fibers and white matter tracts that project to the cerebral cortex causes concussion. Mechanical effects from high levels of acceleration and deceleration (whiplash) and rotational and twisting movements are the primary mechanisms of injury, producing strains and distortions within the brain (see Figure 18-2). As a result of the skull's motion caused by its attachment to the neck, striking the head causes rotational forces that can trigger shearing forces on brain tissues. Stretching and tearing of nerve fibers result in axonal damage. The most severe axonal injuries are located more peripheral to the brainstem, causing extensive cognitive and affective impairments, as seen in survivors of traumatic brain injury from vehicular crashes. Axonal damage reduces the speed of information processing and response and disrupts the individual's attention span.

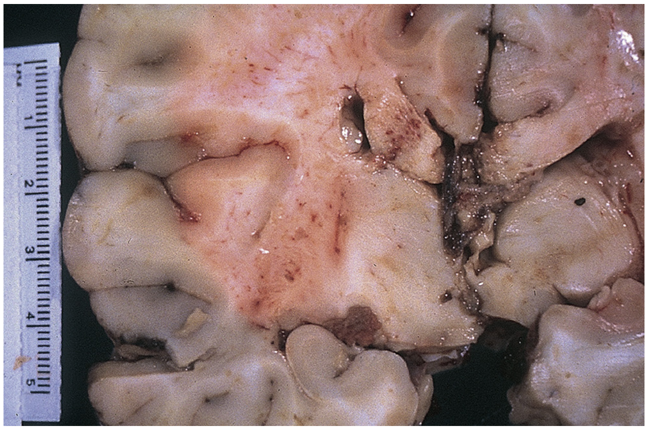

FIGURE 18-8 **Diffuse Axonal Injury.** Gross photograph demonstrating characteristic hemorrhage lesions within the corpus callosum. (Courtesy Walter Kemp, MD, Department of Pathology, University of Texas Southwestern Medical School, Dallas. From Kumar V, Cotran RS, Robbins SL: *Robbins basic pathology,* ed 7, Philadelphia, 2003, Saunders.)

Pathophysiologically, axonal damage can be seen only with an electron microscope and involves numerous axons alone or axonal injury in conjunction with actual tissue tears (Figure 18-8). Areas where axons and small blood vessels are torn appear as small hemorrhages, located particularly in the corpus callosum and dorsolateral quadrant of the rostral brainstem at the superior cerebellar peduncle. Increasingly more damaged axons are visible 12 hours to several days after the injury and secondary brain injury also is occurring (see p. 588). The severity of diffuse injury correlates with how much shearing force was applied to the brain. DAI is not associated with intracranial hypertension immediately after injury; however, secondary brain injury causes acute brain swelling from increased intravascular blood flow within the brain, vasodilation, and increased cerebral blood volume.

Several categories of diffuse brain injury exist: mild concussion, classic concussion, mild DAI, moderate DAI, and severe DAI (see Table 18-1 and Figure 18-1).

Mild concussion (mild traumatic brain injury) is characterized by immediate but transitory clinical manifestations. CSF pressure rises, and ECG and EEG changes occur without loss of consciousness. The Glasgow Coma Scale score is 13 to 15.[8] The initial confusional state lasts from 1 to several minutes, possibly with amnesia for events preceding the trauma (retrograde amnesia). Anterograde amnesia also may exist transiently. Persons may experience head pain and complain of nervousness and "not being themselves" for up to a few days. Three grades have been described:

Grade I: Transient confusion and disorientation accompanied by amnesia (momentary); no loss of consciousness; symptoms resolve within 15 minutes

Grade II: Transient confusion and retrograde amnesia that develops after 5 to 10 minutes (memory loss involves only events occurring several minutes before injury); symptoms last more than 15 minutes

Grade III: Any loss of consciousness (seconds or minutes); confusion and retrograde and anterograde amnesia remain present from impact and persist for several minutes

Classic cerebral concussion (Grade IV) is any loss of consciousness (can last up to 6 hours) accompanied by retrograde and anterograde amnesia. Transient cessation of respiration can occur with brief periods of bradycardia, and a decrease in blood pressure lasting 30 seconds or less occurs. Vital signs stabilize within a few seconds to within normal limits. This is a phenomenon of physiologic, neurologic dysfunction without substantial anatomic disruption. A confusional state persists for hours to days. The individual experiences head pain, nausea, and fatigue. Attentional and memory system impairments may persist for weeks to months and may include inability to concentrate and forgetfulness. Mood and affect changes may persist for weeks to months and may include nervousness, anxiety reactions, depression, irritability, fatigability, and insomnia. There are two forms of Grade IV classic cerebral concussion: uncomplicated classic cerebral concussion (without focal injury) and complicated classic cerebral concussion (accompanied by focal injury [e.g., a cerebral contusion that yields focal signs]).

Some of the effects of a concussion may persist for weeks or months, depending on the severity of the injury. Approximately 15% to 30% of persons have a **postconcussive syndrome** that includes headache, nervousness or anxiety, irritability, insomnia, depression, inability to concentrate, forgetfulness, and fatigability.[9] Treatment entails reassurance, symptomatic relief, and close observation for 24 hours with follow-up care for persistent symptoms.

DAI produces prolonged traumatic coma lasting more than 6 hours because of axonal disruption. Three forms of DAI exist: mild, moderate, and severe. In **mild diffuse axonal injury,** posttraumatic coma lasts 6 to 24 hours. Death is uncommon but residual cognitive, psychologic, and sensorimotor deficits may persist. Mild DAI is a relatively uncommon lesion, occurring in 8% of all severe head injuries and 19% of all cases of DAI. In mild DAI 30% of persons display decerebrate or decorticate posturing (see Figure 17-6); they may experience prolonged periods of stupor or restlessness.

In **moderate diffuse axonal injury,** widespread physiologic impairment exists throughout the cerebral cortex and diencephalon. Actual tearing of some axons in both hemispheres occurs. Basal skull fracture, a focal injury, is commonly associated with moderate DAI. Prolonged coma lasting more than 24 hours is present but prominent brainstem signs do not exist with moderate DAI. Recovery often is incomplete in 93% of those individuals who survive. Moderate DAI is the most common type of DAI and is found in 20% of severe head injuries and 45% of all cases of DAI.

In moderate DAI, the GCS score is 4 to 8 initially and 6 to 8 by 24 hours following the injury. Thirty-five percent of victims have transitory decerebration or decortication. The person often remains unconscious for days or weeks and on awakening is confused. He or she experiences a long period of posttraumatic anterograde and retrograde amnesia and often has permanent deficits in memory, selective attention, vigilance, detection, working memory, data processing, vision or perception, and language, as well as mood and affect changes ranging from mild to severe.

Severe diffuse axonal injury involves severe mechanical disruption of many axons in both cerebral hemispheres and those extending to the diencephalon and brainstem. Severe DAI represents 16% of all severe head injuries and 36% of all cases of DAI. With an initial GCS score of 3, the mortality is 78%;[5] with an initial score between 3 and 8, the mortality is 36%; 16% of persons have either a moderate or a severe disability and 5% survive in a coma (unresponsive) state.[5]

Severe DAI is associated with brainstem signs that disappear in a few weeks. The person experiences immediate autonomic dysfunction that resolves in a few weeks. Increased ICP appears 4 to 6 days after injury. Pulmonary complications occur frequently, with profound sensorimotor and cognitive system deficits. Severely compromised coordinated movements and verbal and written communication, inability to learn and reason, and inability to modulate behavior also are evident.

High-resolution CT scans and MRIs assist in the diagnosis of focal and diffuse brain injuries.[5,10] The goal of treatment is to maintain cerebral perfusion and oxygenation and promote neuroprotection. Implementation of traumatic brain injury guidelines decreases deaths and improves neurologic outcome.[11,12] Specifically, the evidence is inconclusive about the effectiveness of hyperventilation and mild hypothermia. Hypertonic saline or mannitol is used selectively to manage increased intracranial pressure (IICP).[13] Barbiturates have not been shown to be effective in reducing intracranial pressure or preventing adverse outcomes after TBI. The Corticosteroid Randomisation After Significant Head Injury (CRASH) trial showed corticosteroids increase mortality with acute TBI, so these drugs are no longer used. Antiepileptic drugs may be recommended to reduce the onset of early and late seizures. Prophylactic antibiotics have not been shown to reduce the risk of meningitis or death with a skull fracture. Progesterone is under investigation and may improve neurologic outcome.[14] Extensive research is underway to discover effective therapeutic interventions. Fluid and nutrition management has emerged as critically important in the care of individuals with severe brain injuries.[15]

Secondary Brain Injury. **Secondary neuronal injury** occurs when there is brain or spinal cord trauma and in stroke syndromes. It occurs within hours to days of the primary injury. **Secondary brain injury** is the result of both systemic and intracranial processes and is an indirect result of primary brain injury. Systemic hypotension, hypoxia, anemia, hypoglycemia, hyperglycemia, and hypercapnia contribute to secondary brain insults. Mechanisms of secondary injury include altered cerebral blood flow, ischemia, inflammation, cerebral edema, decreased cerebral perfusion pressure (CPP), IICP, and brain

herniation. Molecular alterations occur with stretching and tearing of axonal membranes and ischemia (see Figure 18-1). The complex pathophysiology of secondary brain injury underlies the functional, cognitive, and behavioral changes associated with brain injury and the motor and sensory losses associated with spinal cord injury.

Cerebrovascular autoregulation (constriction or dilation in response to increases or decreases in CPP) is impaired after brain injury and may be transient or persistent with alterations in CO_2 reactivity (i.e., CO_2 vasodilation). Vasospasm commonly occurs, contributing to brain hypoperfusion, and is caused by chronic depolarization of vascular smooth muscle, release of endothelin (vasoconstrictor), and decreased availability of nitric oxide (vasodilator).

Widespread release of excitatory neurotransmitters (e.g., glutamate and aspartate) causes calcium and sodium influx that is neurotoxic (excitotoxicity). Mitochondrial loading with calcium leads to mitochondrial failure, anaerobic metabolism, lactic acid production, and increased levels of reactive oxygen species (ROS), phospholipases, and other enzymes. ROS and phospholipase damage proteins and the phospholipid components of cell and organelle membranes, causing cell swelling, vacuolization, and, ultimately, necrotic or programmed cell death (apoptosis). Energy metabolism is depressed with alteration of gene expression. These events lead to failure of the capillary blood-brain barrier and *vasogenic edema*. The influx of sodium attracts water and results in intracellular cytotoxic edema in neurons, astrocytes, and microglia irrespective of the integrity of the vascular endothelial wall. Edema increases intracranial pressure, contributing to tissue hypoxia and cerebral ischemia.[16,17]

Both primary and secondary injuries cause inflammation (see Chapter 7), which occurs immediately and persists for weeks. Inflammation is critical for wound healing; immune cells, including neutrophils, macrophages, and T-cell lymphocytes, need to infiltrate injured tissue and clear debris, thus promoting formation of scar tissue. However, an overactive response leads to occlusion of the microvasculature with leukocytes and platelets. The release of inflammatory cytokines (e.g., tumor necrosis factor-alpha [TNF-α], interleukins, and interferons), proteases, free radicals, prostaglandins, and complement alters the blood-brain barrier and causes vasoconstriction, brain edema, increased intracranial pressure, reduced cerebral perfusion, and ischemia, aggravating secondary brain injury.[17,18]

Intracranial hemorrhage, whether traumatic or related to a stroke syndrome, may contribute to secondary brain injury. The bleeding is often accompanied by increased ICP, ischemia, oxidative damage, and vasogenic and cytotoxic edema as previously described. In addition, the vascular injury can cause activation of platelets, which contribute to vasoconstriction in large arteries and vasodilation in small arteries. Activated platelets also trigger the release of free radicals from granulocytes, enhancing oxidative stress. Vascular injury causes coagulation disorders from release of increased amounts of tissue factor from endothelial cells, which initiates the coagulation cascade and overwhelms the normal factors that control coagulation. Free heme and free iron are released from red blood cells and both cause the induction of free radicals, lipid peroxidation, and nerve damage.[19]

The management of secondary brain trauma is related to prevention and includes removal of hematomas and management of hypotension, hypoxemia, anemia, intracranial pressure, body temperature, ventilation, fluid replacement, and nutrition. Research is in progress to find specific pharmacologic interventions and neuroprotective agents that limit the progression of secondary injury and to identify biomarkers to guide prevention, prognosis, and treatment[20,21] (see What's New? Progesterone for Treatment of Traumatic Brain Injury [TBI]).

Genetics of Head Injury. Certain genes are up-regulated and others are down-regulated after head trauma. The attention of researchers has been focused predominantly on the *apolipoprotein E (apoE)* gene and its various alleles. Certain alleles have been correlated with increased susceptibility to and severity of head injury. Other alleles have been associated with improved or diminished recovery after head injury. The clinical significance of these findings is not clearly known.[22,23]

WHAT'S NEW?

Progesterone for Treatment of Traumatic Brain Injury (TBI)

There currently are no pharmacologic agents approved for the treatment of TBI. Animal studies and phase II clinical trials, using intravenous progesterone for treatment of moderate to severe brain trauma, have shown preliminary benefits for improved outcome and decreased mortality. Progesterone is lipid soluble; readily crosses the blood-brain barrier; is safe for administration in both men and women; is inexpensive; and is known for its multiple anti-inflammatory, anti-apoptotic, trophic growth–promoting, and neuroprotective properties. Unlike other steroid hormones, progesterone is synthesized directly in the brain by oligodendrocytes and in excitatory neurons, so it can be considered a "neurosteroid" beyond its role as a sex hormone. A phase III clinical trial is now evaluating progesterone for moderate-to-severe TBI in 1140 individuals with final results to be reported in 2015. Additionally, the SyNAPSe trial is evaluating intravenous progesterone in 1200 individuals with severe closed-head trauma in 100 to 120 medical centers throughout the world. These long-term, multicenter studies will contribute evidence to confirm the safety, efficacy, and generalizability of using progesterone for treatment of TBI.

Spinal Cord Trauma

The number of spinal cord injuries (SCIs) in the United States is approximately 273,000, with 12,000 new cases annually; of these, 80.7% are males, mostly young adults. The average age is 40.7 years. Since 2010 the causes include vehicular (36.5%), falls (28%), violence (14%), and sports (9%). The extent of injury has been 41% incomplete quadriplegia, 16% complete quadriplegia, 18.7% incomplete paraplegia, and 18% complete paraplegia.[24]

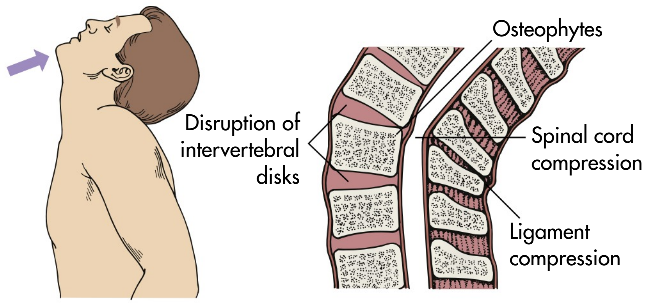

FIGURE 18-9 **Hyperextension Injuries of the Spine.** Hyperextension can result in fracture or nonfracture injuries with spinal cord damage.

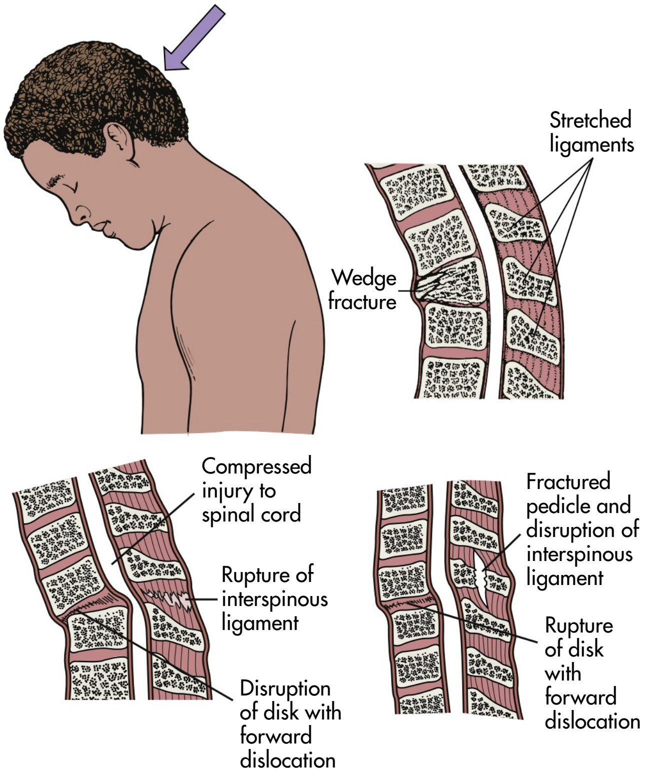

FIGURE 18-10 **Hyperflexion Injury of the Spine.** Hyperflexion produces translation (subluxation) of vertebrae, which compromises the central canal and compresses spinal cord parenchyma or vascular structures.

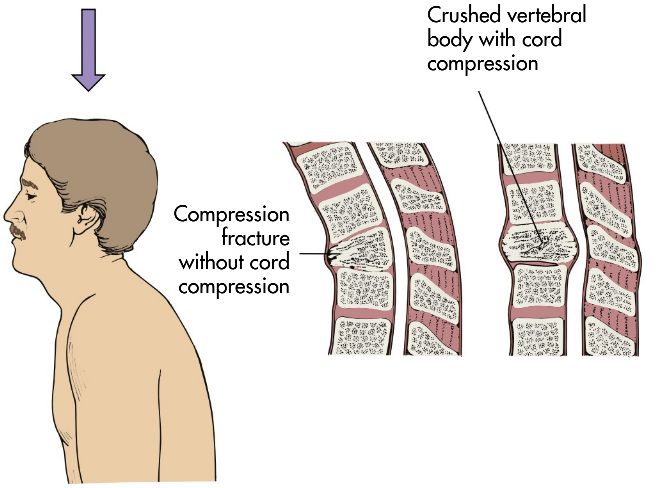

FIGURE 18-11 **Axial Compression Injuries of the Spine.** In axial compression the spinal cord is contused directly by retropulsion of bone or disk material into the spinal canal.

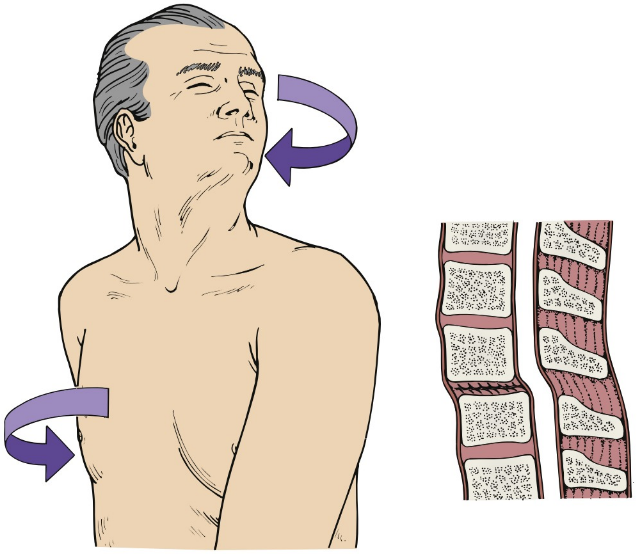

FIGURE 18-12 **Flexion-Rotation Injuries of the Spine.**

PATHOPHYSIOLOGY. **Primary spinal cord injury** occurs with the initial mechanical trauma and immediate tissue destruction. Vertebral fractures or dislocations can cause bone fragments or connective tissues to compress and damage nerve fibers. Vertebral injuries result from acceleration, deceleration, or deformation forces at impact. These forces cause compression, traction, or shearing of tissues. The bones, ligaments, joints, and neural tissue of the vertebral column may be damaged by hyperextension, hyperflexion, vertical compression, or rotation (Figures 18-9 through 18-12). Vertebral fracture and often compression of one or more elements, dislocation of its elements, or both fracture and dislocation can occur (see Figure 15-17 for the structure of the vertebral column). Vertebral injuries can be classified as (1) simple fracture, a single break usually affecting transverse or spinous processes; (2) compressed (wedged) vertebral fracture, in which a vertebral body is compressed anteriorly; (3) comminuted (burst) fracture, in which a vertebral body is shattered into several fragments; and (4) dislocation.

Vertebrae fracture readily with direct and indirect trauma. When the supporting ligaments are torn, the vertebrae move out of alignment, and dislocations occur. A horizontal force moves the vertebrae straight forward; if the individual is in a flexed position at the time of injury, the vertebrae are then in an angulated position. Flexion and extension injuries may result in dislocations. (Mechanisms of vertebral injury are presented in Table 18-2.) Vertebral injuries occur mostly at vertebrae C1-C2 (cervical), C4-C7, and T1-L2 (thoracic-lumbar) (see Figure 15-17). These are the most mobile portions of the vertebral column. The cord occupies most of the vertebral canal in the cervical and lumbar regions. The size makes the cord in these areas more easily injured. The *primary spinal cord injuries* are summarized in Table 18-3. Noncontiguous vertebral injuries are common. Further, primary injury occurs if an injured

TABLE 18-2 MECHANISMS OF VERTEBRAL INJURY

MECHANISMS OF INJURY	VERTEBRAL INJURY	FORCES OF INJURY	LOCATION OF INJURY
Hyperextension	Fracture and dislocation of posterior elements such as spinous processes, transverse processes, laminae, pedicles, or posterior ligaments	Results from forces of acceleration-deceleration and the sudden reduction in the anteroposterior diameter of the spinal cord	Cervical area
Hyperflexion	Fracture or dislocation of the vertebral bodies, disks, or ligaments	Results from sudden and excessive force that propels the neck forward or causes an exaggerated lateral movement of the neck to one side	Cervical area
Vertical compression (axonal loading)	Shattering fractures	Results from a force applied along an axis from the top of the cranium through the vertebral bodies	T12-L2
Rotational forces (flexion-rotation)	Ruptures support ligaments in addition to producing fractures	Adds shearing force to acceleration-deceleration forces	Cervical area

TABLE 18-3 SPINAL CORD INJURIES

INJURY	DESCRIPTION
Cord concussion	Results in a temporary disruption of cord-mediated functions
Cord contusion	Bruising of the neural tissue causing swelling and temporary loss of cord-mediated functions
Cord compression	Pressure on the cord causing ischemia to tissues; must be relieved (decompressed) to prevent permanent damage to the spinal cord
Laceration	Tearing of the neural tissues of the spinal cord; may be reversible if only slight damage is sustained by the neural tissues; may result in permanent loss of cord-mediated functions if spinal tracts are disrupted
Transection	Severing of the spinal cord, causing permanent loss of function
Complete	All tracts in the spinal cord are completely disrupted; all cord-mediated functions below the transection are completely and permanently lost
Incomplete	Some tracts in the spinal cord remain intact, together with functions mediated by these tracts; has the potential for recovery although function is temporarily lost
Preserved sensation only	Some demonstrable sensation below the level of injury
Preserved motor nonfunctional	Preserved motor function without useful purpose; sensory function may or may not be preserved
Preserved motor functional	Preserved voluntary motor function that is functionally useful
Hemorrhage	Bleeding into the neural tissue because of blood vessel damage; usually no major loss of function
Damage or obstruction of spinal blood supply	Causes local ischemia

spine is not adequately immobilized. Primary spinal cord injury may occur in the absence of vertebral fracture or dislocation from longitudinal stretching of the cord with or without flexion and/or extension of the vertebral column. The stretching causes altered axon transport, edema, myelin degeneration, and retrograde or wallerian degeneration.

Secondary spinal cord injury is a pathophysiologic cascade of vascular, cellular, and biochemical events that begins within a few minutes after injury and continues for weeks. The edema, ischemia, excitotoxicity, inflammation, oxidative damage, and activation of necrotic and apoptotic cell death signaling events are similar to those previously described for secondary brain injury.[25] By 5 minutes after injury, venules of the gray matter are congested and distended by erythrocytes. In 15 to 30 minutes, small hemorrhages occur with extravasation of erythrocytes into perivascular spaces of postcapillary and muscular venules. *Microscopic hemorrhages* appear in the central gray matter and pia arachnoid that increase in size within 2 hours. *Edema* in the white matter impairs the microcirculation of the cord. Within 4 hours, numerous swollen axis cylinders develop. Localized hemorrhaging and edema are followed by loss of autoregulation, vasospasm, impaired venous drainage, and reduced vascular perfusion with *development of ischemic areas*. There is myelin disruption, axonal degeneration, and necrosis. The microscopic hemorrhages and edema are maximal at the level of injury and for two cord segments above and below it. Impaired perfusion is aggravated by systemic responses including neurogenic or hemorrhagic shock, and arrhythmias.[26]

Cord swelling increases an individual's degree of dysfunction; therefore distinguishing the functions to be lost permanently from those that are impaired just temporarily becomes difficult. In the cervical region, cord swelling may be life threatening because of the possibility of resulting impairment of diaphragm function (phrenic nerves exit C3-C5) and vegetative functions mediated by the medulla oblongata. Within the first few days of injury, progressive axonal changes occur and necrotic zones develop. Progressive cavitation and coagulation necrosis at the site of injury are termed *posttraumatic infarction.*

Circulation in the white matter tracts of the spinal cord returns to normal in about 24 hours, but gray matter circulation remains altered. Phagocytes appear 36 to 48 hours after injury. Proliferation of microglia and changes in astrocytes occur. Red cells then begin to disintegrate, and resorption of hemorrhages begins. Degenerating axons are engulfed by macrophages in the first 10 days after injury. A cyst with fluid forms. The traumatized cord is replaced by acellular collagenous tissue (a scar), usually in 3 to 4 weeks. Meninges thicken as part of the scarring process.

CLINICAL MANIFESTATIONS. Immediately after cord injury, normal activity of spinal cord cells at and below the level of injury ceases because of loss of the continuous tonic discharge from the brain or brainstem and inhibition of suprasegmental impulses, thus causing spinal shock. **Spinal shock** is characterized by a complete loss of reflex function, flaccid paralysis, sensory deficit, and loss of bladder and rectal control in all segments below the level of the lesion. Disruption of central communication with sympathetic spinal nerves causes a transient drop in blood pressure, poor venous circulation, and disturbed thermal regulation. This damage causes faulty control of diaphoresis (sweating) and heat radiation through capillary dilation. The hypothalamus cannot regulate body heat through vasoconstriction and increased metabolism; therefore, the individual's body temperature assumes the temperature of the air. Spinal shock may persist for as short a time as a few days or as long as 3 months. Indications that spinal shock is terminating include the reappearance of reflex activity, hyperreflexia, spasticity, and reflex emptying of the bladder.

Neurogenic shock occurs with cervical or upper thoracic cord injury and may be seen in addition to spinal shock. Neurogenic shock is caused by the absence of sympathetic activity through loss of supraspinal control and unopposed parasympathetic tone mediated by the intact vagus nerve. Symptoms include vasodilation, hypotension, bradycardia, and hypothermia.

Continued loss of motor and sensory function depends on the extent and level of injury. All motor, sensory, reflex, and autonomic functions cease below any transected area and may cease below concussive, contused, compressed, or ischemic areas (Table 18-4). Paralysis of the lower half of the body with both legs involved is termed *paraplegia.* Paralysis involving all four extremities is termed *quadriplegia* (tetraplegia). In complete quadriplegia the level of injury is above C6, and all upper extremity function is lost. In incomplete quadriplegia, function at or above C6 is preserved, leaving the shoulder, upper arm, and some forearm muscle control intact. With acceleration injuries the greatest stress point is C4-C5. With a deceleration force the greatest stress point is at C5-C6.

TABLE 18-4 CLINICAL MANIFESTATIONS OF SPINAL CORD INJURY

STAGE	MANIFESTATIONS
Spinal Shock Stage	
Complete spinal cord transection	Loss of motor function
	1. Quadriplegia with injuries of cervical spinal cord
	2. Paraplegia with injuries of thoracic spinal cord
	Muscle flaccidity
	Loss of all reflexes below level of injury
	Loss of pain, temperature, touch, pressure, and proprioception below level of injury
	Pain at site of injury caused by a zone of hyperesthesia above the injury
	Atonic bladder and bowel
	Paralytic ileus with distention
	Loss of vasomotor tone in lower body parts; low and unstable blood pressure
	Loss of perspiration below level of injury
	Loss or extreme depression of genital reflexes such as penile erection and bulbocavernous reflex
	Dry and pale skin, possible ulceration over bony prominences
	Respiratory impairment
Partial spinal cord transection	Asymmetric flaccid motor paralysis below level of injury
	Asymmetric reflex loss
	Preservation of some sensation below level of injury
	Vasomotor instability less severe than with complete cord transection
	Bowel and bladder impairment less severe than that seen with complete cord transection
	Preservation of ability to perspire in some portions of the body below level of injury
	Brown-Séquard syndrome (associated with penetrating injuries, hyperextension and flexion, locked facets, and compression fractures)
	1. Ipsilateral paralysis or paresis below level of injury
	2. Ipsilateral loss of touch, pressure, vibration, and position senses below level of injury
	3. Contralateral loss of pain and temperature sensations below level of injury
	Central cervical cord syndrome (acute cord compression between bony bars or spurs anteriorly and thickened ligamentum flavum posteriorly associated with hyperextension)
	1. Motor deficits in upper extremities, especially hands; more dense than in lower extremities
	2. Varying degrees of bladder dysfunction
	Burning hand syndrome (variant of central cord syndrome; half of cases have an underlying spine fracture/dislocation present)
	1. Severe burning paresthesias and dysesthesias in the hands and/or feet
	Anterior cord syndrome (compromise of anterior spinal artery by occlusion or pressure effect of disk)
	1. Loss of motor function below level of injury
	2. Loss of pain and temperature sensations below level of injury
	3. Touch, pressure, position, and vibration senses intact

TABLE 18-4 CLINICAL MANIFESTATIONS OF SPINAL CORD INJURY—cont'd

STAGE	MANIFESTATIONS
	Posterior cord syndrome (associated with hyperextension injuries with fractures of vertebral arch) 1. Impaired light touch and proprioception *Conus medullaris syndrome* (compression injury at T12 from disk herniation or burst fracture of body of T12) 1. Flaccid paralysis of legs 2. Flaccid paralysis of anal sphincter 3. Variable sensory deficits *Cauda equina syndrome* (compression of nerve roots below L1 caused by fracture and dislocation of spine or large posterocentral intervertebral disk herniation) 1. Lower extremity motor deficits 2. Variable sensorimotor dysfunction 3. Variable reflex dysfunction 4. Variable bladder, bowel, and sexual dysfunction *Syndrome of neuropraxia* (seen as post–athletic injury, associated with congenital spinal stenosis) 1. Dramatic but transient neurologic deficits including quadriplegia *Horner syndrome* (injury to preganglionic sympathetic trunk or postganglionic sympathetic neurons of superior cervical ganglion) 1. Ipsilateral pupil smaller than contralateral pupil 2. Sunken ipsilateral eyeball 3. Ptosis of affected eyeball 4. Lack of perspiration on ipsilateral side of face
Heightened Reflex Activity Stage	
	Emergence of Babinski reflexes, possibly progressing to a triple reflex; possible development of still later flexor spasms Reappearance of ankle and knee reflexes, which become hyperactive Contraction of reflex detrusor muscle, leading to urinary incontinence Appearance of reflex defecation Mass reflex with flexion spasms, profuse sweating, piloerection, and bladder and occasional bowel emptying may be evoked by an autonomic stimulation of skin or from a full bladder Episodes of hypertension Defective heat-induced sweating Eventual development of extensor reflexes, first in muscles of hip and thigh, later in leg Possible paresthesias below level of transaction: dull, burning pain in lower back, abdomen, buttocks, and perineum

Return of spinal neuron excitability occurs slowly. Depending on the degree of damage, either of the following can occur: (1) motor, sensory, reflex, and autonomic functions return to normal; or (2) autonomic neural activity in the isolated segment develops. The sequence of hyperactivity phases, which vary in length, may include: (1) minimal reflex activity, (2) flexor spasms, (3) alternation between flexor and extensor spasms, and (4) predominant extensor spasms.

The initial clinical manifestations associated with acute spinal cord injury are: (1) rapid loss of voluntary movements in body parts below the level of injury, (2) sensations in the lower extremities and possibly lower trunk (depending on the level of injury), and (3) spinal and autonomic reflexes below the level of injury. The duration of this areflexic state is highly variable. In most persons, reflex activity returns in 1 to 2 weeks.

Gradually reflexes return and become increasingly easier to elicit. A pattern of flexion reflexes emerges first, involving the toes and later the feet and legs. Reflex voiding and bowel elimination appear. Flexor spasms accompanied by profuse sweating, piloerection, and automatic bladder emptying (together called a **mass reflex**) may develop. The ability to sweat when overheated may be disrupted, and extensor spasms may develop, usually after full development of flexor spasms. Sometimes after several months, episodes of autonomic hyperreflexia occur.

Autonomic hyperreflexia (dysreflexia) is a syndrome of sudden, massive reflex sympathetic discharge associated with spinal cord injury at level T5-T6 or above. Supraspinal control of the sympathetic nervous system is disrupted, causing an imbalance between the sympathetic and the parasympathetic nervous systems. The pathophysiology of hyperreflexia involves the stimulation of sensory receptors below the level of the cord lesion. The sensory input ascends the spinal cord and activates the thoracolumbar sympathetic nerves. The intact sympathetic nervous system reflexively responds with vasoconstriction of the muscular, splanchnic, and cutaneous vascular beds. The paroxysmal increase in blood pressure causes baroreceptors in the cerebral vessels, the carotid sinus, and the aorta to stimulate parasympathetic vasodilation above the level of the cord lesion. The heart rate decreases but not enough to overcome the hypertension. The visceral and peripheral vessels do not dilate because efferent impulses cannot pass through the injured cord (Figure 18-13).

Autonomic hyperreflexia is characterized by debilitating symptoms: paroxysmal hypertension (up to 300 mmHg systolic), bradycardia (30 to 40 beats/minute), a pounding headache, blurred vision, sweating above the level of the lesion with flushing of the skin, nasal congestion, nausea, and piloerection caused by pilomotor spasm. The symptoms may develop singly

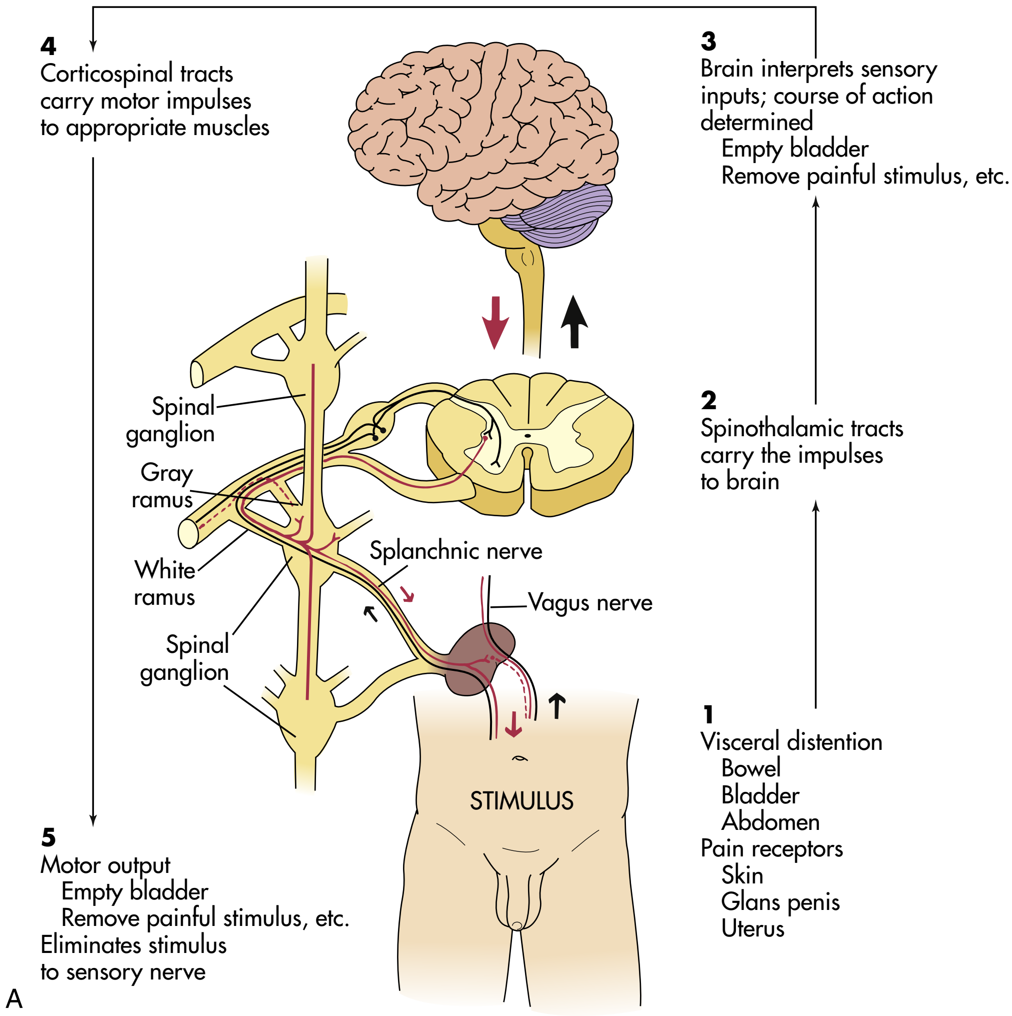

FIGURE 18-13 Autonomic Hyperreflexia. **A,** Normal response pathway.

or in combination (syndrome) and often are associated with somatic (distended bladder or rectum) or sensory stimulation. The condition is life threatening and requires immediate treatment because cerebrovascular accident (CVA) is possible. The head of the bed should be elevated and the stimulus should be determined and removed. Emptying of the bladder or bowel usually relieves the syndrome. Medical treatment may include topical nitroglycerin paste above the level of the lesion, calcium channel blockers (e.g., nefedipine), or α-adrenergic receptor blocking agents.[27] Prevention of autonomic hyperreflexia with bowel and bladder management programs is an effective approach.

EVALUATION AND TREATMENT. Diagnosis of spinal cord injury is made on the basis of physical examination and imaging (e.g., MRI). For a suspected or confirmed vertebral fracture or dislocation, regardless of the presence or absence of spinal cord injury, the immediate intervention is immobilization of the spine to prevent further injury. Decompression and surgical fixation may be necessary and performed early. Corticosteroids may be given at the time of injury to decrease secondary cord injury and continued for 24 to 48 hours, depending on time of initiation following injury. Therapeutic hypothermia has shown some encouraging evidence for improved outcomes, particularly for cervical cord injuries, but more research is needed.[28] Several clinical trials are in progress that address treatment of acute spinal cord injury, including cell-based therapies, immune modulators, vasculature selective treatments, and functional electrical stimulation.[29] Nutrition, lung function, skin integrity, and bladder and bowel management must be addressed. Plans for rehabilitation require early consideration. Impairments are permanent because endogenous repair events fail to restore the damaged axonal circuits.[30,31]

Degenerative Disorders of the Spine

Degenerative Disk Disease

Degenerative disk disease (DDD) is a common finding in individuals 30 years of age and older. It is, in part, a process of normal aging and includes a genetic component and environmental interactions that may increase susceptibility to lumbar disk disease by disrupting normal building and maintenance of cartilage.[32] Causes include biochemical (e.g., inflammatory mediators) and biomechanical alterations (e.g., mechanical loading and compression) of the intervertebral disk tissue. Diminished blood supply and loss of disk proteoglycans cause

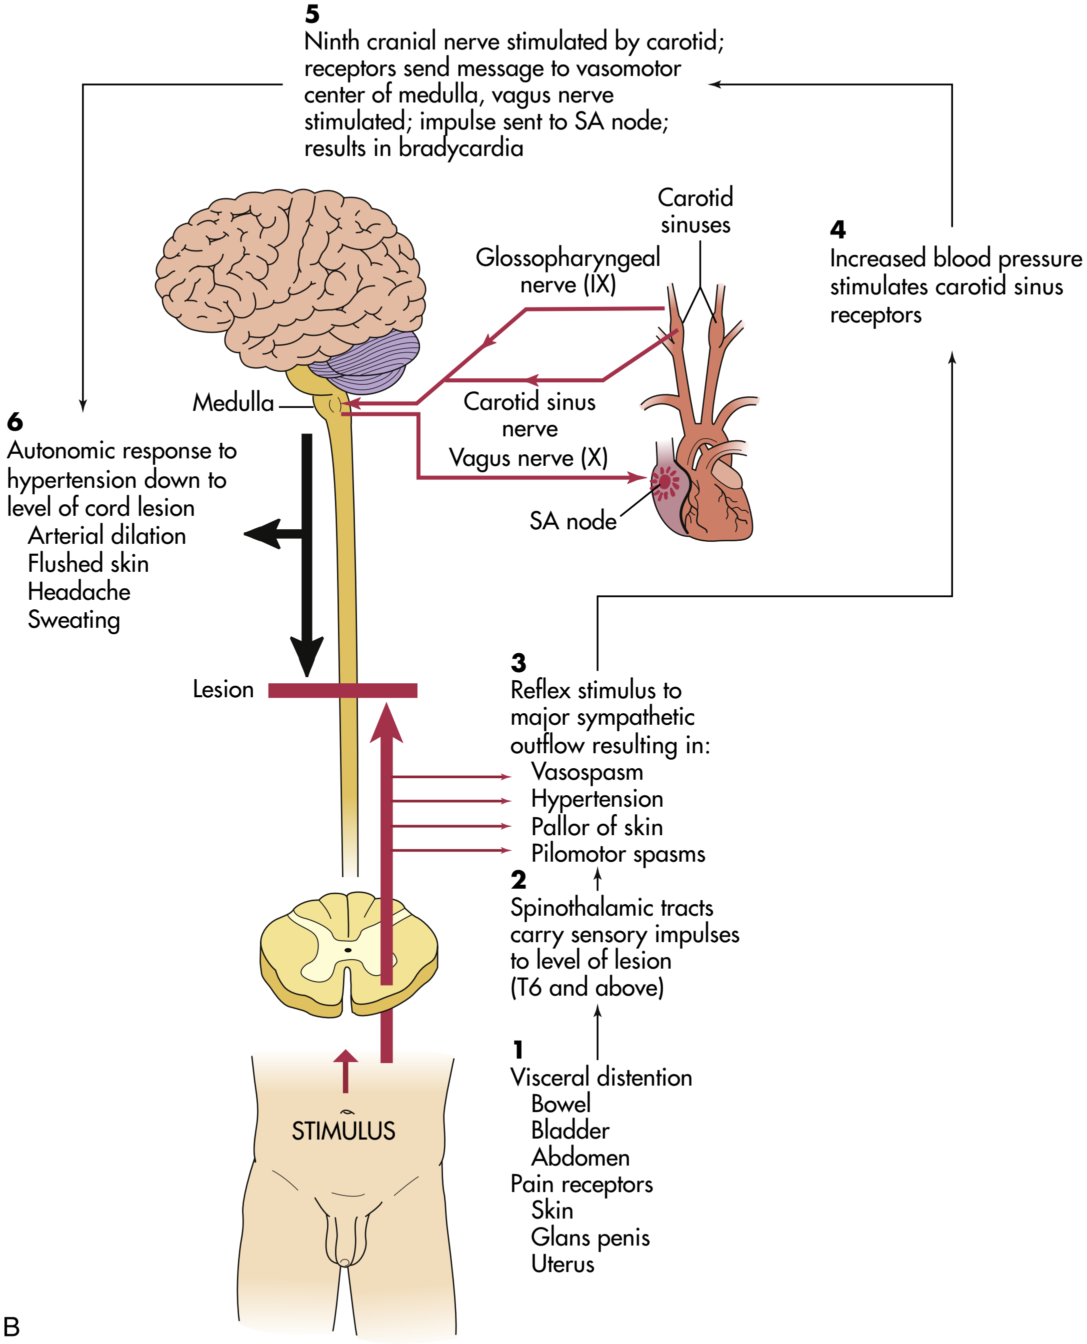

FIGURE 18-13, cont'd B, Autonomic dysreflexia pathway. *SA,* Sinoatrial. (Modified from Rudy EB: *Advanced neurological and neurosurgical nursing,* St Louis, 1984, Mosby.)

subsequent disk dehydration and alterations in disk structure and function. Splits in the annulus fibrosis can permit herniation of the nucleus pulposus, compressing nerves or placing strain on the spine. Fibrocartilage replaces the gelatinous mucoid material of the nucleus pulposus as the disk changes with age. There may be shrinkage of the nucleus pulposus that produces prolapse or folding of the annulus with secondary osteophyte formation at the margins of the adjacent vertebral body. The pathologic findings in DDD include disk protrusion, spondylolysis or subluxation (or both), degeneration of vertebrae (spondylolisthesis), and spinal stenosis.[33]

Symptoms result from either (1) protrusion of the disk or annulus or (2) narrowing of the spinal canal or intervertebral foramen by osteophytes. A congenital narrow canal or congenitally short pedicles may be present. Posterior disk protrusion in the cervical, thoracic, and lumbar regions leads to spinal cord compression causing *myelopathy* (pathology in the spinal cord). Posterolateral disk protrusions, with or without a contribution from the vertebral body or apophyseal joint osteophytes, lead to nerve root compression causing *radiculopathy* (nerve root damage).

Thoracic disk disease is rarely symptomatic. Lumbosacral disk disease *(lumbar spondylosis)* involves degeneration of the

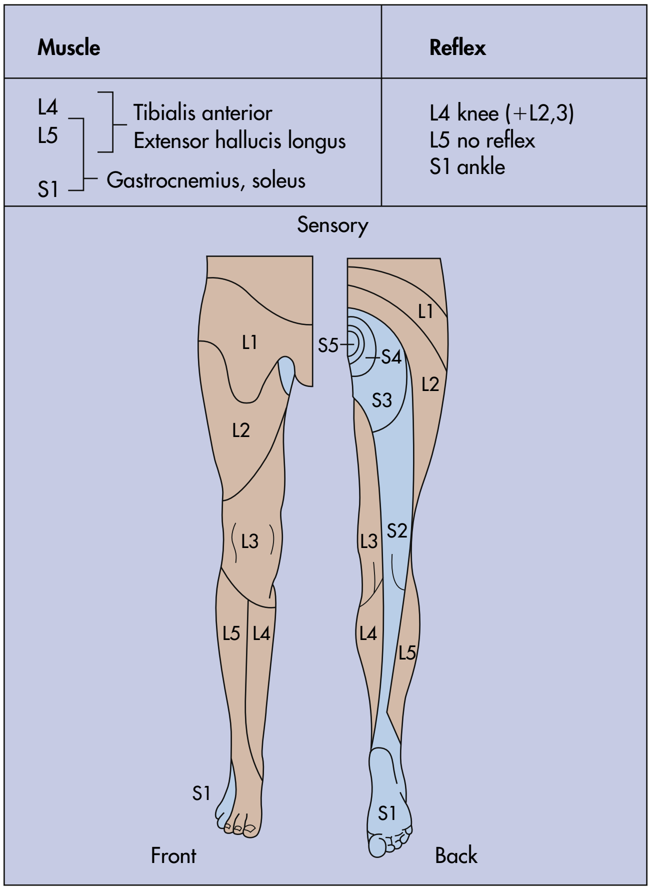

FIGURE 18-14 Motor, Sensory, and Reflex Changes in Lumbosacral Root Disorders. (From Perkin DG et al: *Atlas of clinical neurology,* ed 3, Philadelphia, 2011, Saunders.)

lower two lumbar disks in 90% of persons. There may be (1) lateral disk protrusion (10% of cases), manifesting as pain referred to the anterior thigh and leg; (2) posterolateral disk protrusion; or (3) central disk protrusion, manifesting with pain, lower extremity weakness, impaired sphincter function, and saddle anesthesia. Clinical manifestations of posterolateral protrusions (Figure 18-14) include pain in the back, the sacroiliac joint, and the medial aspect of the buttock and upper thigh; radicular pain exacerbated by movement and straining (medial calf suggests L5, lateral calf suggests S1 root compression); sensory symptoms that are common and segmental in distribution; focal tenderness on palpation of the back; limited range of motion in the back and scoliosis secondary to paravertebral spasms; restricted straight-leg raising (root at or below L5); positive femoral stretch test (roots of L2, L3, or L4); and focal signs that are determined by the root affected.

Spondylolysis. **Spondylolysis** is a degenerative process of the vertebral column and associated soft tissue. It is characterized by a structural defect of the spine involving the lamina or neural arch of the vertebra. The most common site affected is the lumbar spine. This defect occurs in the portion of the lamina between the superior and inferior articular facets called the *pars interarticularis.* Mechanical pressure may cause a forward displacement of the deficient vertebra called *spondylolisthesis.*

Heredity plays a significant role, and spondylolysis is associated with an increased incidence of other congenital spinal defects. As a result of torsional and rotational stress, "microfractures" occur at the affected site and eventually cause dissolution of the pars interarticularis.

Spondylolisthesis. **Spondylolisthesis** is an osseous defect of the pars interarticularis allowing a vertebra to slide forward in relation to the vertebra below, commonly occurring at L5-S1. It is more prevalent in adolescent athletes.[34] Spondylolisthesis is graded from 1 to 4 on the basis of the percentage of slip that has occurred. Individuals with grade 3 or 4 are considered for operative decompression or stabilization, or both. Grades 1 and 2 usually are managed symptomatically and with nonsurgical methods.

Cervical spondylolysis is facet hypertrophy and disk degeneration with narrowing in the cervical spine predominantly at C5-C6 and C6-C7.[35] It may present as a cervical radiculopathy or a cervical myelopathy. Clinical manifestations of cervical radiculopathy include neck or occipital pain as well as pain in the medial aspects of the scapula, the shoulder, or arm. Sensory symptoms, such as tingling or numbness, follow a dermatomal pattern; weakness follows the pattern of innervation of the affected nerve root. Occipital or suboccipital headache is another symptom. Clinical manifestations of cervical myelopathy include difficulty walking, altered sensation in the feet, and sphincter disturbances (occurs late).

Spinal Stenosis. In **spinal stenosis** the spinal canal may be congenitally narrowed or narrowed by a bulging annulus, a facet hypertrophy, or a thick/ossified posterior longitudinal ligament entrapping a single nerve involving many roots. It is classified as acquired (more common) or developmental (such as occurs in achondroplastic dwarfism). It is categorized by area of the spine affected: cervical, thoracic, or lumbar. Surgical decompression is recommended for those with long-term symptoms and those who remain unresponsive to medical management.

Low Back Pain

The annual incidence of, or percentage of population affected with, low back pain ranges from 6.3% to 15.4%. Men and women are affected equally; however, women report low back symptoms more often after the age of 60 years. About 1% to 2% of individuals with acute low back pain are disabled.[36] Several risk factors have been identified in the pathogenesis of low back pain. They include involvement caused by occupations that require repetitious lifting in the forward bent-and-twisted position, exposure to vibrations caused by vehicles or industrial machinery, psychosocial workplace factors, and obesity. Osteoporosis increases the risk of spinal compression fractures and may be the reason older adult women report more symptoms than men. Genetic predispositions for low back pain include isthmic spondylolisthesis (vertebra slides forward or slips in relation to a vertebra below), spinal osteochondrosis, and spinal stenosis associated with achondroplasia.[37]

PATHOGENESIS. Most cases of low back pain are idiopathic or nonspecific, and clinicians are unable to provide a precise diagnosis for most individuals with this disorder.[38] Local processes may be involved in low back pain, including tension caused by

tumors or disk prolapse, bursitis, synovitis, rising venous and tissue pressures (found in degenerative joint disease), abnormal bone pressures, problems with spinal mobility, inflammation caused by infection (as in osteomyelitis), bony fractures, ligamentous sprains, and inflammation of the lumbar facet joints. Pain can be referred from viscera or the posterior peritoneum. Other causes of low back pain include bone diseases, such as osteoporosis or osteomalacia, and hyperparathyroidism.[39]

Anatomically, low back pain must come from innervated structures, but deep pain is widely referred and varies from person to person. The nucleus pulposus has no intrinsic innervation; however, when extruded or herniated through a prolapsed disk, it irritates the dural membranes and is responsible for pain referred to the associated segmental area (see Figure 18-14). The interspinous bursae can be a source of low back pain between L3, L4, L5, and S1, but also may affect L1, L2, and L3 spinous processes, depending on the closeness of the adjacent pair of spines. The anterior and posterior longitudinal ligaments of the spine and the interspinous and supraspinous ligaments are abundantly supplied with pain receptors, as is the ligamentum flavum. All of these ligaments are vulnerable to traumatic tears (sprains) and fracture. The role of muscle injury in the production of low back pain remains uncertain, even though sprains and strains are the most common diagnoses. The muscle spasms that often are produced during sieges of low back pain are thought to be produced by as yet unknown sensory or motor-reflex pathways. The most commonly encountered causes of low back pain include lumbar disk herniation, degenerative disk disease, spondylolysis, spondylolisthesis, and spinal stenosis. (For a discussion of disk herniation and rupture, see following text.) Chronic low back pain can cause central sensitization (see Chapter 16) and abnormal endogenous pain modulation.

CLINICAL MANIFESTATIONS. Low back pain affects the area between the lower rib cage and gluteal muscles and often radiates into the thighs. About 1% of individuals with acute low back pain have sciatica or pain in the distribution of the sciatic nerve or lumbar and sacral nerve roots. Sciatica often is accompanied by neurosensory and motor deficits, such as weakness. Major or progressive motor or sensory deficit, cauda equina syndrome (new-onset bowel or bladder incontinence or urinary retention, loss of anal sphincter tone, saddle anesthesia), history of cancer metastatic to bone, and suspected spinal infection can be associated with chronic low back pain.

EVALUATION AND TREATMENT. Diagnosis of low back pain is made by personal history; physical examination; electromyography (EMG), epidurography, diskography, and imaging (MRI and CT) for specific clinical conditions; and nerve conduction studies. Most individuals with acute low back pain benefit from a nonspecific short-term treatment regimen including nonsteroidal anti-inflammatory medications, exercises, physical therapy, and education. Individuals with chronic low back pain (pain for more than 3 months) can be treated with anti-inflammatory and muscle relaxant medications, exercise programs, massage, topical heat, spinal manipulation, cognitive-behavioral therapy, and interdisciplinary care.[39] Surgical treatments for identified pathologic conditions include diskectomy and spinal fusions. Radiotherapy is used for treatment of facet-related pain after diagnostic nerve block. Evaluation of treatment outcomes should include pain, function, and quality of life.[40]

FIGURE 18-15 **Disk Bulge, Protrusion, and Herniation.** Sagittal T2-weighted image demonstrates examples for all stages of disk pathology. Viewing from rostral to caudal, a disk bulge *(arrow),* a small and more prominent protrusion *(arrowheads),* and a herniation *(double arrowhead)* are seen. (From Daroff RB et al: *Bradley's neurology in clinical practice,* Philadelphia, 2012, Saunders.)

Herniated Intervertebral Disk

Herniation of an intervertebral disk is a displacement of the disk material (nucleus pulposus or annulus fibrosis) beyond the intervertebral disk space (Figure 18-15). Men are more affected than women, with the highest incidence in the 30- to 50-year age group. The lumbosacral disks (L4-L5, L5-S1) are most commonly affected. Disk herniation occasionally occurs in the cervical area, usually at C5-C6 and C6-C7. Herniations at the thoracic level are extremely rare. Risk factors for herniation include weightlifting sports and certain work activities, such as repeated lifting. Rupture of an intervertebral disk usually is caused by trauma or degenerative disk disease, or both. The injury may occur immediately, within a few hours, or months to years after injury.

PATHOPHYSIOLOGY. In a herniated disk the ligament and posterior capsule of the disk usually are torn, allowing the gelatinous material (the nucleus pulposus) to extrude. This extrusion compresses the nerve root, compromising the vascular supply and causing inflammatory-like changes. Occasionally the injury tears the entire disk loose, and it protrudes onto the nerve root or compresses the spinal cord. One or more nerve roots may be compressed. This multiple nerve root compression is found especially at the L5-S1 level, where the cauda equina may be compressed. Large amounts of extruded nucleus pulposus or complete disk herniation (i.e., of both the capsule and the nucleus pulposus) may compress the spinal cord.

CLINICAL MANIFESTATIONS. The location and size of the herniation into the spinal canal, together with the amount of space that exists inside the spinal canal, determine the clinical manifestations associated with the injury. A herniated disk in the lumbosacral area is associated with pain that radiates along the sciatic nerve course over the buttock and into the calf or ankle. The pain occurs with straining, including coughing and sneezing, and usually on straight-leg raising. Other clinical manifestations include limited range of motion of the lumbar spine; tenderness on palpation in the sciatic notch and along the sciatic nerve; impaired pain, temperature, and touch sensation in the L5-S1 or L4-L5 dermatomes of the leg and foot; decreased or absent ankle jerk reflex; and mild weakness of the foot.

With the herniation of a lower cervical disk, paresthesias and pain are present in the upper arm, forearm, and hand in the affected nerve root distribution. Neck and nerve root pain may be increased by neck motion and straining, including coughing and sneezing. Neck range of motion is diminished. Slight weakness and atrophy of biceps or triceps may occur; the biceps or triceps reflex may decrease. Occasionally signs of corticospinal and sensory tract impairments appear. These include motor weakness of the lower extremities, sensory disturbances in the lower extremities, and presence of a Babinski reflex.

EVALUATION AND TREATMENT. Diagnosis of a herniated intervertebral disk is made on the basis of the history and physical examination, EMG results, imaging procedures when there are signs of systemic disease, and nerve conduction studies. Radiologic evidence of disk herniation does not reliably correlate with symptoms or predict low back pain. Many individuals with disk herniation on imaging have no symptoms.[41] Clinical improvement occurs in most people over weeks to months. The herniated disk portion on serial imaging tends to regress over time.[42] There is little evidence to support drug treatments, including the use of analgesics, antidepressants, or muscle relaxants.[43] Randomized controlled trials are needed to evaluate conservative therapy (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs], bed rest, epidural injections of nonsteroidals, activity, acupuncture, massage, exercise, heat, or ice).[44,45] A surgical approach is indicated if there is evidence of progressive neurologic deficit (e.g., weakness, decreased deep tendon reflexes, and bladder/bowel reflexes) or cauda equina syndrome (saddle anesthesia, decreased or absent reflexes in the lower extremities, and neurogenic bowel or bladder dysfunction).[46]

Cerebrovascular Disorders

Cerebrovascular disease is the most frequently occurring neurologic disorder. More than 50% of persons admitted to general hospitals with neurologic problems have cerebrovascular disease. Any abnormality of the brain caused by a pathologic process in the blood vessels is referred to as a *cerebrovascular disease*. Included in this category are lesions of the vessel wall (e.g., aneurysm or malformations) and strokes or cerebrovascular accidents.

Cerebrovascular Accidents (Stroke Syndromes)

The incidence of new and recurrent stroke is 795,000, and approximately 185,000 of these are recurrent. Strokes are the third leading cause of death in the United States, resulting in about 134,148 deaths. The incidence of stroke is about two times higher in blacks than whites. Stroke tends to run in families. Of all strokes, 87% are ischemic (thrombotic or embolic), 10% are intracerebral hemorrhagic, and 3% are subarachnoid hemorrhagic.[47] No identifiable cause can be established by conventional diagnostic tests in many ischemic strokes and they are classified as “undetermined” or “cryptogenic.” Strokes in children are presented in Chapter 20.

The mildest outcome of a cerebrovascular accident (CVA) is so minimal as to be almost unnoticed. The most severe outcomes are hemiplegia, coma, and death. Strokes are classified according to pathophysiology: ischemic (thrombotic or embolic) is the most common, global hypoperfusion (as in shock), or intracerebral hemorrhage.[47] Hypertension is the single greatest risk factor for stroke.[48] Risk factors for stroke include the following[49]:

1. Arterial hypertension
2. Intracranial atherosclerosis
3. Insulin resistance and diabetes mellitus
4. High total cholesterol or low high-density lipoprotein (HDL) cholesterol level, elevated lipoprotein-A level
5. Hyperhomocysteinemia
6. Congestive heart disease and peripheral vascular disease
7. Asymptomatic carotid stenosis
8. Polycythemia and thrombocythemia
9. Atrial fibrillation and patent ductus arteriosus
10. *Chlamydia pneumoniae* infection promotes atherosclerosis[50]
11. Sickle cell disease
12. Postmenopausal hormone therapy
13. High sodium intake, >2300 mg; low potassium intake, <4700 mg
14. Smoking
15. Physical inactivity
16. Obesity
17. Chronic sleep deprivation
18. Depression

Ischemic Stroke

PATHOPHYSIOLOGY. **Thrombotic strokes (cerebral thrombosis)** arise from arterial occlusions caused by thrombi formed in the arteries supplying the brain or in the intracranial vessels. The development of a cerebral thrombosis most frequently is attributed to atherosclerosis and inflammatory disease processes (arteritis) that damage arterial walls. Increased coagulation can lead to thrombus formation. Conditions causing inadequate cerebral perfusion (e.g., dehydration, hypotension, prolonged vasoconstriction from malignant hypertension) increase the risk of thrombosis. Over 20 to 30 years, atheromatous plaques (stenotic lesions) tend to form at branchings and curves in the cerebral circulation. The smooth stenotic area can degenerate, forming an ulcerated area of vessel wall. Platelets and fibrin adhere to the damaged wall, and clots form, gradually occluding the artery. The thrombus may enlarge both distally and proximally in the vessel. Portions of the clot detach and travel up the vessel to distant sites where occlusion occurs, producing a stroke syndrome.

Transient ischemic attacks (TIAs) are transient episodes of neurologic dysfunction (weakness, numbness, sudden confusion, loss of balance, loss of vision, sudden severe headache) resulting from focal cerebral ischemia. However, use of brain imaging techniques (e.g., diffusion-weighted imaging) in persons with symptoms lasting less than 24 hours often reveals a brain infarction that requires treatment intervention to prevent stroke. About 30% of individuals experiencing a TIA will have a stroke within 1 year. Risk stratification for early stroke is enhanced when imaging is combined with a risk stratification score (e.g., the ABCD2 score, which considers age, neurologic symptoms, symptom duration, and diabetes).[51]

Embolic stroke involves fragments that break from a thrombus formed outside the brain or in the heart, aorta, or common carotid artery. Other sources of embolism include fat, air, tumor, bacterial clumps, and foreign bodies. The embolus usually involves small vessels and obstructs at a bifurcation or other point of stenosis, thus causing ischemia. An embolus may obstruct the lumen entirely and remain in place or shatter into fragments and become part of the vessel's blood flow. Risk factors for an embolic stroke are atrial fibrillation (15% to 25% of strokes), left ventricular aneurysm or thrombus, left atrial thrombus, recent myocardial infarction, rheumatic valvular disease, mechanical prosthetic valve, nonbacterial thrombotic endocarditis, bacterial endocarditis, patent foramen ovale, and primary intracardiac tumors.[52] In persons who experience an embolic stroke, a second stroke usually follows at some point because the source of emboli continues to exist. Embolization is usually in the distribution of the middle cerebral artery (the largest cerebral artery).

Cerebral Infarction. Cerebral infarction results when an area of the brain loses blood supply and becomes ischemic because of vascular occlusion (embolic or thrombotic). The pathologic manifestation is either (1) a global process that affects neurons most susceptible to ischemia (pyramidal and striatal neurons), Purkinje cells of the cerebral hemispheres, and the border zones at the very end of the circulation of the artery; or (2) a focal process with a central zone of infarction surrounded by a zone of reversible ischemia, the ischemic penumbra, which if perfused in 1 hour will survive. Proposed pathogenesis may include: (1) abrupt vascular occlusion (e.g., embolus), (2) gradual vessel occlusion (e.g., atheroma), and (3) vessels that are stenosed but not completely occluded. Cerebral thrombi and cerebral emboli are the most common causes of occlusion, but atherosclerosis and hypotension are the dominant underlying processes.

Cerebral infarctions are ischemic. In ischemic infarcts (pale infarcts, "white stroke"), cytotoxic ischemic events and interaction between blood elements and blood vessels combine to produce brain injury. The affected area becomes slightly discolored and softens about 6 to 12 hours after the occlusion. Necrosis, swelling around the insult, and mushy disintegration have appeared by 48 to 72 hours after infarction. At a microscopic level, neuronal cell bodies change, myelin sheaths and axis cylinders are interrupted and disintegrate, and loss of oligodendrites and astrocytes occurs. Secondary cellular and biochemical events contribute to neuronal injury and death (see Secondary Brain Injury, p. 588).

A syndrome of luxury perfusion (increased blood flow to the brain but decreased O_2 uptake by cerebral tissue) in areas adjacent to the infarct develops first from the loss of autoregulation. The vascular bed in this area dilates. Later, capillary sprouting (neovascularization) supports this luxury perfusion syndrome.

In hemorrhagic infarcts ("red strokes"), bleeding occurs into the infarcted area as a result of restoration of blood flow. Reperfusion occurs when the embolus fragments, or lysis or compressive forces lessen, allowing blood flow to be reestablished into the infarcted area. Most hemorrhagic infarcts are located in the cerebral cortex. Unfortunately, reperfusion can compromise recovery by accelerating the sequence of metabolically damaging events including oxidative stress (reperfusion injury).

Lacunar Stroke. A **lacunar stroke (lacunar infarct)** is a microinfarct smaller than 1 cm in diameter and involves occlusion of the small perforating arteries, predominantly in the basal ganglia, internal capsules, and pons. Lacunar infarcts are caused by lipohyalinosis, subintimal lipid-loading foam cells, and fibrinoid materials that thicken the arterial walls. The small arterioles lengthen, become tortuous, and develop subintimal dissections and microaneurysms. They are associated with hyperlipidemia, smoking,[53] hypertension, and diabetes mellitus. Because of the subcortical location and small area of infarction, these strokes may have pure motor and sensory deficits.

CLINICAL MANIFESTATIONS. Because neurons surrounding the ischemic or infarcted areas undergo changes that disrupt plasma membranes, cellular edema results, causing compression of capillaries. Most persons survive an initial hemispheric ischemic stroke unless massive cerebral edema develops. Massive brainstem infarcts, caused by basilar thrombosis or embolism, are almost always fatal.

Clinical manifestations of thrombotic or ischemic stroke vary, depending on the artery obstructed. Different sites of obstruction create different occlusion syndromes (Table 18-5).

EVALUATION AND TREATMENT. Treatment of ischemic stroke is focused on (1) restoring brain perfusion in a timeframe that does not contribute to reperfusion injury, (2) counteracting the ischemic cascade pathways, (3) lowering cerebral metabolic demand so that the susceptible brain tissue is protected against impaired perfusion, (4) preventing recurrent ischemic events, and (5) promoting tissue restoration. Thrombolysis (i.e., tissue-type plasminogen activator [tPA]) given within 3 and up to 4.5 hours of onset of symptoms reduces dependency at 6 months when the diagnosis of ischemic stroke has been confirmed and contraindications are eliminated. Endovascular intra-arterial thrombolysis can be used to treat those who cannot receive tPA.[54] Because of the short time window of efficacy, some individuals are not eligible for tPA therapy and antiplatelet agents are administered. Aspirin, clopidogrel, or aspirin plus extended-release dipyridamole have been shown to effectively reduce death and dependency at 6 months when initiated within 48 hours. Systemic anticoagulants (unfractionated heparin, low-molecular-weight heparin, or fondaparinux) are used to prevent venous thromboembolism, particularly in immobilized individuals.[55] Acute ischemic stroke frequently presents with hypertension, but the systemic blood pressure should not be treated unless the systolic pressure exceeds 220 mmHg or the

TABLE 18-5 STROKE SYNDROMES SECONDARY TO OCCLUSION OR STENOSIS

LOCATION/VESSEL	AREA OF BRAIN INFARCTED	SIGNS AND SYMPTOMS NOTED
Anterior and Central Circulation		
NOTE: The internal carotid artery enters the circle of Willis and supplies the lateral anterior and central portions of the cerebral hemispheres through the middle cerebral artery and the paramedial frontal lobe superior to the corpus callosum through the anterior cerebral artery; penetrating branches serve the deeper layers of the hemispheres.		
Internal carotid	If collateral circulation is intact, commonly no infarction has occurred; if infarcted, location is same as in the middle cerebral artery	• Arterial pressure may be low in the retina • Bruit over the internal carotid artery • Possible retinal emboli • History of transient ischemic attacks (TIAs) • Positive noninvasive studies
Middle cerebral artery (MCA) (most common area); either stem or branches of MCA	Cortical motor area (face, arm, leg) and/or posterior limb, internal capsule, corona radiata	• **Motor:** contralateral hemiparesis or hemiplegia, greater in face and arm than leg
	Cortical sensory area (face, arm, leg) and/or posterior limb of internal capsule	• **Sensation:** contralateral loss in same distribution as motor loss
	Broca area and deep fibers in the dominant hemisphere	• **Speech:** expressive (motor) disorder with anomia (left hemisphere most commonly affected) with nonfluent aphasia and some comprehension defects
	Broca area and deep fibers in the nondominant hemisphere	• **Speech:** dysarthria
	Optic radiations deep in the temporal lobe	• **Vision:** contralateral homonymous hemianopsia or quadranopsia • **Motor:** mirror movement
	Location not known	• **Respirations**: Cheyne-Stokes respirations, contralateral hyperhidrosis, occasional mydriasis
	Posterior limb or internal capsule and adjacent corona radiate	• **Motor:** pure motor hemiplegia
	Penetrating branches of MCA (lenticulostriate branches) into the basal nuclei	• **Motor:** varying degrees of contralateral weakness of face, arm, or leg • **Sensory:** little or no loss; if present, contralateral following the motor distribution • **Speech:** transcortical sensory aphasia (communicating pathways are interrupted) • **Perception:** transient visual and sensory neglect on the left if a right lesion
Anterior cerebral artery (ACA) (least common)	Proximal segment: corona radiata (rarely)	• **Motor:** when present, a mild contralateral hemiparesis, greater in leg; with bilateral occlusion of ACA, cerebral paraplegia in both legs can occur
	Main stem (complete occlusion is uncommon, thus areas affected differ and collateral circulation may alleviate signs or symptoms); medial aspect of frontal lobes, caudate nucleus, and corpus callosum are supplied by the ACA	• **Motor:** contralateral paralysis or paresis (greater in foot and thigh); mild upper extremity weakness • **Sensory:** mild contralateral lower extremity deficiency with loss of vibratory and/or position sense, loss of two-point discrimination • **Speech:** may have transcortical motor and sensory aphasia if left hemisphere • Frontal lobe releasing signs • Apraxia
Posterior Circulation		
NOTE: The posterior circulation includes the posterior cerebral artery, the vertebral arteries, and the basilar artery; the anatomic territory covered includes the posterior aspects of the hemispheres, the central areas of the thalamus and midbrain, and the brainstem; occlusion of the vessels is most commonly by emboli; effects of infarct in these vessels and their penetrating vessels can be specific or devastatingly global; many complex syndromes have been identified.		
Vertebral arteries	Medulla and spinal cord tracts, anterior spinal artery and penetrating branches (medial medullary syndrome)	• **Motor:** contralateral hemiparesis (face spared) and/or impaired contralateral proprioception; flaccid weakness or paralysis of the tongue and/or dysarthria

TABLE 18-5 STROKE SYNDROMES SECONDARY TO OCCLUSION OR STENOSIS—cont'd

LOCATION/VESSEL	AREA OF BRAIN INFARCTED	SIGNS AND SYMPTOMS NOTED
Basilar artery (three sets of branches)	Midline structures of pons (paramedian branches); three general areas of infarction are common: (1) medial inferior pontine syndrome, (2) medial midpontine syndrome, and (3) medial superior pontine syndrome Corticospinal and corticobulbar tracts in pons, sensory tracts of medial and lateral lemnisci, vestibular nuclei, inferior and middle cerebellar peduncles, cranial nerve nuclei and/or fibers, cerebellar connections in tectum, descending sympathetic pathways, central brainstem, pontine tegmentum (vertebrobasilar syndrome)	• **Motor:** contralateral hemiparesis or hemiplegia, ipsilateral lower motor neuron facial palsy, "locked-in syndrome" • **Sensory:** contralateral loss of vibratory sense, sense of position with dysmetria, loss of two-point discrimination, impaired rapid alternating movements • **Visual:** inferior pontine: diplopia; impaired abduction of ipsilateral eye: internuclear ophthalmoplegia; medial superior: diplopia, internuclear ophthalmoplegia, skewed deviation • **Motor:** upper motor neuron type of weakness: paralysis in combinations involving face, tongue, throat, and extremities; dysphagia, facial weakness, dysmetria, ataxia (either trunk or extremities), weak mastication muscles • **Sensation:** combinations of impaired sensation (vibratory, two-point, position sense, pain, temperature), facial hypesthesia, anesthesia of cranial nerve V
Posterior cerebral artery (PCA)	Central territory (thalamic area, dentothalamic tract, cerebral peduncle, red nucleus, subthalamic nucleus, and cranial nerve III)	• **Motor:** contralateral hemiplegia with possible dysmetria, dyskinesia, hemiballism or choreoathetosis, dystaxia, cerebellar ataxia, and tremor; contralateral upper motor neuron palsy; several syndromes are associated: (1) Weber: cranial nerve III palsy and contralateral hemiplegia; (2) thalamoperforate syndrome: superior crossed cerebellar ataxia or inferior crossed cerebellar ataxia with cranial nerve III palsy (Claude syndrome); (3) decerebrate attacks • **Sensory:** contralateral sensory loss of all modalities without agraphia • **Function:** prosopagnosia (inability to recognize familiar faces), topographic disorientation, memory deficits, alexia, inability to read, color anomia • **Level of consciousness:** in bilateral PCA syndromes, coma with absent doll's eyes reflex or loss of alertness may occur; if tegmentum of midbrain near hypothalamus and third ventricle is damaged, akinetic mutism may occur
Small Vessel Disease		
Note: Small penetrating vessels in brain parenchyma that supply areas near the basal ganglia are most vulnerable to infarction although any small vessels can occlude deep in the brain and cause injury, producing neurologic signs or symptoms; such infarcts are commonly called *lacunes* (small pit or hollow), a term that is changing in meaning; they can be caused by emboli but are most commonly associated with microatheromas; although they can be found in otherwise healthy people, those with concurrent atherosclerosis, arterial hypertension, and/or diabetes have a higher incidence of this type of infarct.		
	Internal capsule, most commonly	• **Motor:** contralateral hemiparesis on a single side, with equal deficit in face, arm, and leg; often unaccompanied by detectable signs of sensory, visual, and speech loss, depending on location; old term is "pure motor stroke" although evidence suggests that other neurologic signs are present but overlooked because of low intensity
	Thalamus, most commonly	• **Sensory:** complete or partial loss in face, arm, trunk, and leg that appears exactly midline; may be accompanied by pain, hyperesthesias, and uncomfortable sensations (hemisensory stroke)
	Pons	• Dysarthria, clumsy hand
	Pons, midbrain, capsule or parietal white matter	• Hemiparesis, ataxia on same side

diastolic pressure exceeds 120 mmHg. Overly aggressive treatment of hypertension can compromise collateral perfusion of the ischemic penumbra.[56] When the pathophysiology of stroke is stabilized, all individuals should receive BP-lowering therapy to maintain BP lower than 140/90 mmHg.[57-59] Hypothermia has been used for neuroprotection in ischemic stroke with some promising results, but additional studies are needed to determine clinical practice guidelines.

Neuroprotective agents (calcium channel antagonists, citicoline, gamma-aminobutyric acid [GABA] agonists, glycine antagonists, magnesium, *N*-methyl-D-aspartate antagonists, tirilazad) have not been shown to significantly reduce the risk

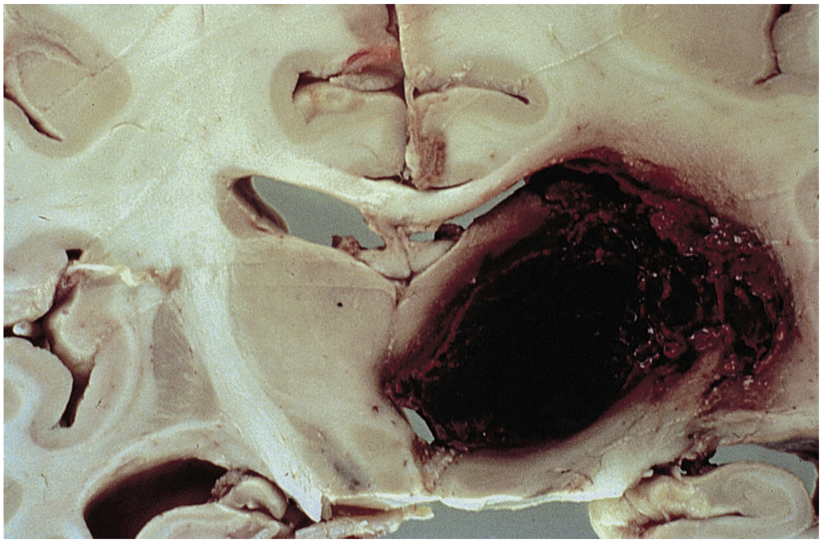

FIGURE 18-16 **Hypertensive Hemorrhage.** Cross section of the pons showing a hypertensive hemorrhage. (From Damjanov I: *Pathology for the health professions,* Philadelphia, 2012, Saunders.)

of poor outcome including death or improve outcomes with ischemic stroke. New neuroprotective agents are being evaluated.[60] For acute ischemic stroke, cholesterol reduction using statins appears to provide neuroprotection and improve both incidence and survival.[61]

Hemorrhagic Stroke. **Hemorrhagic stroke (spontaneous intracranial hemorrhage [ICH])** is spontaneous bleeding into the brain. It is the third most common cause of CVA and accounts for 8% to 18% of CVAs in whites but 30% in blacks and Asians.[53] There are about 40,000 ICHs in the United States per year.[62] Risk factors for hemorrhagic stroke include hypertension, previous cerebral infarct, coronary artery disease, and diabetes mellitus. The most common causes of spontaneous primary hemorrhagic strokes are hypertension (56% to 81%), ruptured aneurysms, arteriovenous malformation and fistula, amyloid angiopathy, and cavernous angioma.[62] ICH can occur secondary to traumatic brain injury, bleeding into ischemic brain infarction or tumor, or bleeding disorder or anticoagulation therapy.

PATHOPHYSIOLOGY. A hypertensive hemorrhage is associated with a significant increase in systolic and diastolic pressure over several years and usually occurs within the brain tissue. The pathogenesis of hypertensive cerebral hemorrhage is not fully understood. Hypertension involves primarily smaller arteries and arterioles, resulting in thickening of the vessel walls and increased cellularity of the vessels and hyalinization. Necrosis may be present. Microaneurysms in these smaller vessels or arteriolar necrosis precipitates the bleeding.

Hemorrhages are described as massive, small, slit, or petechial. A massive hemorrhage is several centimeters in diameter; a small hemorrhage is 1 to 2 cm in diameter; a slit hemorrhage lies in the subcortical area; and a petechial hemorrhage is the size of a pinhead bleed. The most common sites for hypertensive hemorrhages are in the putamen of the basal ganglia (a portion of the lentiform nucleus) (40%), the thalamus (15%), the cortex and subcortex (22%), the pons (8%) (Figure 18-16), caudate (7%), and cerebellar hemispheres (8%).

With bleeding, a mass of blood is formed and its volume increases. In massive intracerebral hemorrhage (volume greater than 150 ml), cerebral perfusion falls to zero and cerebral blood flow stops, resulting in death. In strokes with less than massive hemorrhage, adjacent brain tissue is displaced and compressed. Necrosis around the hematoma is present within 6 hours. Edema forms and the blood-brain barrier is disrupted. An inflammatory reaction in surrounding brain tissue appears rapidly and peaks in several days.[62] Figure 18-17 illustrates additional detail. Rupture or seepage of blood into the ventricular system occurs in many cases.[62] The cerebral hemorrhage resolves through reabsorption. Macrophages and astrocytes appear to dissipate the blood. A cavity forms, which is surrounded by a dense gliosis after removal of the blood.

CLINICAL MANIFESTATIONS. With hemorrhagic stroke, clinical manifestations vary according to the location and size of the bleed. Focal neurologic deficits are found in 80% of individuals experiencing hemorrhagic strokes; altered consciousness occurs in 50%. Once a deep unresponsive state occurs the immediate prognosis is grave, and the individual rarely survives. If the person survives, however, recovery of function frequently is possible.

Individuals experiencing intracranial hemorrhage from a ruptured or leaking aneurysm have one of three sets of symptoms: (1) onset of an excruciating generalized headache with an almost immediate lapse into an unresponsive state; (2) headache, but with consciousness maintained; and (3) sudden lapse into unconsciousness. If the hemorrhage is confined to the subarachnoid space, there may be no local signs. If bleeding spreads into the brain tissue, hemiparesis/paralysis, dysphasia, or homonymous hemianopsia may be present. Warning signs of an impending aneurysm rupture may include headache, transient unilateral weakness, transient numbness and tingling, and transient speech disturbance. Warning signs, however, often are not present.

EVALUATION AND TREATMENT. Clinical guidelines for the management of spontaneous intracerebral hemorrhage have been published by the American Heart Association/American Stroke

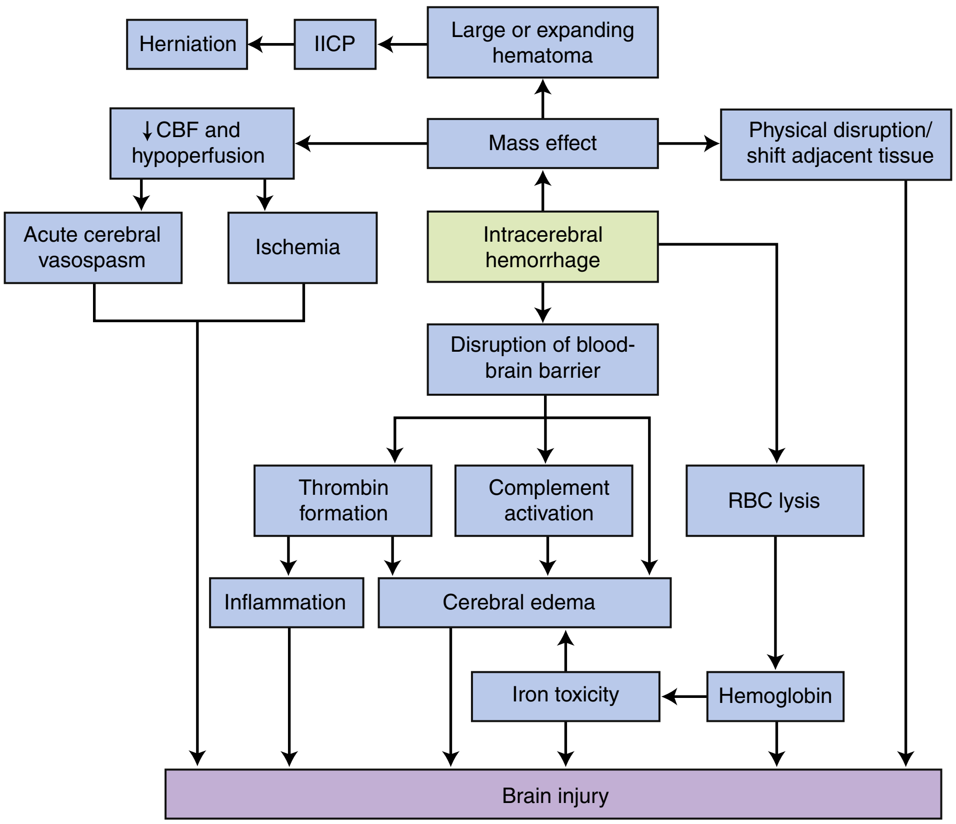

FIGURE 18-17 **Injury Mechanisms Promoted by Intracerebral Hemorrhage.** Hemorrhages can induce neuronal injury through mass effect, particularly in large hematomas that can *cause* increased intracranial pressure and herniation. Hemorrhages may also cause tissue damage through cerebral edema and secondary "neurotoxic" mechanisms caused by activation of the coagulation cascade and inflammation. Not all potential interactions are shown (e.g., thrombin may potentiate iron-induced injury; the complement and inflammatory systems overlap and several factors contribute to cerebral edema). *CBF,* Cerebral blood flow; *IICP,* increased intracranial pressure; *RBC,* red blood cell. (Data from Mocco J et al: *Neurosurg Focus* 15:22[5]:E7, 2007; Schubert GA, Thome C: *Front Biosci* 13:1594–1603, 2008; Xi G, Keep RF, Hoff JT: *Lancet Neurol* 5[1]:53–63, 2006.)

Association.[63] Diagnosis of hemorrhagic stroke considers the health history, clinical presentation, laboratory tests, and neuroimaging procedures (CT and MRI). Treatment needs to be initiated within 3 to 4 hours of symptom onset for reversibility of brain ischemia. Care in multidisciplinary stroke rehabilitation units appears to be most effective at reducing disability, dependency and length of hospital stay for all stroke syndromes.[64]

Treatment of a hemorrhagic stroke, regardless of cause, is focused on: (1) stopping or reducing the bleeding, (2) controlling increased ICP, (3) preventing a rebleed, (4) preventing vasospasm, and (5) promoting tissue restoration. Treatment for hemorrhagic stroke includes limiting hematoma enlargement and preventing or controlling seizures and cerebral edema. Known coagulopathies should be corrected and oral anticoagulation reversed. Hematoma enlargement is limited when recombinant activated factor VII is given within 4 hours of onset but it does not improve outcome and is associated with thromboembolic complications.[65] Surgical evacuation does not appear to be an effective treatment for supratentorial ICHs but may be indicated for a large posterior fossa hematoma.[66] Hypertension management is individualized. Elevated blood pressure can expand the hematoma and low blood pressure can contribute to ischemia.[58,67]

Prophylactic treatment of seizures is controversial and when used it is on a short-term basis (e.g., 3 days).[68] Osmotic therapies (e.g., mannitol) are used for the treatment of increased intracranial pressure and cerebral edema in hemorrhagic stroke.[69] Supportive care is provided for airway management; respiratory function; blood pressure control; avoidance of fever; and maintenance of fluids, glucose, electrolytes, and nutrition.

Intracranial Aneurysm. Intracranial aneurysms (weak bulging areas of an arterial vessel wall) may result from arteriosclerosis, congenital abnormality, trauma, inflammation, or infection. Cocaine use has been linked to aneurysm formation. The size of the aneurysm may vary from 2 mm to 3 cm. Most aneurysms are located at bifurcations in or near the circle of Willis, in the vertebrobasilar arteries, or within the carotid system—85% to 95% are in the anterior portion of the circle of Willis (see Figure 15-20 and p. 420). Aneurysms may be single, but in 20% to 25% of cases, more than one is present. In these instances the aneurysms may be unilateral or bilateral. The incidence of rupture is 11 in 100,000 per year. Peak incidence of rupture is from 50 to 60 years of age. Women have a slightly greater incidence of aneurysms.

PATHOPHYSIOLOGY. No single pathologic mechanism exists.[69a] A combination of genetic, congenital, and acquired factors

(hypertension) is present.[70] Abnormalities in multiple layers of the blood vessel are found. The endothelial layer is thin, the internal elastic lamina is not present or fragmented, and the muscularis layer of the media ends at the aneurysm. Atherosclerotic changes are found. Aneurysm development is attributed to hemodynamic and wall shear stress and flow turbulence, particularly at bifurcations, and sites of inflammation and vascular remodeling. They are a symptom of underlying vascular disease. Hypertension and certain connective tissue disorders in which there are abnormalities in the extracellular matrix exacerbate aneurysm formation.[70] The aneurysm wall is composed of fibrous tissue. Aneurysms may be classified on the basis of shape and form (Figure 18-18).[71]

Saccular aneurysms (berry aneurysms) occur frequently (in approximately 2% of the population) and are the result of a combination of a congenital abnormality in the media of the arterial wall and degenerative changes. The sac grows over time. A saccular aneurysm may be (1) round with a narrow stalk connecting it to the parent artery (Figure 18-19), (2) broad based without a stalk, or (3) cylindrical. Saccular aneurysms are rare in childhood; their highest incidence of rupturing or bleeding is among people 20 to 50 years of age.

Fusiform aneurysms (giant aneurysms), by definition greater than 25 mm in diameter, make up 5% of all intracranial aneurysms. They occur as a result of diffuse arteriosclerotic changes and are found most commonly in the basilar arteries or terminal portions of the internal carotid arteries. They act as space-occupying lesions. **Mycotic aneurysms** result from arteritis caused by bacterial emboli (e.g. associated with bacterial endocarditis); these aneurysms are uncommon. **Traumatic (dissecting) aneurysms** are caused by a weakening of the arterial wall by a fracture line, by a penetrating missile, or after neurosurgical or imaging (e.g., angiographic) procedures.

What causes an aneurysm to rupture is not known.[70] Rupture causes hemorrhage into the subarachnoid space (subarachnoid hemorrhage) (see p. 605) with rapid spread, producing localized changes in the cerebral cortex and focal irritation of nerves and arteries. Because of compression, bleeding ceases with the formation of a fibrin-platelet plug at the point of rupture. Blood undergoes reabsorption through arachnoid villi within 3 weeks.

CLINICAL MANIFESTATIONS. Aneurysms are frequently asymptomatic. In routine autopsy, 5% of persons are found to have one or more intracranial aneurysms. Clinical manifestations may arise from cranial nerve compression, but the signs vary, depending on the location and size of the aneurysm. Most often, cranial nerves III, IV, V, and VI are affected (see Table 15-6). Unfortunately the most common first indication of an aneurysm is an acute subarachnoid hemorrhage, intracerebral hemorrhage, or combined subarachnoid-intracerebral hemorrhage (see pp. 602 and 605).

EVALUATION AND TREATMENT. Diagnosis before a bleeding episode is made using arteriographic examination. Intracranial aneurysms may be found incidently during CT or MRI imaging for other conditions. After a subarachnoid or an intracerebral hemorrhage, a tentative diagnosis of an aneurysm that has bled is based on clinical manifestations, history, and CT and MRI results. The treatment of choice for an aneurysm is surgical management. The location and size of the aneurysm and the person's clinical status determine whether invasive therapy is feasible.[72,73]

Vascular Malformations

Vascular malformations are rare congenital vascular lesions. They are about one-tenth as common as aneurysms and can cause hemorrhagic stroke, epilepsy, chronic headache, or focal neurologic deficits.[74] Four types of vascular malformation exist: arteriovenous malformation, cavernous angioma, capillary telangiectasis, and venous angioma. Most are sporadic, although multiple lesions are observed in families.[75] In an **arteriovenous malformation (AVM),** arteries feed directly into veins through a vascular tangle of malformed vessels without a true capillary bed. AVMs occur as frequently in males as in females, and occasionally are found in families. Although usually present at birth, AVMs exhibit a delayed age of onset and symptoms most commonly occur before 30 years of age. They usually rupture in the

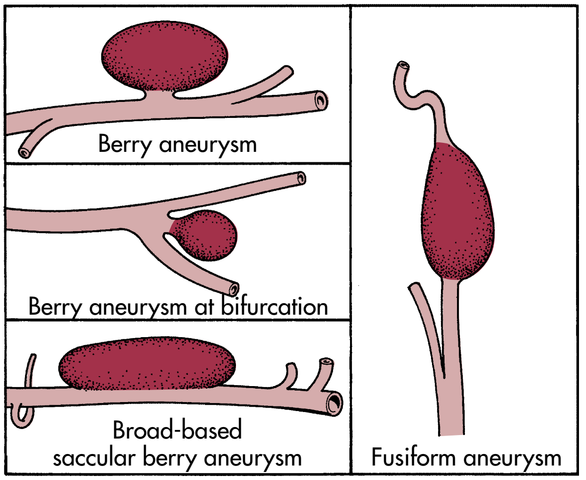

FIGURE 18-18 Types of Aneurysms.

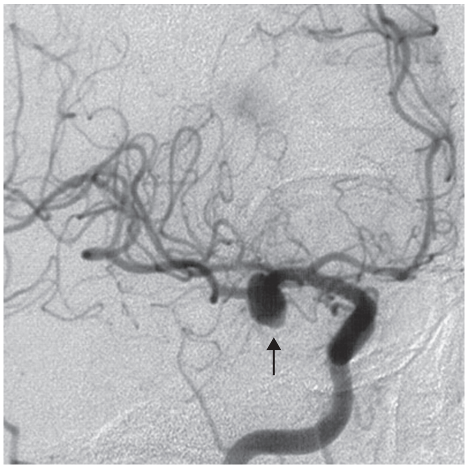

FIGURE 18-19 **Berry Aneurysm, Angiogram.** In this lateral view with contrast filling a portion of the cerebral arterial circulation can be seen a berry aneurysm *(arrow)* involving the middle cerebral artery of the circle of Willis at the base of the brain. (From Klatt EC: *Robbins and Cotran atlas of pathology,* Philadelphia, 2006, Saunders.)

second and third decades of life. **Cavernous angiomas (malformations)** are sinusoidal collections of blood vessels without interspersed normal brain tissue. They rarely hemorrhage and comprise 2% to 4% of hemorrhagic strokes. A **capillary telangiectasis** is dilated capillaries with interspersed normal brain tissue found deep in the brain, particularly in the brainstem; hemorrhage is rare. These vascular malformations are associated with Rendu-Osler-Weber disease (AVM in various areas of the body). **Venous angioma,** the most common vascular malformation found at autopsy (3% of cases), is considered a subset of developmental venous anomalies that occur secondary to arrested development. The result is primitive embryologic veins in a radial pattern feeding a central vein. These rarely hemorrhage.[76]

PATHOPHYSIOLOGY. AVMs are developmental abnormalities that represent persistence of embryonic patterns of blood vessels, do not have a normal blood vessel structure, and are abnormally thin (Figure 18-20). The involved vessels are considered by some researchers to enlarge over time. Their size is highly variable, from malformations of a few millimeters to large ones that extend from the cortex to the ventricle. The large AVMs also may involve the dura mater, including the falx cerebri and the tentorium cerebelli. The AVM may be fed by one or several arteries. There is usually high flow through the feeding arteries and draining veins. These feeder vessels become tortuous over time and often are dilated. With moderate to large AVMs, sufficient blood is shunted into the malformation to deprive surrounding tissue of adequate blood perfusion. There also are theories that propose sporadic AVMs develop as a postnatal consequence of an active angiogenic and inflammatory response to some inciting vascular event, such as trauma or infection.[77]

CLINICAL MANIFESTATIONS. Clinical manifestations vary: about 20% of persons with an AVM have a characteristic chronic nondescript headache, although some experience migraine; about 20% to 25% experience seizure disorders caused by compression. Initially, the seizures tend to be focal or jacksonian; generalization often occurs over time. (Seizures are discussed in Chapter 17.) About 40% to 70% suffer an intracerebral, a subarachnoid, or a subdural hemorrhage.[74] Bleeding from an AVM into the subarachnoid space causes clinical manifestations identical to those associated with a ruptured aneurysm. If bleeding is into the brain tissue, focal signs that develop resemble a stroke-in-evolution. Ten percent of persons experience hemiparesis or other focal signs. Hemiparesis usually is caused by compression or rupture. At times, noncommunicating hydrocephalus (see Chapters 17 and 20) develops with a large AVM that extends into the ventricle lining. AVMs account for up to 1% of all sudden deaths.[78]

EVALUATION AND TREATMENT. A systolic bruit over the carotid in the neck, the mastoid process, or (in a young person) the eyeball is almost diagnostic of an AVM. CT, magnetic resonance angiography (MRA), transcranial Doppler (TCD), and MRI are used in initial diagnosis, followed by an arteriogram to identify feeding vessels. Treatment options are microsurgery, embolization, stereotactic radiosurgery (SRS), or combinations of treatment. Observation only depends on age, overall health, lesion-specific factors (size, location, and angiographic anatomy), and individual-specific factors. The risk of bleeding is about 6% in the first year and 2% to 4% each year thereafter with no intervention.[79]

Subarachnoid Hemorrhage

With a **subarachnoid hemorrhage (SAH),** blood escapes from a defective or injured vasculature into the subarachnoid space (Figure 18-21). Previous family history of SAH is one of the strongest predictors of aneurysmal SAH. Heavy alcohol use, hypertension, smoking, anticoagulation use, and oral contraceptive use are associated with SAH. Individuals at risk for a SAH are those with a saccular intracranial aneurysm (80% of cases), intracranial AVM, or hypertension and those who have sustained head injuries. The mortality is approximately 50%,

FIGURE 18-20 Vascular Malformation, Gross. A vascular malformation represented by a mass of irregular tortuous vessels over the left posterior parietal region of the brain. (From Klatt EC: *Robbins and Cotran atlas of pathology,* Philadelphia, 2006, Saunders.)

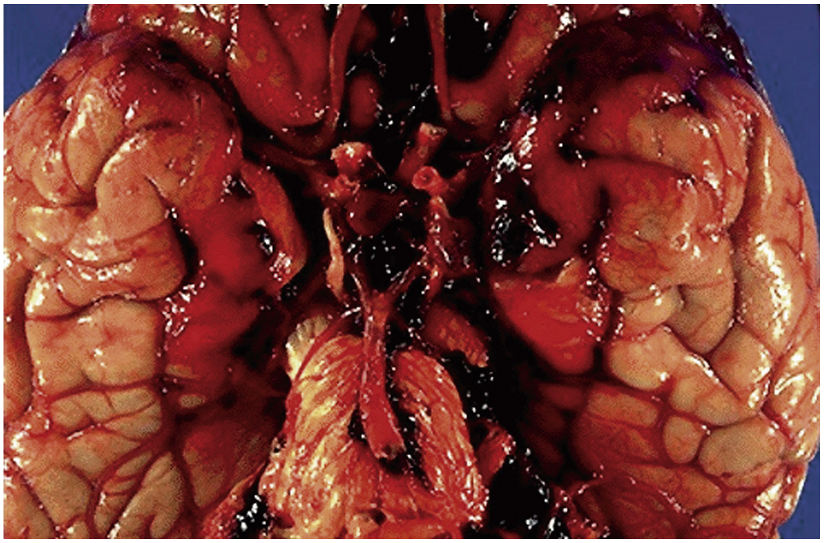

FIGURE 18-21 Subarachnoid Hemorrhage, Gross. Subarachnoid hemorrhage resulting from rupture of a berry aneurysm. (From Klatt EC: *Robbins and Cotran atlas of pathology,* Philadelphia, 2006, Saunders.)

and about one third of survivors are dependent. SAHs often recur, especially from a ruptured intracranial aneurysm.[80]

PATHOPHYSIOLOGY. When a vessel is leaking, blood oozes into the subarachnoid space. When a vessel tears, blood under pressure is pumped into the subarachnoid space. The blood is extremely irritating to the meningeal and other neural tissues and so produces an inflammatory reaction in these tissues. Additionally, the blood coats nerve roots, clogs arachnoid granulations (impairing CSF reabsorption), and clogs foramina within the ventricular system (impairing CSF circulation). ICP immediately increases to almost diastolic levels. ICP returns to near baseline in about 10 minutes. Cerebral blood flow and cerebral perfusion pressure (CPP) decrease. The expanding hematoma acts like a space-occupying lesion, compressing and displacing brain tissue. Granulation tissue is formed and scarring of the meninges, with resulting impairment of CSF reabsorption and secondary hydrocephalus, often results.

Subarachnoid hemorrhage has a unique pathophysiologic cascade triggered by the sudden appearance of blood in the subarachnoid space. Eighty percent of persons with SAH have infarction on MRI, which is the major cause of death and disability, and 33% of persons have asymptomatic vasospasm in the first 2 weeks following an SAH.[81]

The cause for **cerebral vasospasm (CVS)** and **delayed cerebral ischemia (DCI)** is unclear. DCI is related to but not explained by the CVS. Development of CVS requires the presence of blood and its breakdown products as a consequence of the SAH. It also appears that oxyhemoglobin is a powerful precipitator of CVS. It scavenges nitric oxide (a vasodilator), and its breakdown triggers a free radical cascade that disrupts multiple blood vessel layers and initiates release of inflammatory factors. It appears that CVS, disruption of cerebral autoregulation, microthrombi, and spreading cortical depression contribute to DCI. Autoregulation may be impaired in SAH and the combination of narrowed blood vessels, because of spasm and disrupted autoregulation, impairs perfusion, resulting in ischemia and infarction.[82]

CLINICAL MANIFESTATIONS. Early manifestations associated with leaking vessels are episodic headache, transient changes in mental status or level of consciousness, nausea or vomiting, focal neurologic defects including visual or speech disturbances, cranial nerve palsies, or stiff neck. A ruptured vessel often is accompanied by a sudden throbbing, "explosive" headache that is associated with nausea and vomiting, visual disturbances, motor deficits, and loss of consciousness. These signs can be related to a dramatic rise in ICP as blood is released directly into the CSF. Meningeal irritation and inflammation often occur, causing neck stiffness (nuchal rigidity), photophobia, blurred vision, irritability, restlessness, and low-grade fever. A positive Kernig sign (in which straightening the knee with the hip and knee in a flexed position produces pain in the back and neck regions) and a positive Brudzinski sign (in which passive flexion of the neck produces neck pain and increased rigidity) may appear. No localizing signs are present if the bleed is confined completely to the subarachnoid space.

The Hunt and Hess SAH grading system is based on description of the clinical manifestations (Table 18-6). Rebleeding is a significant risk with a high mortality (up to 70%). The period of greatest risk is the first month, with the peak incidence of rebleeding during the first 2 weeks after the initial bleed. Rebleeding is manifested by a sudden increase in blood pressure and ICP, along with a deteriorating neurologic status.

EVALUATION AND TREATMENT. The diagnosis of a subarachnoid hemorrhage is based on the clinical presentation, imaging results, and cerebrospinal fluid evaluation.[83,84] Treatment is directed at control of intracranial pressure, prevention of ischemia and hypoxia of neural tissues, and prevention of rebleeding episodes. Antifibrinolytic drugs may be used to stop rebleeding in selected cases. Blood pressure is allowed to remain in the high normal range or is elevated to that level. Calcium channel blockers, such as nimodipine, are used to prevent or reverse vasospasm. Volume expansion or hemodilution through continuous or bolus administration of hetastarch and administration of plasma protein factors to maintain a hematocrit of 33%

are used to expand blood volume and augment cerebral perfusion in selected cases. Surgical clipping of the aneurysm may be done. Endovascular placement of platinum coils and balloon embolization to occlude the aneurysm are used. Cerebral angioplasty can be tried for vasospasm. Evaluation of new treatments is in progress.[85-87]

Headache Syndromes

Headache is a common neurologic disorder and is usually a benign symptom. However, it can be associated with serious disease, such as brain tumor, meningitis, giant cell arteritis, and cerebrovascular disease. The primary headache syndromes discussed here are the chronic, recurring type not associated with structural abnormalities or systemic disease and include migraine, cluster, paroxysmal hemicrania, and tension headaches. Characteristics of the major types of headache syndromes are summarized in Table 18-7.

Migraine

Migraine is an episodic neurologic disorder whose marker is headache lasting 4 to 72 hours. Migraine is more common in those 25 to 55 years of age, and can occur in young children. The incidence of migraine by age 85 years is about 18% in males and 44% in females. Onset after 55 years of age is rare.[88] Hormonal factors account for most of the gender differences. A positive family history is common as is a genetic predisposition.

Migraine is diagnosed when it is not attributable to any other disorder and when any two of the following features occur: unilateral head pain, pulsating pain, pain worsening with activity, moderate or severe pain intensity, and at least one of the following: nausea or vomiting, or both, or photophobia and phonophobia.[89]

Migraine is a multifactorial disorder caused by a combination of multiple genetic and environmental factors. Specific gene associated migraine includes familial hemiplegic migraine, sporadic hemiplegic migraine, and cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy. Migraine sufferers have an increased risk for epilepsy, depression, anxiety disorders, and stroke.[90] Migraine may be precipitated by triggers. Individuals with migraine are likely to have a genetically determined reduced threshold for triggers with further reduced threshold caused by endogenous factors (e.g., altered sleep patterns [becoming tired or too much sleep], missed meals, overexertion, weather change, stress or relaxation from stress, hormonal changes [such as menstrual periods], excess afferent stimulation [bright lights, strong smells], and chemicals [alcohol or nitrates]).[88]

The International Headache Society has broadly classified episodic migraine into two major subtypes: migraine with aura and migraine without aura.[91] In migraine with aura, at least some of the attacks are temporarily associated with distinct aura symptoms suggestive of focal brain dysfunction (flashing lights, visual loss). There are no associated focal neurologic symptoms in migraine without aura. Two thirds of those with migraines have migraine without aura. **Chronic migraine** is a progression of episodic migraine with a prevalence of about 2%. Criteria for these headaches include the following: it occurs on more than 15 days per month for at least 3 months; no excessive use of opiate or barbiturate medications is involved; and on more than 8 days per month there is migraine without aura or treatment provides relief before symptoms develop.[91]

The pathophysiologic basis for migraine is complex and not clearly established. It includes neurologic, vascular, hormonal, and neurotransmitter components. Migraine pain appears to be related to activation of the peripheral and central arms of the

TABLE 18-6 SUBARACHNOID HEMORRHAGE CLASSIFICATION SCALE

CATEGORY	DESCRIPTION
Grade I	Neurologic status intact; mild headache, slight nuchal rigidity
Grade II	Neurologic deficit evidenced by cranial nerve involvement; moderate to severe headache with more pronounced meningeal signs (e.g., photophobia, nuchal rigidity)
Grade III	Drowsiness and confusion with or without focal neurologic deficits; pronounced meningeal signs
Grade IV	Stuporous with pronounced neurologic deficits (e.g., hemiparesis, dysphasia); nuchal rigidity
Grade V	Deep coma state with decerebrate posturing and other brainstem dysfunction

From Cook HA: Aneurysmal subarachnoid hemorrhage: neurosurgical frontiers and nursing challenges. In Winkleman C, editor: *AACN clinical issues in critical care nursing,* Philadelphia, 1991, Lippincott; Hunt WE, Hess RM: *J Neurosurg* 28(1):14–20, 1968.

TABLE 18-7 CHARACTERISTICS OF COMMON HEADACHES

	MIGRAINE WITH OR WITHOUT AURA	CLUSTER HEADACHE/PROXIMAL HEMICRANIA	TENSION TYPE OF HEADACHE
Age of onset	Childhood, adolescence, or young adulthood	Young adulthood, middle age	Young adulthood, middle age
Gender	Female	Male	Not gender specific
Family history of headaches	Yes	No	Yes
Onset and evolution	Slow to rapid	Rapid	Slow to rapid
Time course	Episodic	Clusters in time	Episodic, may become constant
Quality	Usually throbbing	Steady	Steady
Location	Variable, often unilateral	Orbit, temple, cheek	Variable
Associated features	Prodrome, vomiting	Lacrimation, rhinorrhea, Horner syndrome	None

trigeminal system, cortical spreading depression, and distinct activity of brainstem nuclei.

The clinical phase of a migraine attack and associated pathophysiology are as follows[92-95]:

1. *Premonitory phase:* Up to one third of migraine patients have premonitory symptoms at least some of the time for several hours before aura or headache onset (e.g., neck pain, depression, yawning, food cravings); the pathogenesis is unknown but evidence suggests dopaminergic/hypothalamic involvement.[96]
2. *Migraine aura:* Up to one third of migraine patients have aura symptoms at least some of the time that may last 1 hour or sometimes much longer; migraine aura is defined as a spreading, focal, neurologic disturbance manifested as visual, sensory, or motor symptoms; the pathophysiologic mechanism appears to be a cortical spreading depression (CSD) (focal hyperemia [vasodilation] followed by spreading oligemia [vasoconstriction]), a reduction in electrical activity, and a decrease in blood flow that slowly spreads across the cerebral cortex from the occipital region.[97]
3. *Headache phase:* This phase includes associated symptoms and may last from 4 to 72 hours (usually about 1 day). The genesis of migraine pain is unknown and there is debate about whether the initiating mechanisms are central or peripheral, vascular or nonvascular.[98] Proposed pain mechanisms include: (1) activation of trigeminal cervical afferent neurons (arise from the ophthalmic division of the trigeminal ganglion and in the upper cervical dorsal roots in the posterior fossa) that innervate cerebral vessel nociceptors—activation of trigeminal sensory nerves releases vasoactive peptides that cause a sterile, inflammatory response around vessels in the meninges; (2) abnormal processing of trigeminal pain from the dural vessels and upper cervical muscles by the diencephalon (thalamus and hypothalamus), brainstem, or high cervical spinal cord; (3) central sensitization from an increased response of thalamic neurons to stimulation—allodynia; (4) dilation of the terminal branches of the external carotid artery.[99-101]
4. *Recovery phase*: This phase may take several hours to days.

Migraine without aura is often located on one side of the head. In migraine with aura, the most common prodromal symptoms are visual (scotomas with luminous angles and scintillating edges, and hemianopsia). Sensory deficits and aphasia also may be present. The aura develops within 5 to 20 minutes and remits within 60 minutes, followed by headache and other symptoms, including nausea, vomiting, photophobia, and scalp tenderness; 10% experience diarrhea.

In susceptible women, migraine occurs most frequently before and during menstruation and is decreased during pregnancy and menopause. Excessive levels of estrogen during menstruation stimulate receptors in the trigeminal ganglia and periaqueductal gray that manifest as menstrual migraine.[102] Estrogens also may act directly on vascular smooth muscle, modulate activity of vasoactive substances at the neurovascular junction, and activate vasoregulatory responses in the hypothalamus. However, no direct evidence has been found to link circulating female sex hormones with the frequency and severity of migraine.

The diagnosis of migraine is made from health history and physical examination. Clinicians must be skilled in their understanding of different types of headaches, risk factors, family history, and clinical features. Differential diagnosis is confirmed with CT, MRI, and EEG. A significant number of individuals with migraine have depression as a comorbidity.

The management of migraine includes education that migraine is a chronic physiologic, not psychosomatic, disorder. Avoidance of triggers, adequate sleep, regular eating habits, and daily relaxation and meditation can create a headache-protective environment. With the onset of acute migraine, a dark room, ice, and sleep can provide relief. The pharmacologic management of migraine varies with each individual and is related to the severity of the attack. Drug considerations should include antiemetics, NSAIDs, ergotamine and dihydroergotamine, and serotonin receptor agonists (e.g., sumatriptan). Triptans, transcutaneous estrogen, and magnesium administration may help some women with menstrual migraine. Gastric absorption may be decreased during an attack, and routes of administration other than oral (e.g., nasal sprays, intravenous, and rectal) may be used. There are several emerging drugs that may target the molecular pathophysiology of migraine pain.[103] The prophylaxis of migraine is considered when attacks cannot be treated effectively. Several drugs may be considered and should *not* be used in combination. Examples include beta-blockers, a calcium antagonist (flunarizine), serotonin antagonists (lisuride, methysergide), NSAIDs, dihydroergotamine (DHE), valproic acid, and amitriptyline. There are many new drugs under evaluation.[104]

Cluster Headache

Cluster headaches are one of a group of disorders referred to as trigeminal autonomic cephalagia[105] and occur primarily in men between 20 and 50 years of age. Cluster headache has been known also as *histamine cephalalgia, Horton syndrome,* and *erythromelalgia.* These uncommon headaches occur in clusters for a period of days followed by a long period of spontaneous remission. Cluster headache has an episodic and a chronic form with extreme pain intensity and short duration. If the cluster of attacks occurs more frequently without sustained spontaneous remission, they are classified as *chronic cluster headaches* (20% of cases) (see Table 18-7). Triggers are similar to those that cause migraine headache.

Trigeminal activation occurs but the mechanism is unclear. There is unilateral trigeminal distribution of severe pain with ipsilateral autonomic manifestations, including tearing on the affected side, ptosis of the ipsilateral eye, and congestion of the nasal mucosa. The pathogenic mechanism for pain is related to the release of vasoactive peptides, the formation of neurogenic inflammation, and the activation of the pain matrix. Autonomic dysfunction is characterized by sympathetic underactivity and parasympathetic activation. The rhythmicity of attacks is associated with changes in the inferior posterior hypothalamus. There may be altered serotonergic nerve transmission, but at different loci than in migraine headache.[106]

The headache attack usually begins without warning and is characterized by severe, unilateral tearing; and burning, periorbital, and retrobulbar or temporal pain lasting 30 minutes to 2 hours. One or several attacks may occur in a day, usually at the same time of day or night. The same side is affected in subsequent episodes, and the attack activates the trigeminal-autonomic reflex. Associated symptoms include lacrimation, reddening of the eye, nasal stuffiness, eyelid ptosis, and nausea. Pain often is referred to the midface and teeth. Alcohol can stimulate an attack during a cluster headache in about 50% to 70% of cases, but it is not a triggering factor during remission.

Prophylactic drugs are used to treat cluster headache, as well as avoidance of triggers. The most effective are calcium channel antagonists (verapamil), lithium carbonate, topiramate, valproic acid, gabapentin, and baclofen. Acute attacks are managed with oxygen inhalation and intravenous sumatriptan, or inhaled ergotamine administration and nerve stimulation.[107]

Chronic paroxysmal hemicrania (CPH) is a cluster-type headache with unilateral head pain that occurs with more daily frequency (4 to 12 times per day) but with shorter duration (20 to 120 minutes). The remission phases are often shorter. The attacks are more common in women, usually after pregnancy. The symptoms are similar to cluster headache. As with cluster headache, there is an episodic and a chronic form. The pathophysiology involves a disorder of sympathetic hyperactivity, but the mechanism is different from that of cluster headache because there is effective relief of symptoms with indomethacin.[108]

Tension-Type Headache

Tension-type headache (TTH) is the most prevalent type of primary headache. It is not a vascular or migrainous headache. The average age of onset is during the second decade of life. It is a mild to moderate bilateral headache with a sensation of a tight band or pressure around the head. The onset of pain is usually gradual. *Episodic tension-type headache* may last for several hours or several days. It is not aggravated by physical activity. *Chronic tension-type headache* evolves from episodic tension-type headache and represents headache that occurs at least 15 days per month for at least 3 months.[91] Many individuals have both tension-type and migraine headaches.

The pathogenesis of TTH is not clear; however, there is a probable genetic predisposition. Both a central mechanism and a peripheral mechanism operate in causing tension headache. The central mechanism probably involves hypersensitivity of pain fibers from the trigeminal nerve that leads to central sensitization. The peripheral sensitization of myofacial sensory afferents may contribute to muscular hypersensitivity and the development of chronic TTH.[109] Headache sufferers have more localized pain and tenderness of pericranial muscles.

Mild headaches are treated with ice, and more severe forms are treated with aspirin or NSAIDs. Chronic tension-type headaches are best managed with a tricyclic antidepressant, such as amitriptyline. Cognitive-behavioral therapy and relaxation training reduce symptoms of chronic tension-type headache. Long-term use of analgesics or other drugs, such as muscle relaxants, antihistamines, tranquilizers, caffeine, and ergot alkaloids, should be avoided.[110]

Infection and Inflammation of the Central Nervous System

The CNS may be infected by bacteria, viruses, fungi, parasites, and mycobacteria. Viruses causing acute and chronic CNS infections are listed in Table 18-8. The infecting microorganisms gain entry to the nervous system by (1) hematogenous spread through arterial blood or (2) direct extension from another site of infection.[111] Neurologic infections produce disease by several mechanisms: direct neuronal or glial infection; mass lesion formation; inflammation with subsequent edema; interruption of cerebrospinal fluid pathways; neuronal damage, or vasculopathy; and secretion of neurotoxins (Figures 18-22 through 18-24). Syndromes are acute and subacute bacterial meningitis, epidural and brain abscess, encephalitis, peripheral neuropathy, or neurosyphilis depending on the infecting microorganism. Signs and symptoms are produced because of (1) interference with the function of the nervous system tissue being invaded or compressed or (2) the inflammatory response produced by the body in response to infection. The cardinal signs of CNS infection are fever, head or spine pain, and generalized or focal neurologic dysfunction.[112]

Meningitis

Meningitis is inflammation of the brain or spinal cord. Infectious meningitis may be caused by bacteria, viruses, fungi, parasites, or toxins. (The pathophysiology of infection is discussed in Chapter 10.) The infection may be acute, subacute, or chronic with the pathophysiology, clinical manifestations, and treatment differing for each type of microorganism. In **aseptic meningitis** no specific pathogen can be identified and the disease is treated symptomatically.

Bacterial meningitis is primarily an infection of the pia mater and arachnoid villi, the subarachnoid space, the ventricular system, and the CSF. About 1 in 100,000 persons are affected annually.[113] Meningococcus *(Neisseria meningitidis)* and pneumococcus *(Streptococcus pneumoniae)* are the most common causes of bacterial meningitis. Meningococcus has been identified worldwide. Meningococcal meningitis occurs predominantly in men and boys and in the fall, winter, and spring of the year. Epidemics of meningococcal meningitis occur in approximately 10-year cycles, predominantly affecting children and adolescents. With pneumococcal meningitis, young persons and those more than 40 years of age are mostly affected. Predisposing conditions are otitis or sinusitis (25%), immunocompromised status (16%), and pneumonia (12%).[113,114]

Meningitis (viral meningitis, nonpurulent meningitis, lymphocytic meningitis) is believed to be limited to the meninges. An identifiable bacteria cannot be found in the cerebrospinal fluid. The most at-risk populations and the time of year when occurrences are seen depend on the virus and on the immune status of the individual. Viral meningitis produces a variety of symptoms and is caused by a variety of viruses. The most common are enteroviral viruses (echovirus, coxsackievirus, and nonparalytic poliomyelitis), arboviruses, and herpes simplex type 2.[115] Treatment is primarily supportive and the disease usually resolves within 7 to 10 days.

TABLE 18-8 VIRUSES CAUSING ACUTE AND CHRONIC CNS DISEASES

VIRUS	FAMILY	NUCLEIC ACID	CNS DISEASE	CELL TROPISM	NONHUMAN HOST	ROUTE OF ENTRY TO CNS	TREATMENT
Viruses Causing Acute CNS Diseases							
Herpes simplex viruses 1 and 2	Herpesviridae	DNA	Meningoencephalitis	Neuron	ND	Intraneuronal	Acyclovir
Rabies virus	Rhabdoviridae	RNA	Encephalomyelitis	Neuron	Carnivores	Intraneuronal	Postexposure prophylaxis; RIG and vaccine
West Nile virus	Flaviviridae	RNA	Meningoencephalomyelitis	Neuron	Birds, horses	Hematogenous	IVIG, interferon-alpha
Nipah virus	Paramyxoviridae	RNA	Encephalitis	Neuron, endothelia	Pigs, fruit bats	Hematogenous	Ribavirin
Equine encephalitis viruses	Togaviridae	RNA	Meningitis, encephalitis	Neuron, astrocytes	Horses	Hematogenous	Supportive care
Mumps virus	Paramyxoviridae	RNA	Meningitis, encephalitis, myelitis	Neuron, ependymal cell	ND	Hematogenous	IVIG
Rubella virus	Togaviridae	RNA	Meningitis, encephalitis	Not specified	ND	Hematogenous	Plasmapheresis
Coxsackievirus, echovirus	Picornaviridae	RNA	Meningitis, meningoencephalitis, myelitis	Neuron	ND	Hematogenous	Pleconaril
Poliovirus	Picornaviridae	RNA	Meningitis, myelitis	Neuron	ND	Hematogenous	Pleconaril
California encephalitis virus	Bunyaviridae	RNA	Meningitis, encephalitis	Neuron	Small mammals	Hematogenous	Ribavirin
Viruses Causing Chronic CNS Disease							
Human immunodeficiency virus	Retroviridae	RNA	Encephalitis, meningitis, myelitis	Microglia, macrophage, astrocytes	ND	Hematogenous	HAART and neuroprotective agents
Human T-cell leukemia viruses 1 and 2	Retroviridae	RNA	Myelitis	Astrocyte, leukocyte	ND	Hematogenous	Zidovudine, lamivudine, glucocorticoids
JC virus	Polyomaviridae	DNA	Progressive multifocal leukoencephalopathy	Oligodendrocyte, astrocyte	ND	Hematogenous	Interferon-alpha, cidofovir
Varicella-zoster virus	Herpesviridae	DNA	Leukoencephalitis, cerebellitis, meningitis, myelitis	Neurons, satellite cell	ND	Hematogenous	Acyclovir, valacyclovir
Measles virus	Paramyxoviridae	RNA	Encephalitis; SSPE	Neuron	ND	Hematogenous	Ribavirin, interferon-alpha, isoprinosine
Cytomegalovirus	Herpesviridae	DNA	Encephalitis	Neuron, ependymal cell, oligodendrocyte, monocytoid cell, endothelia	ND	Hematogenous	Foscarnet, ganciclovir, cidofovir, fomivirsen, valganciclovir
Epstein-Barr virus	Herpesviridae	DNA	Encephalitis, meningitis, myelitis	Infiltrating mononuclear cells	ND	Hematogenous	Acyclovir, ganciclovir (?)

Fungal meningitis is a chronic, much less common condition than bacterial or viral meningitis. The most common fungal infections of the nervous system are histoplasmosis, cryptococcosis, coccidioidomycosis, mucormycosis, candidiasis, and aspergillosis. The infection occurs most often in persons with impaired immune responses or alterations in normal body flora. It develops insidiously, usually over days or weeks.

Tubercular meningitis is a common and serious form of CNS tuberculosis especially in persons with acquired immunodeficiency syndrome (AIDS). Miliary tubercles form in the brain and meninges. At some point the tuberculomas erode the pia mater, and the mycobacteria enter the CSF, producing a hypersensitivity reaction that results in a purulent exudate involving the basal meninges, cerebrum, and spinal nerves. Cerebral ischemia and infarction occur from vasculitis. Symptoms include headache, low-grade fever, nausea and vomiting,

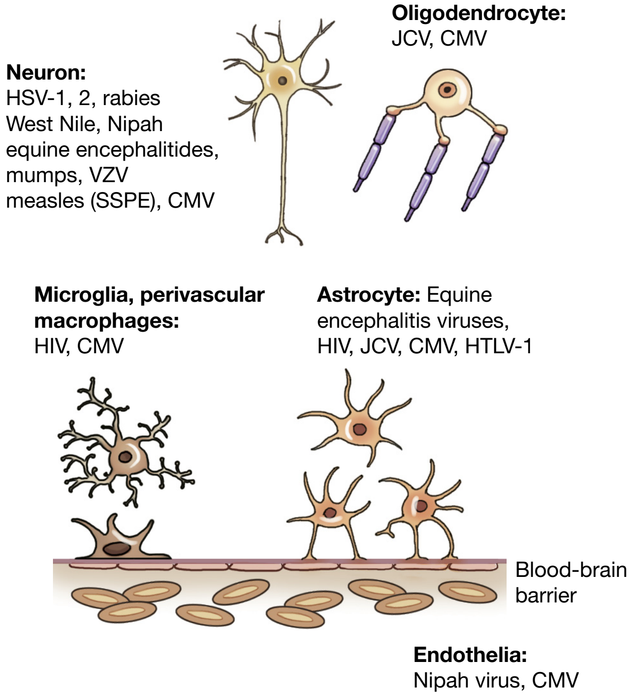

FIGURE 18-23 Viral Infection in the Central Nervous System (CNS). Viruses infect specific cell types within the CNS depending on the specific properties of the virus together with individual cell membrane proteins expressed on permissive cell types. Normally the brain is protected from circulating pathogens and toxins by the blood-brain barrier. *CMV,* Cytomegalovirus; *HIV,* human immunodeficiency virus; *HSV,* herpes simplex virus; *HTLV-1,* human T-cell lymphotropic virus type 1 (causes T-cell leukemia); *JCV,* John Cunningham virus (a polyomavirus causing progressive multifocal leukoencephalopathy); *SSPE,* subacute sclerosing panencephalitis; *VZV,* varicella-zoster virus. (Adapted from Power C, Noorbakhsh G: Central nervous system viral infections: clinical aspects and pathogenic mechanisms. In Gilman S, editor: *Neurobiology of disease,* p 488, Burlington, MA, 2007, Elsevier.)

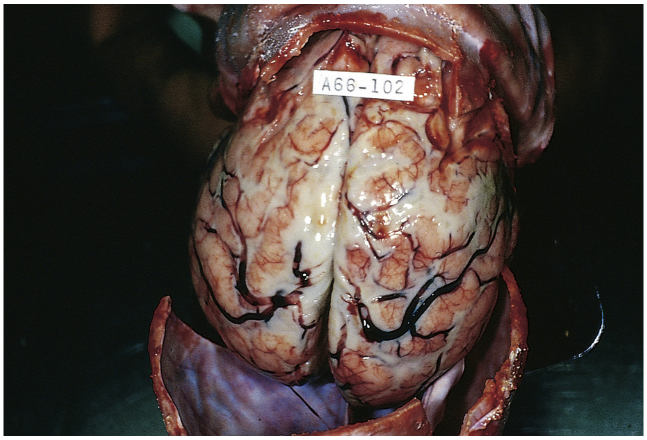

FIGURE 18-25 **Acute Leptomeningitis.** The leptomeninges contain abundant creamy, purulent exudate, most prominently over the superior surface of the cerebrum. The underlying brain is swollen, and the vessels are congested. (From Kumar V, Cotran RS, Robbins SL: *Robbins basic pathology,* ed 7, Philadelphia, 2003, Saunders.)

irritability, difficulty sleeping, and fatigue. These signs and symptoms increase to confusion, stiff neck, significant behavioral changes, and seizures. Hydrocephalus and cranial nerve palsies or cerebral infarcts may occur. Recovery rate is 90% with early diagnosis and treatment with appropriate antituberculosis therapy.[116]

PATHOPHYSIOLOGY. In bacterial meningitis, a systemic or bloodstream infection or a direct extension from an infected area (e.g., from a respiratory tract, ear, or paraspinal infection; as a result of dental work) is the access route to the subarachnoid space. The method of CNS entry is through the choroid plexuses or areas of altered blood-brain barrier or by hematogenous spread. Bacteria multiply in the subarachnoid space. The bacteria or their toxins function as irritants and induce an inflammatory reaction by the meninges (pia mater and arachnoid), the CSF, and the ventricles. The meningeal vessels undergo change, becoming hyperemic and increasingly permeable. Neutrophils migrate into the subarachnoid space, producing an exudate that thickens the CSF and interferes with normal CSF flow around the brain and spinal cord (Figure 18-25). The exudate has the potential to obstruct arachnoid villi and produce hydrocephalus and interstitial edema. The amount of purulent exudate increases rapidly (especially around the base of the brain), causing further inflammation. The exudate extends into the sheaths of the cranial and spinal nerves and into the perivascular spaces of the cortex. Meningeal cells become edematous. The exudate and vasogenic edema increase ICP. The small and medium-sized subarachnoid arteries, veins, and choroid plexuses undergo inflammatory changes and become engorged, disrupting blood flow and potentially producing thrombosis. Secondary infection of the brain may occur. The cortical neurons also show some changes, including an increase in the number of microglia and astrocytes.

In viral meningitis, the virus reaches the CNS by hematogenous spread. The virus enters the brain either directly or indirectly, through infected migrating leukocytes, and then infects vascular endothelial cells. The virus then enters the subarachnoid space, leading to meningitis. The immune response leads to release of inflammatory cytokines with increased permeability of the blood-brain barrier and entry of circulating immunoglobulins that combat the virus.

Fungi in the nervous system usually produce a granulomatous reaction with formations of granulomas or gelatinous masses. These usually develop in the meninges at the base of the brain. Fungi also may extend along the perivascular sites in the subarachnoid space and into the brain tissue, producing arteritis with thrombosis, infarction, and communicating hydrocephalus. Meningeal fibrosis develops later in the inflammatory process. Cranial nerve dysfunction, caused by compression, often results from the granulomas and fibrosis.

CLINICAL MANIFESTATIONS. The clinical manifestations of a bacterial meningitis can be grouped as: (1) inflammation and irritation—generalized meningeal signs, throbbing headache that becomes more severe, photophobia that becomes more severe, nuchal rigidity, positive Kernig and Brudzinski signs; (2) local tissue dysfunction—cranial nerve palsies, focal neurologic deficits (such as hemiparesis/hemiplegia, ataxia), and seizures; (3) mass effect—decreased level of consciousness, nausea, vomiting, and increased intracranial pressure; and (4) vascular compromise. The irritation and damage to the cranial nerves produced by the inflamed sheaths manifest as follows:

Cranial nerve II: papilledema, blindness
Cranial nerves III, IV, and VI: ptosis, visual field deficits, diplopia
Cranial nerve V: photophobia
Cranial nerve VII: facial paresis
Cranial nerve VIII: deafness, tinnitus, vertigo

Neck stiffness and pain, and possibly head retraction, reflect the irritability of spinal accessory and cervical spinal nerves. Often the vomiting center is irritated, causing projectile vomiting. Confusion and decreasing responsiveness are evidence of cortical involvement. In meningococcal meningitis, petechial or purpuric rash involving the skin and mucous membranes occurs. As ICP increases, papilledema may develop and delirium may progress to the point that the individual becomes unconscious.

The clinical manifestations of viral meningitis are mild compared with those associated with bacterial meningitis. Mild generalized throbbing headache, mild photophobia, mild neck pain, stiffness, fever, and malaise are manifestations of viral meningitis. Symptoms of aseptic meningitis are similar to those of viral meningitis.

Fungal meningitis develops slowly and insidiously. The first manifestations are often those of dementia or communicating hydrocephalus (see Chapter 17). The individual is characteristically afebrile.

EVALUATION AND TREATMENT. Diagnosis of bacterial meningitis is based on physical examination and the results of nasopharyngeal smear and antigen tests. CSF cultures are required to diagnose fungal meningitis. Bacterial meningitis and fungal meningitis are treated with appropriate antibiotic therapy, but resistant strains are an increasing problem. Other supportive measures may be needed. Viral meningitis is managed pharmacologically with antiviral drugs and corticosteroids in

FIGURE 18-26 Brain Abscess. The abscess is sharply demarcated, indicating that it has been present for some time. Purulent exudate is visible in the center of the abscess. Because antibiotics penetrate very poorly into abscesses, surgical drainage is often necessary to treat such lesions. (From Kumar V, Cotran RS, Robbins SL: *Robbins basic pathology,* ed 7, Philadelphia, 2003, Saunders.)

addition to supportive care. There are vaccinations to prevent meningococcal, pneumococcal, and *Haemophilus influenzae* meningitis.[117]

Brain or Spinal Cord Abscess

Abscesses are localized collections of pus within the parenchyma of the brain or spinal cord and include subdural and extradural empyemas. They are rare and develop in about 1 per 100,000 hospital admissions and are more common in males. Abscesses occur (1) after open trauma and during neurosurgery; (2) from contiguous spread of infection, such as the middle ear, mastoid cells, nasal cavity, and nasal sinuses; (3) through metastatic or hematogenous distribution from distant foci, such as the heart, lungs, pelvic organs, skin, tonsils, abscessed teeth, osteomyelitis (with the exception of cranial bones), and dirty needles (especially in compromised hosts); and (4) from cryptogenic (unknown) factors arising without other associated areas of infections. *Streptococci, Staphylococci,* and *Bacteroides,* often in combination with anaerobes, are the most common bacteria that cause abscesses; however, yeast and fungi also have been found in CNS abscesses. *Toxoplasma gondii* is producing an ever-increasing number of CNS abscesses in persons with acquired immunodeficiency syndrome (AIDS). Most CNS abscesses are located in the frontal and temporal lobes (Figure 18-26). Immunosuppressed persons are particularly at risk.

Brain abscesses are classified as extradural, subdural, or intracerebral. **Extradural brain abscesses (empyemas)** are associated with osteomyelitis in a cranial bone. **Subdural brain abscesses (empyemas)** arise from a sinus infection or a vascular source. **Intracerebral brain abscesses** arise from a vascular source. **Spinal cord abscesses** are classified as epidural or intramedullary. Epidural spinal abscesses usually originate as osteomyelitis in a vertebra; the infection then spreads into the epidural space. (Osteomyelitis is discussed in Chapter 44.)

PATHOPHYSIOLOGY. Microorganisms gain entrance to the CNS from adjacent sites by direct extension from osteomyelitis or spread along the wall of a vein. Infective emboli carry the microorganisms from distant sites. The virulence of the pathogen and the immune response of the host are important determinants of outcome.[118] Brain abscess evolves through four stages regardless of infecting microorganism except in the immunosuppressed host, where the process may be incomplete. The stages are as follows:

1. *Early cerebritis* (days 1 to 3): A localized inflammatory process develops in which perivascular infiltration or inflammatory cells, composed of neutrophils, plasma cells, and mononuclear cells, surround a central core of coagulative necrosis; marked cerebral edema surrounds the area.
2. *Late cerebritis* (days 4 to 9): The necrotic center is surrounded by an inflammatory infiltrate of macrophages and fibroblasts; rapid new blood vessel formation occurs around the abscess; a thin capsule of fibroblasts and reticular fibers gradually develops; the area is still surrounded by cerebral edema.
3. *Early capsule formation* (days 10 to 13): The necrotic center decreases in size; the inflammatory infiltrate changes in character and contains an increasing number of fibroblasts and macrophages; mature collagen evolves, forming a capsule.
4. *Late capsule formation* (days 14 and longer): A well-formed necrotic center surrounded by a dense collagenous capsule develops.[119]

A free (nonencapsulated) abscess is associated with a higher mortality. Existing abscesses also tend to spread and form daughter abscesses.

Abscesses arising from the ear frequently are located in the middle or inferior temporal lobe or in the anterolateral cerebellar hemispheres. Abscesses originating from the oral, nasal, or sinus areas most commonly are located in the frontal and temporal lobes. Abscesses from distant foci often occur in multiple numbers in the distal portion of the middle cerebral arteries. In extradural abscesses, pus and granulation tissue accumulate in the extradural space.

CLINICAL MANIFESTATIONS. Clinical manifestations of brain abscesses are associated with (1) intracranial infection, such as fever and increased sedimentation rate; or (2) an expanding intracranial mass, such as headache, nausea, vomiting, decreasing cognitive abilities, paresis, and seizures. Early clinical manifestations of brain abscesses are low-grade fever, headache, neck pain and stiffness with mild nuchal rigidity, confusion, drowsiness, sensory deficits, and communication deficits. Headache is the most common early symptom. Later clinical manifestations may include inattentiveness (distractibility), memory deficits, decreased visual acuity and narrowed visual fields, papilledema, ocular palsy, ataxia, and dementia. Symptoms depend on the location of the abscess. The development of symptoms may be very insidious, often making an abscess difficult to diagnose. Extradural brain abscesses are associated with localized pain, purulent drainage from the nasal passages or auditory canal, fever, localized tenderness, and neck stiffness; occasionally the individual experiences a focal seizure. Clinical manifestations of spinal cord abscesses have four stages: (1) spinal aching; (2) root pain, which is usually severe, accompanied by spasms of the back

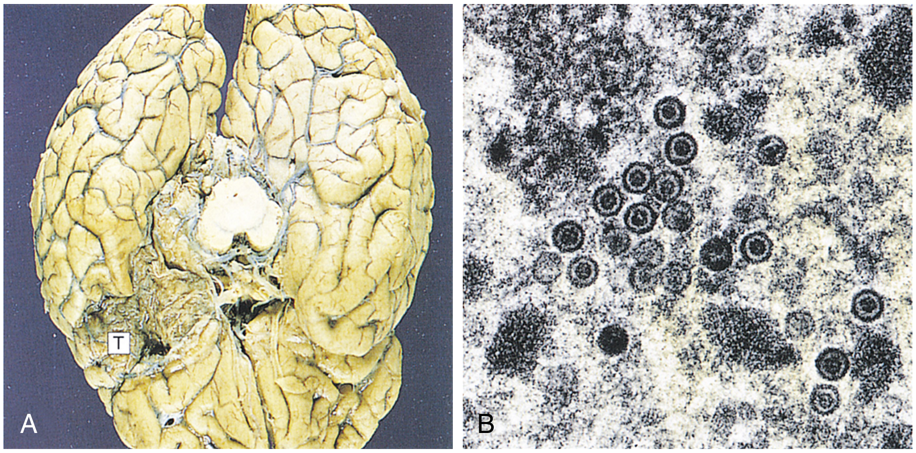

FIGURE 18-27 Herpes Simplex Encephalitis. In herpes simplex encephalitis **(A)** necrosis of the temporal lobes *(T)* is a typical development. Brain biopsy is useful in diagnosis when the virus can be seen by electron microscopy **(B)** as rounded particles with a dense core. Virus also can be identified by immunostaining or culture. In early cases, polymerase chain reaction (PCR) can be used to identify viral deoxyribonucleic acid (DNA) in cerebrospinal fluid samples. (From Stevens A, Lowe JS, Scott I: *Core pathology,* ed 3, London, 2009, Mosby.)

muscles and limited vertebral movement because of pain and spasm; (3) weakness caused by progressive cord compression; and (4) paralysis.[120]

EVALUATION AND TREATMENT. The diagnosis is suggested on the basis of clinical features and confirmed with MRI or contrast-enhanced CT. Surgical aspiration or excision is usually indicated.[121] Multiple or surgically inaccessible abscesses are treated with antibiotics, often in conjunction with corticosteroid therapy to treat the cerebral edema. In addition, ICP may require management.[122] Because decompression is necessary, spinal cord abscesses are treated with surgical excision or aspiration. Antibiotic administration and supportive therapy also are instituted.

Encephalitis

Encephalitis is an acute febrile illness, usually of viral origin, with nervous system involvement. The most common encephalitides are caused by arthropod-borne (mosquito-borne) viruses and herpes simplex viruses, almost exclusively herpes simplex type 1 in adults (Figure 18-27). Etiologic agents for viral encephalitis are presented in Table 18-8. Referred to as *infectious viral encephalitides,* encephalitis also may occur as a complication of systemic viral diseases such as poliomyelitis, rabies, mononucleosis, rubella, or rubeola. Encephalitis also may follow vaccination with a live attenuated virus vaccine if the vaccine has an encephalitis component. Such vaccines include measles, mumps, rubella; varicella; rotavirus; and yellow fever. Typhus, trichinosis, malaria, and schistosomiasis also are associated with encephalitis. Toxoplasmosis may acutely reactivate in immunosuppressed hosts when the once-dormant parasite in cyst form disseminates in brain tissues.

With the exception of the California viral encephalitis, which is endemic, the arthropod-borne encephalitides occur in epidemics, varying in geographic and seasonal incidence (Table 18-9). Eastern equine encephalitis is the most serious but least common of the encephalitides.[123] West Nile virus is presented in Box 18-1.

PATHOPHYSIOLOGY. Viruses gain access to the CNS through the bloodstream, olfactory bulb, or choroid plexus, or through an intraneuronal route from peripheral nerves.[124] Evidence of meningeal involvement appears in all encephalitides. The arthropod-borne viral encephalitides cause widespread nerve cell degeneration. Edema and areas of necrosis with or without hemorrhage develop. Increased ICP develops and may progress to herniation. Large degenerative injuries are found in eastern equine encephalitis, whereas the other arthropod-borne viral encephalitides have microscopic areas of injury and degeneration. Infectious encephalitis may result from a postinfectious autoimmune response to the virus or from direct invasion of the CNS by the virus. Herpes simplex type 1 has a tendency to infect the inferomedial surfaces of the temporal and frontal lobes and causes hemorrhagic necrosis.

CLINICAL MANIFESTATIONS. Encephalitis may range from a mild infectious disease to a life-threatening disorder. The dramatic clinical manifestations of encephalitis are fever, delirium, or confusion progressing to unconsciousness, seizure activity, cranial nerve palsies, paresis and paralysis, involuntary movement, and abnormal reflexes. Signs of marked ICP may be present.

EVALUATION AND TREATMENT. Diagnosis is based on health history and clinical presentation aided by CSF examination and culture, serologic examination, white blood cell (WBC) count, CT scan, or MRI. (Treatment available for the viral encephalitides is listed in Table 18-8.) Supportive therapy is initiated, and measures to control ICP are paramount.

Neurologic Complications of Acquired Immunodeficiency Syndrome

Approximately 40% to 60% of all persons with AIDS have neurologic complications (see Chapter 10 for the pathophysiology of AIDS). On postmortem examination, 75% have nervous system pathologic findings. The CNS pathologic findings result from (1) the primary human immunodeficiency virus (HIV) infection; (2) the immune dysregulation of early HIV infection and progressive immunosuppression in late HIV infections

TABLE 18-9 CLASSIFICATION AND CHARACTERISTICS OF ARTHROPOD VIRUSES CAUSING ENCEPHALITIS

VIRUSES	INCUBATION PERIOD (DAYS)	VIRUS	LOCATION	VECTOR	SEASON	AFFECTED POPULATION
Eastern equine encephalitis	5-10	Togaviridae *Alphavirus* (formerly group A arbovirus)	Swampy areas of eastern United States and Michigan	Mosquito	June to October	Infants, children, and adults >50 years
Western equine encephalitis	5-10	Same as above	All parts of United States: eastern, central, and western	Mosquito	July to October	All ages
Venezuelan equine encephalitis	2-5	Same as above	Texas, Florida, Mexico; Central and South America	Mosquito	All year	Infants and young children
St. Louis encephalitis	4-21	Flaviviridae *Flavivirus*	All parts of United States: eastern, central, and western	Mosquito	June to October	Adults >40 years; older adults more often affected than younger ages
La Cross encephalitis including California	5-15	Bunyaviridae *Bunyavirus* (California virus serogroup)	Midwestern United States, eastern seaboard, and Canada	Woodland mosquito	July to September	Children <15 years
West Nile encephalitis	3-14	Flaviviridae *Flavivirus*	Lower 48 states of United States	Mosquito	Summer and fall	Older adults most seriously

BOX 18-1 EMERGENCE OF WEST NILE VIRUS

West Nile (WN) virus, a *Flavivirus* transmitted predominantly by the *Culex* mosquito, emerged in New York state in 1999. By the end of 2004, human cases had been found in the 48 contiguous states. Humans and horses, as well as other mammals, are incidental hosts. Birds and mosquitoes are life cycle hosts. Summer and fall are peak times of infection incidence. The highest amount of virus carried by mosquitoes is in early fall. Besides mosquito transmission, WN virus can be transmitted through blood transfusions and organ transplants. Health experts believe transmission from mother to unborn child and through breast milk is possible. Novel strains are emerging increasing the risk for epidemics.

Three clinical forms of West Nile virus have emerged: WN fever, WN encephalitis; and WN meningitis, although some individuals have other clinical manifestations. Some persons develop WN fever. The febrile illness of acute onset may be clinically unrecognizable as WN. About 20% of those infected have mild symptoms that last 4 to 6 days; symptoms generally include fever and may include weakness, nausea, vomiting, headache, mental status changes, diarrhea, rash, and lymphadenopathy. WN encephalitis is marked by disorientation, stupor, coma, seizures, and movement disorders including tremor, ataxia, extrapyramidal signs, and paralysis. WN meningitis is characterized by meningeal signs of severe headache, high fever, and nuchal rigidity. Myelitis and polyradiculitis also may be present. Myocarditis, pancreatitis, and fulminant hepatitis are rare. Abnormalities in the brain stem, thalamus, basal ganglia, and cerebellum are often seen on MRI in people with severe infection—about 1 in 150 develop nervous system involvement. Identifiable risk factors for this are very young or advanced age, immunocompromised status, and pregnancy.

A preliminary diagnosis is made if IgM for the virus is found in serum or CSF. A rapid test became available in 2007. Plaque reduction neutralization assay (PRNA) is the confirmatory test. Interferon-alpha is used during treatment along with supportive care for those with severe infection. Several vaccines are under development.

resulting in opportunistic infections, neoplasms, and systemic illness; and (3) the complications of therapy.[125] A variety of CNS complications of HIV exist (Box 18-2). Multiple CNS pathologic conditions may be experienced by one person. The most common neurologic disorder is HIV-associated dementia; others are peripheral neuropathies, vacuolar (spongy softening) myelopathy, opportunistic infections of the CNS, neoplasms, and, less commonly, stroke syndromes.[126]

HIV-infected macrophages/monocytes in blood are attracted to the brain by up-regulation of proinflammatory mediators such as monocyte chemoattractant protein-1 (MCP-1), tumor necrosis factor-alpha (TNF-α), and adhesion molecules on endothelial cells. Up-regulation enables transendothelial migration of activated macrophages/monocytes and causes neuroinflammation. Brain HIV-infected macrophages and microglia may be a sanctuary site for HIV because drugs have more difficulty crossing the blood-brain barrier, and there may be drug-resistant viral mutations and reinfection of the vascular system.[127]

Human Immunodeficiency Virus–Associated Neurocognitive Disorders (HANDs). A variety of names have been used for **human immunodeficiency virus–associated neurocognitive disorders (HANDs),** including HIV-associated dementia (HAD), HIV-associated cognitive dysfunction, HIV encephalopathy,

BOX 18-2 NERVOUS SYSTEM COMPLICATIONS OF HIV-1 INFECTIONS

CNS Complications of HIV-1 Infection

- Diffuse cerebral disorders
  - Minor cognitive and motor deficits (MCMDs)
  - HIV-associated dementia neurocognitive disorder (HAND)
- Meningitis
  - Atypical aseptic meningitis
    - Acute: typical meningitis signs
    - Chronic: headache syndrome
  - Nonviral infection
    - *Cryptococcus neoformans*
  - Other fungal infections
    - Mycobacterial infections
- Myelopathy
  - Spinal vacuolar myelopathy
- Focal brain disorders
  - Opportunistic viral infections
    - Progressive multifocal leukoencephalopathy
  - Herpesviruses
  - Nonviral infections
    - *Toxoplasma gondii*
  - Bacterial infections
  - Neoplasms
    - Primary CNS neoplasms
    - Metastatic neoplasms
  - Cerebrovascular complications
  - Complications resulting from systemic HIV therapy

Peripheral Nervous System Complications of HIV-1 Infections

- Distal symmetric peripheral neuropathy (polyneuropathy)
- Inflammatory demyelinating polyradiculoneuropathy
- Mononeuropathy multiplex
- Progressive polyradiculopathy
- Other causes of peripheral nervous system dysfunction
- Herpes zoster radiculitis
- Cranial neuropathies

CNS, Central nervous system; *HIV,* human immunodeficiency virus.

subacute encephalitis, HIV-associated dementia complex, HIV cognitive motor complex, AIDS encephalopathy, AIDS dementia complex, or AIDS-related dementia. Both adults and children may be affected with progressive cognitive dysfunction in conjunction with motor and behavioral alterations. The syndrome typically develops later in the disease but may be an early or a singular manifestation. The syndrome is more prevalent in drug users with HIV.[128]

The neurologic syndromes develop from properties of the virus, genetic characteristics of the host, and interactions with the environment (including treatment). At the time of primary HIV infection, HIV infects the perivascular macrophages, microglial cells, and astrocytes, particularly in the basal ganglia and deep white matter. Affected macrophages, macrophage-derived multinucleated cells, and microglia cause an immune-mediated demyelination process in white matter. Focal and diffuse demyelination of white matter and spongy changes of the spinal cord are present.

HIV-associated neurocognitive disorder is insidious in onset and unpredictable in its course. Most individuals experience a steady progression of mental decline characterized by abrupt accelerations of signs over several months to more than 1 year, although some experience an abrupt onset or an accelerated course. The triad of clinical manifestations are neurocognitive impairment, behavioral disturbance, and motor abnormalities. Clinical manifestations are summarized in Table 18-10.

Diagnosis is difficult, especially in early stages. The individual's health history, along with physical examination findings and supporting CSF, CT, and MRI data, helps establish the diagnosis although the brain may appear normal until there is advanced disease. Specific screening tools have been developed to assist in diagnosis. Highly active antiretroviral therapy (HAART) with more efficient CNS drug penetration has reduced the prevalence and improved survival for severe HAND, but milder forms of the disease may persist because of

TABLE 18-10 CLINICAL MANIFESTATIONS OF HIV-RELATED DEMENTIA

Early Stages

- *Cognitive impairments*
  - Short-term memory deficit
  - Decreased concentration/attention
  - Confusion and disorientation
  - Visuospatial perception deficits
- *Psychotic symptoms*
  - Hallucinations and delusions
  - Suspiciousness and delusions
  - Agitation and inappropriate behavior
- *Changes in personality or behavior*
  - Apathy, depression
  - Impaired judgment, erratic behavior
  - Social withdrawal
  - Rigidity of thought
  - Speech impairment
- *Motor symptoms*
  - Ataxia, loss of coordination, weakness
  - Tremors
- *Generalized systemic symptoms*
  - Fatigue, sleep changes (hypersomnia)
  - Anorexia, weight loss
  - Enuresis
  - Hypersensitivity to drugs and alcohol

Advanced Stages

- *Cognitive symptoms*
  - Global cognitive impairment
  - Impaired social relationship
  - Disorientation
  - Psychomotor retardation, decreased spontaneity
  - Agitation (e.g., nighttime delusions)
  - Coma, vegetative state
- *Motor symptoms*
  - Ataxia
  - Spastic weakness
  - Paraplegia, quadriparesis
  - Hyperreflexia, myoclonus, seizures
  - Bladder and bowel incontinence

Data from Clark C: Psychiatric aspects of AIDS, Chapter 71. In Jacobson JL, Jacobson AM, editors: *Psychiatric secrets,* ed 2, Philadelphia, 2001, Hanley & Belfus; Stern TA et al: *Massachusetts General Hospital comprehensive clinical psychiatry,* ed 1, St Louis, 2008, Mosby.

longer life. Research is continuing to evaluate the best treatment protocols and the possible neurotoxicity of HAART.[129]

HIV Myelopathy. **HIV myelopathy** involving diffuse degeneration of the spinal cord may occur with HIV. **Vacuolar myelopathy** is believed to be a direct consequence of HIV. The lateral and posterior columns of the lumbar spinal cord are affected. A progressive spastic paraparesis with ataxia is the predominant clinical manifestation. Leg weakness, upper motor neuron signs, incontinence, and posterior column sensory loss may be present. Diagnosis is made on the basis of history, physical findings, and supporting data from diagnostic procedures. Vacuolar myelopathy is treated supportively and does not respond to antiretrovirals.[125]

HIV-Associated Peripheral Neuropathy. Some **HIV-associated peripheral neuropathies** occur early, may coincide with seroconversion, are immune-mediated, and respond to standard immunotherapies. Other peripheral neuropathies primarily develop with advanced HIV infection and immunocompromised states and are facilitated by HIV replication, neurotoxicity from antiretroviral therapies, and coinfection with opportunistic pathogens.

HIV neuropathy may have one or a combination of several presentations: a predominantly sensory neuropathy, an autonomic neuropathy, a mononeuritis multiplex, an inflammatory demyelinating polyneuropathy (e.g., a Guillain-Barré–like syndrome), and a myopathy. The peripheral nervous system may sustain injury in HIV, manifesting as a peripheral neuropathy or radiculopathy. A progressive radiculopathy of predominantly the dorsal roots of the lumbar and sacral nerves may occur, involving severe myelin and axonal loss.

HIV-associated distal symmetric polyneuropathy, a sensory neuropathy occurring late in the disease, is the most commonly occurring neuropathy with slowly progressive numbness and paresthesias and burning sensations in the extremities and feet. Weakness and decreased or absent distal reflexes may be present.

The most common myopathy is polymyositis; it may be present initially or develop later. Inflammation leads to muscle cell degeneration and necrosis resulting in weakness of extremities with myalgia and fatigue.

Viral Meningitis and HIV. Some people develop an acute viral meningitis at approximately the time of seroconversion. This may well represent the initial infection of the nervous system by the HIV. Symptoms include headache, fever, and meningismus.

Opportunistic Infections and HIV. Opportunistic infections may be bacterial, fungal, protozoal, or viral in origin and produce nervous system disease. Typically bacterial infections are caused by unusual microorganisms. Cryptococcal infection is the most common fungal disorder and the third leading cause of neurologic disease with HIV. In *Cryptococcus neoformans,* small granulomas and cysts are found in the cerebral cortex and later may be present in deep cerebral tissues. The symptoms are vague, such as fever, headache, malaise, and meningismus. Herpes encephalitis and herpes varicella-zoster radiculitis may develop. Papovavirus (especially JC virus) in the immunocompromised person with HIV may produce a demyelinating disorder called *progressive multifocal leukoencephalopathy (PML).* This virus is found in 90% of healthy persons but is dormant. The virus reactivates to cause PML in 15% of persons with HIV. Sensory and motor deficits, aphasia, and apraxia are common clinical manifestations. The condition is progressive and there is no effective treatment.[130]

Cytomegalovirus Infection. Cytomegalovirus encephalitis is common with AIDS but often not diagnosed while a person is alive. The encephalitis may be present as an acute illness with encephalitis features accompanied by nystagmus and cranial nerve signs. Retinitis is found in 50% of those affected.

Parasitic Infection. **Toxoplasmosis** is the most common opportunistic infection and occurs in one third of persons with HIV. CNS toxoplasmosis typically manifests as focal encephalitis. *Toxoplasma gondii,* a protozoan, is thought to reactivate from latent lesions to produce a well-demarcated necrotizing process. Lesions may be multiple and exist throughout the cerebral hemispheres.

Clinical manifestations of CNS toxoplasmosis are focal but highly variable and include clumsiness to hemiplegia, aphasia, seizures, ataxia, cognitive changes, and constitutional symptoms. Fever and headache are common. Toxoplasmosis is difficult to diagnose but is treated effectively with pyrimethamine and sulfadiazine.

HIV-Associated Central Nervous System Neoplasms. HIV-associated CNS neoplasms have declined significantly with HAART, particularly primary CNS lymphoma. Other neoplasms associated with HIV include systemic non-Hodgkin lymphoma and metastatic Kaposi sarcoma. Metastasis of a Kaposi sarcoma to the CNS is uncommon.[131]

Lyme Disease

Lyme disease, a tick-borne spirochete bacterial infection, is a common arthropod-borne infection in the United States. It affects all age groups and involves the peripheral and central nervous systems. Transmission is most likely in the late summer or early fall in areas where there are deer, mice, and other animals that are primary reservoirs for infected ticks. Infected ticks are endemic in the Midwest, Western wooded and coastal areas, the mid- to northeast Atlantic, Europe, and eastern Asia. Lyme disease is caused by *Borrelia burgdorferi (B.b.)* introduced by tick bite, requiring about 36 to 72 hours of attachment and feeding. During feeding the microorganism is transferred from the gut of the tick to the salivary glands and then into the skin of the host. *B.b.* larvae evade immune surveillance by inhibiting complement killing, producing surface proteins that block phagocytic recognition (antigenic variation), and hiding in the extracellular matrix. *B.b.* incubates for 3 to 32 days and then migrates to the skin, lymph nodes, and other body systems. The pathologic process progresses through three stages[132]:

Stage I (acute localized): Within 1 month after the bite, the disease is characterized by a bull's-eye–like (5 cm in diameter) burning and centrifugally expanding erythema migrans rash followed by acute disseminated disease with general malaise, flulike symptoms (fever, muscle pain), stiff neck, and headache (seen in 50% to 90% of cases).

Stage II (systemic infection): Skin manifestations continue with or without acute widespread dissemination of

antibodies and immune complexes and cardiac and neurologic involvement (within a week up to a month). About 10% of cases show cardiac signs and symptoms (palpitations, dizziness, shortness of breath, arrhythmias, and first-degree heart block). Neurologic signs occur in 10% to 15% of those affected and include headache, chronic aseptic (lymphocytic) meningitis, Bell palsy, encephalitis, and radiculitis. Pathologically, there is meningeal inflammation, perivascular inflammatory cell formation, and focal demyelination.

Stage III (chronic stage): The third stage may occur up to 2 years after the bite and involves arthritis and involvement of brain parenchyma with encephalitis, chronic neuropathy (paresthesias, radiculopathy), and encephalopathy (cognitive deficits, memory loss).

B.b. infection can be difficult to diagnoses. Treatment of choice is antibiotic therapy. Minor recurring symptoms are common in 50% of individuals. Some individuals experience post–Lyme disease syndrome after antibiotic treatment, with fatigue, musculoskeletal pain, and short-term memory difficulty.[133]

Demyelinating Disorders

Demyelinating disorders are the result of damage to the myelin nerve sheath. They can occur in either the central (e.g., multiple sclerosis) or the peripheral (e.g., Guillain-Barré syndrome, which also involves a polyneuropathy [see p. 622]) nervous system. Causes of the disorders include genetics, infections, autoimmune reactions, environmental toxins, and unknown factors. Multiple sclerosis is the most common and is presented in the next section.

Multiple Sclerosis

Multiple sclerosis (MS) is a chronic inflammatory disease involving degeneration of CNS myelin, scarring or formation of plaque, and loss of axons. MS is caused by an autoimmune response to self-antigens in genetically susceptible individuals. About 0.1% of the population is affected (400,000 persons in the United States and 2.1 million worldwide).[134] Prevalence rates vary with geographic location (higher in temperate regions far above the equator) and racial groups (highest in whites, although it occurs in all races).

The onset of MS is usually between 20 and 40 years of age with a peak of age 30. Male to female ratio is about 1:2. MS is the most prevalent CNS demyelinating disorder and a leading cause of neurologic disability in early adulthood. Life expectancy is not greatly altered by MS and the disease course often extends over 30 years. The etiology of MS is unknown. Genetic and environmental factors and interactions are implicated in disease onset. Although the disorder does not exhibit a defined inheritance pattern, 15% of those with MS have an affected relative. Multiple genes affect risk of development of MS. A genetic link exists in the human leukocyte antigen (HLA) complex, a large cluster of genes responsible for many immune functions. Several genetic polymorphisms are probably involved.[135] Vitamin D deficiency, cigarette smoking, and Epstein-Barr virus infection are environmental risk factors.[136]

The first demyelinating event, or “clinically isolated syndrome” (CIS), is a single episode of neurologic dysfunction lasting greater than 24 hours that can be a prelude to MS. Characteristic episodes include optic neuritis, solitary brainstem lesions, and transverse myelitis.[137]

PATHOPHYSIOLOGY. MS is a diffuse and progressive CNS disease that affects white and gray matter. Autoreactive T and B cells recognize myelin autoantigens and trigger inflammation in the CNS, leading to the loss of myelin sheaths and nerve conductivity and subsequently to the death of neurons (Figure 18-28). MS is described as occurring when a previous infectious insult to the nervous system has occurred in a genetically susceptible individual with a subsequent abnormal CNS immune response. Various mechanisms cause irreversible tissue damage (inflammation,

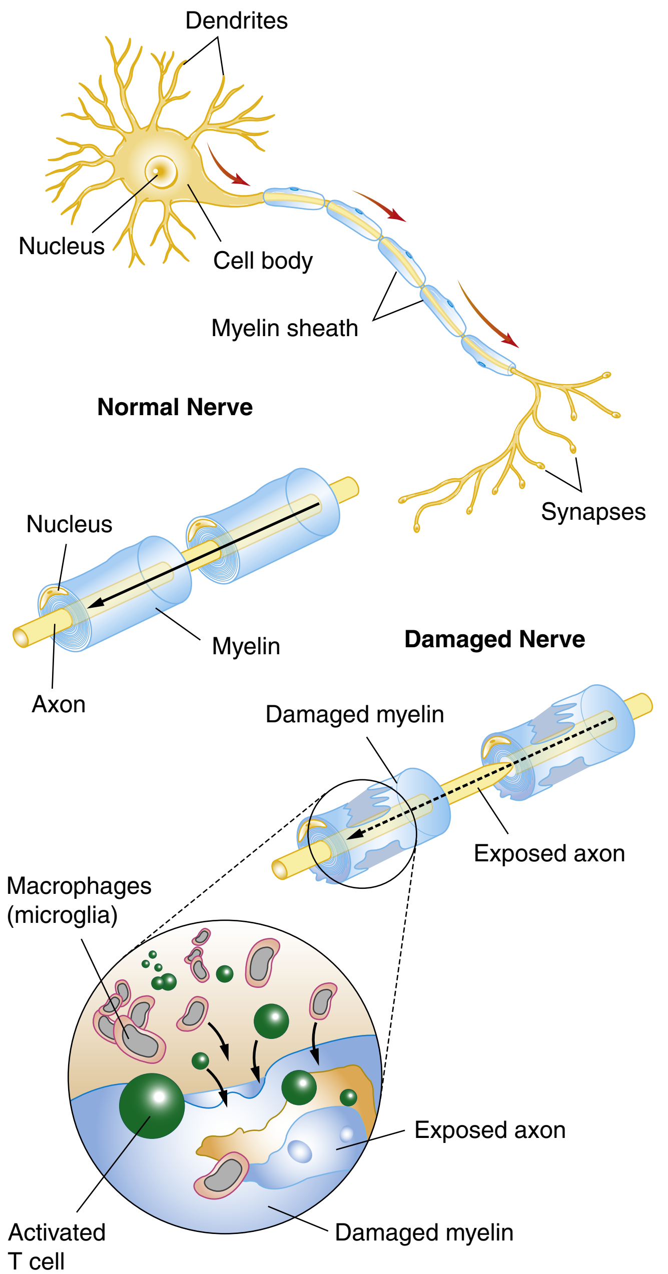

FIGURE 18-28 Pathogenesis of Multiple Sclerosis.

oligodendrocyte injury, demyelination, scarring or plaque formation, and axonal degeneration) that characterizes MS. These degenerative processes begin early in the course of the disease and continue to progress throughout a person's life. Demyelinated axons are more fragile and susceptible to further damage and, when degeneration exceeds self-repair ability (remyelination), permanent disability results. Myelin destruction and axonal damage begin before symptom onset (early inflammatory demyelination).

The innate and adaptive immune systems are activated in the pathology of MS. The immunopathology of MS involves[138] the following events:

1. Activation of CD4+ and CD8+ T cells; cells cross the blood-brain barrier and enter the CNS and attack myelin
2. Production of interleukin-12 (IL-12) and IL-23 (proinflammatory cytokines)
3. Lack of IL-10 (an anti-inflammatory cytokine)
4. Production of IL-17 (proinflammatory cytokine) by Th17 cells
5. Expression of integrins to facilitate adherence and passage of immune cells into the CNS
6. Promotion of chemokine migration of immune cells into the CNS that is up-regulated in MS
7. Contribution of B lymphocytes and plasma cells to the inflammatory response and direct damage to myelin and axons; B cells are more active in chronic or progressive forms of MS (B cells produce autoantibodies, secrete inflammatory cytokines, and activate T cells by presenting antigen)[139,140]
8. Activation of complement (promotes inflammation) during the acute phase; may be neuroprotective during relapse[141]
9. Presence of cells of inflammation including eosinophils, neutrophils, and macrophages

As the disease progresses, inflammatory changes in the CNS increase, and loss of brain volume progresses more rapidly.[142,143] The demyelination disrupts sodium, calcium, and potassium ion channels and calcium influx is proinflammatory and neurotoxic. Activated microglia and macrophages release nitric oxide and oxygen free radicals. Activated immune cells also produce glutamate, a neurotoxin.[144]

MS is characterized not only by focal inflammatory changes but also by diffuse injury throughout the CNS (MS lesions) (Figure 18-29). MS lesions may occur anywhere in white or gray matter. In addition, other neurodegenerative processes that involve the entire CNS are taking place, including: (1) changes in gray matter in the cortex, basal ganglia, brainstem, and spinal cord with substantial loss over time; (2) brain atrophy that begins early in the disease and is highly correlated with disability and progressive MS; and (3) direct dysfunction of or damage to oligodendrocytes that manufacture myelin.[145,146] Normal-appearing white matter also is highly abnormal microscopically with the presence of wallerian degeneration, diffuse inflammation, extensive microglial activation, neurotoxic substances, and gene activation that disrupt cellular processes.[145] Iron deposits in both gray and white matter have been found in MS, and the pathologic significance may be associated with mitochondrial and oxidative injury.[147] Research is in progress to determine if chronic cerebrospinal venous insufficiency is a pathogenic factor in MS.[148] In established disease the multifocal, multistaged feature of MS lesions gives rise to the aphorism that the lesions are "scattered in space and time." Symptoms therefore are multiple and variable among individuals with the disease.

CLINICAL MANIFESTATIONS. A variety of events (e.g., infection, trauma, or pregnancy) occurring immediately before the onset or exacerbation of symptoms are regarded as precipitating factors related to MS. Most of the pregnancy-related exacerbations

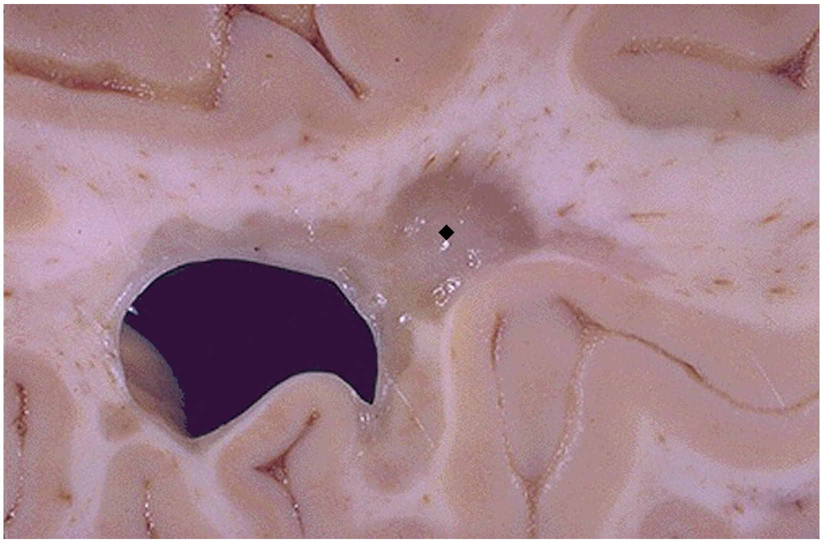

FIGURE 18-29 Multiple Sclerosis, Gross. Seen here in periventricular white matter is a large "plaque" (◆) of demyelination that has a sharp border with adjacent normal white matter. Such plaques have a gray-tan appearance and are typically associated with the clinical appearance of transient or progressive loss of neurologic function in multiple sclerosis (MS). Because MS is often multifocal, and the lesions appear in various white matter locations in the central nervous system over time, the clinical course and findings can be quite varied. (From Klatt EC: *Robbins and Cotran atlas of pathology,* Philadelphia, 2006, Saunders.)

BOX 18-3 ESTABLISHED SYNDROMES OF MULTIPLE SCLEROSIS

Mixed or Generalized Type (50% of Persons)
Optic signs—optic neuritis
Brainstem signs—internuclear ophthalmoplegia, diplopia, vertigo (vomiting), nystagmus, dysarthria
Cerebellar signs—see below

Spinal Type (30% to 40% of Persons)
Spastic ataxia
Deep sensory changes in the extremities
Bladder and bowel symptoms

Cerebellar or Pontobulbar-Cerebral Type (5% of Persons)
Motor ataxia
Hypotonia
Asthenia

Amaurotic Form (5% of Persons)
Blindness

occur 3 months postpartum, suggesting a relation to the stresses of labor and the increased fatigue during the postpartum period rather than to the pregnancy itself.[149] The major classifications of MS are relapsing-remitting, primary progressive, secondary progressive, and progressive-relapsing. Initially 90% of persons present with a relapsing, remitting course; 10% present with a primary progressive course; and 90% develop a progressive course in 10 to 20 years after onset of the disease. However, once walking problems develop, disease progression occurs quickly regardless of disease type. Usually persons with late MS have one of the established syndromes—mixed, spinal, or cerebellar (Box 18-3). The initial syndrome depends on the portion of the CNS that is most involved. After years of disease, 50% of individuals appear to have established syndromes of mixed involvement.

Optico-Spinal Multiple Sclerosis. **Optico-spinal multiple sclerosis (OSMS)** has the manifestations of optic nerve and spinal cord axonal loss. The condition usually evolves rapidly over hours to days and is highly suggestive of MS. Involvement may be unilateral or bilateral. Subjective symptoms are impaired central vision (blurring, fogginess, haziness) and impaired color perception. Signs are decreased central visual acuity; central or paracentral scotoma (area of diminished vision); acquired color vision deficit, especially to red and green; and defective pupillary reaction to light. A variety of field defects may occur. In the acute phase these symptoms may reflect optic papillitis (inflammation and swelling of the optic disc) or retrobulbar neuritis with a normal disc. Immune injury damages the optic nerve and inflammatory edema compresses the blood supply in the tight optic canal. One third of persons recover completely, and most others improve significantly.[150]

The brainstem lesions involve cranial nerves III through XII at the root, nuclear, or corticobulbar (upper motor neuron) level. Internuclear ophthalmoplegia, nystagmus, and dysarthria are the most common brainstem symptoms, followed by deafness, vertigo and vomiting, tinnitus, facial weakness, and facial sensory deficit. Internuclear ophthalmoplegia is lateral gaze paralysis caused by involvement of the medial longitudinal fasciculus, the brainstem pathway that coordinates eye movement. Diplopia and eyeball pain are common complaints. Bilateral internuclear ophthalmoplegia in a young adult is virtually diagnostic of MS.

Cognitive dysfunction has been demonstrated to occur early in the disease course. The person experiences decreased short-term memory, recent memory impairment, decreased concentration, word-finding problems, and planning difficulties. Mood alterations are common in MS. Depression is far more common than euphoria.

Neuromyelitis optica (NO; Devic disease) is a demyelinating disease that also selectively affects the optic nerve and spinal cord (usually grouped within three to four vertebrae). It was previously considered to be a severe variant of MS because of the similar pathologic features and its resemblance to optico-spinal MS that occurs in the Asian population. However, aquaporin-4 (AQP4) IgG autoantibodies play a pathogenic role in NO and it may be a distinct disorder or overlap with OSMS.[151]

Spinal Multiple Sclerosis. The spinal type of MS is the second most common type, chiefly involving the spinal tracts and dorsal column. Weakness, numbness, or both in one or more limbs are initial symptoms in 50% of cases of MS. Subjective corticospinal (upper motor neuron) symptoms (stiffness, slowness, weakness) are often unilateral and are a component of fatigability. Spinal signs are usually bilateral (symmetric), with lower limbs more often and more severely affected than upper limbs; spastic paraparesis is probably the most common single neurologic finding in MS.

Bladder and bowel symptoms occur with major spinal cord involvement. Urgency and hesitancy generally precede incontinence. Bladder dysfunction most often involves a small, spastic bladder, although occasionally a large, flaccid bladder may develop with retention problems. Neurogenic impotence often occurs when sphincter symptoms are present. Bowel incontinence is rare, but constipation is common with severe disease. Subjective dorsal column symptoms are symmetric paresthesias (tingling and numbness) in an unpredictable pattern but with a predilection for lower extremities over upper extremities. Dorsal column signs are vibration, position, and two-point discrimination deficits. Sensory complaints often are not substantiated by objective physical findings but by further diagnostic tests.

Cerebellar Multiple Sclerosis. Nystagmus and ataxia can present initially and reflect cerebellar and corticospinal involvement. Cerebellar deficits are usually symmetric, with all four limbs involved. With combined corticospinal and cerebellar involvement, the individual has a spastic ataxic gait and ataxia of the arms. Pure cerebellar symptoms are those of motor ataxia, hypotonia, and asthenia (weakness). Manifestations of motor ataxia are decomposition of movement, inability to perform rapid alternating movements (dysdiadochokinesia), and dysmetria. Charcot triad describes a combination of dysarthria, intention tremor, and nystagmus associated with cerebellar multiple sclerosis. Hypotonia is manifested by decreased resistance to passive movement, hypoactive deep tendon reflexes, and pendular knee jerk reflex.

TABLE 18-11 DIAGNOSTIC EVALUATION FOR MULTIPLE SCLEROSIS

Clinical Signs and Symptoms	Signs and symptoms indicating disease of the brain or spinal cord not attributable to another diagnosis with two or more episodes lasting at least 24 hours and occurring at least 1 month apart
Tests	
Magnetic resonance imaging	
T2 weighted	Demyelinated plaques, both active and inactive
Gadolinium enhanced	Active demyelinating plaques
Cerebrospinal fluid analysis	Oligoclonal bands of immunoglobulin G Elevated immunoglobulin G index
Evoked potentials	Slowed nerve impulse conduction

Short-lived attacks of neurologic deficits are the temporary appearance or worsening of symptoms. The mechanism of these attacks is complete reversible conduction block in partially demyelinated axons. Conditions that cause short-lived attacks include: (1) minor increases in body temperature or serum Ca^{++} concentration and (2) functional demands exceeding conduction capacity. An increase in body temperature or serum Ca^{++} level increases current leakage through demyelinated neurons. Individuals with MS may become dramatically worse when body temperature is raised. Hypercalcemia induced by decreased serum pH may aggravate symptoms of MS. Physical and emotional stress imposes functional demands that may exceed conduction capacity of affected neurons.

Paroxysmal attacks are sensory or motor symptoms of abrupt onset and short duration (a few seconds or minutes). These symptoms include paresthesias, dysarthria and ataxia, and tonic head turning. The mechanism of paroxysmal attacks is nonsynaptic transmission in which nerve impulses are directly transmitted between adjacent demyelinated axons. These impulses arise focally and spuriously in the cervical portion of the spinal cord or in the brainstem. A common paroxysmal symptom, called *Lhermitte sign,* is the momentary paresthesia (shock-like or tingling sensation) that shoots down the trunk or limbs during active or passive flexion of the neck. Bending the neck evokes nonsynaptic impulses in demyelinated axons of the dorsal column in the spinal cord. A person with MS may have many paroxysmal attacks each day. Inciting events include sensory stimulation, voluntary movement, hyperventilation, and emotional stress. Paroxysmal attacks tend to persist for weeks or months and may be followed by progressive symptoms of MS.

EVALUATION AND TREATMENT. The diagnostic criteria for MS were revised in 2010 and are known as the McDonald criteria.[152] Clinical examination in combination with MRI, to demonstrate MS lesions in time and space, and CSF findings are used to make an early diagnosis (Table 18-11) so that treatment may begin sooner. Persistently elevated CSF immunoglobulin G (IgG) index is found in about two thirds of individuals with MS, and oligoclonal bands of IgG on electrophoresis are found in more than 90% of persons. Evoked response (ER) studies aid diagnosis by detecting decreased conduction velocity in visual, auditory, and somatosensory pathways. MRI is used to assist diagnosis and assess prognosis although there are limitations to detecting the full extent of the lesions.[153]

The treatment goal in MS is prevention of permanent neurologic damage. Acute relapses are treated with corticosteroids to speed recovery. Both oral and injectable disease-modifying drugs are used to decrease the number of relapses, promote remyelination and repair, prevent demyelination, suppress selective B-cell and T-cell function, and prevent disability.[154] Vitamin D supplementation may reduce the risk of MS and promote a more favorable progression.[155]

Symptom management for fatigue, weakness, vertigo, ataxia, tremor, heat intolerance, spasticity, bladder dysfunction, bowel dysfunction, sexual dysfunction, sensory sensations, pain, cognitive difficulties, depression, and psychosocial issues is essential. Many treatments are only partially effective, particularly for fatigue and spasticity. Supportive and rehabilitative management is directed toward preventing the complications of immobility, especially pressure sores and infections of the pulmonary and genitourinary systems. Interdisciplinary inpatient rehabilitation may improve function in the short term.[156]

PERIPHERAL NERVOUS SYSTEM AND NEUROMUSCULAR JUNCTION DISORDERS

Peripheral Nervous System Disorders

Neuropathies

The axons traveling to and from the brainstem and spinal cord neuronal cell bodies may be injured by a multitude of disease processes. Distinct anatomic areas of the axon may be injured or the spinal nerves may be affected at the spinal roots, at the plexus before peripheral nerve formation, or at the peripheral nerves themselves. Cranial nerves do not have roots or plexuses so are affected only within the nerves. Autonomic nerve fibers may be injured as they travel within certain cranial nerves or emerge through the ventral root and plexuses to travel in the peripheral nerves of the body.

Neuropathies can be classified as (1) generalized symmetric polyneuropathies, (2) generalized neuropathies, and (3) focal or multifocal neuropathies. **Generalized symmetric polyneuropathies** are characterized by symmetric involvement of sensory, motor, or autonomic fibers although, with clinical signs, one type of fiber may predominate. Generalized symmetric polyneuropathies further subdivide into **distal axonal polyneuropathy** and **demyelinating polyneuropathy.** Distal axonal polyneuropathy affects peripheral axons and is the generalized peripheral neuropathy commonly seen. The clinical feature of distal axonal polyneuropathy is involvement of the longest nerves of the body, those going to the feet, first. Sensory impairment is greater than motor impairment. Symptoms are burning pain, tingling, and numbness of the feet. Small nerve fiber damage produces decreased pain and temperature sensation, as well as burning, numbness, and tingling. Large nerve fiber injury causes decreased light touch, vibration, and position sense.

The two most common causes are diabetes mellitus and alcohol abuse; occasionally, neurotoxic therapeutic agents also are the cause. Within the classification of distal axonal neuropathies is another group of neuropathies called *autonomic neuropathy*. This neuropathy can involve virtually any sympathetic or parasympathetic nerve fiber with impairment of cardiovascular, gastrointestinal, urogenital, thermoregulatory, sudomotor, and pupillomotor autonomic function. Autonomic neuropathies have a progressive course and are usually reversible. The myelin or Schwann cells are affected in demyelinating polyneuropathy, which occurs far less frequently. Weakness is the predominant sign with far less sensory impairment. Acute and chronic inflammatory demyelinating neuropathies comprise this group, of which Guillain-Barré syndrome is the most widely recognized disorder (see below).

Generalized neuropathies affect the cell body of only one type of peripheral neuron. The dorsal root ganglion cell is affected in sensory neuropathies, producing numbness that may begin in a focal or asymmetric distribution or in a distal symmetric pattern. **Sensory neuropathies** are seen in leprosy, some industrial solvent poisonings, some hereditary disorders, and chloramphenicol toxicity. **Motor neuropathies** are caused by anterior horn cell disease, such as amyotrophic lateral sclerosis or paralytic poliomyelitis. There is weakness or paralysis that may be symmetric or asymmetric.

Focal neuropathy or **multifocal neuropathies** affect sensory and motor fibers in one or more nerves, as is seen in common compression neuropathies such as carpal tunnel syndrome (median nerve compression), ulnar nerve compression (at the elbow), peroneal nerve compression, or sciatic nerve compression. Focal neuropathies can involve one or more cranial nerves. Plexus injuries and radiculopathies also fall into this category.

PATHOPHYSIOLOGY. Although distinct pathophysiologic processes are recognized in a neuropathy, these are not disease specific and may exist simultaneously in any one neuropathy. Wallerian degeneration, in which the axon and myelin distal to the site of axonal interruption degenerate, may be present (see Chapter 15). This type of degeneration is characteristic of a traumatic nerve injury in which the nerve is severed. In demyelinating neuropathies the axon may be spared and only the myelin degenerates. In axonal degeneration distal degeneration of the axon occurs first and is followed by degeneration of the myelin and the axis cylinder. Many pathologic processes may give rise to neuropathy, and one or more nerves may be involved.

CLINICAL MANIFESTATIONS. When the axons are affected, muscle strength, muscle tone, and muscle bulk also are affected. Whole muscles or groups of muscles are paretic or paralyzed, and the muscles of the feet and legs often are affected first and more severely. These long, large axons are thought to (1) be more vulnerable to injury because of their size and length, (2) have more Schwann cells available to be injured, and (3) exhibit a "dying back" phenomenon caused by difficulty of the nerve cell body in maintaining the terminal portion of the axon. If unchecked, the pathologic process tends to involve the hands and arms because these have the next longest and largest axons.

Tone and the deep tendon reflexes in the affected muscles generally are decreased in a neuropathy. Atrophy is distributed according to the peripheral nerves involved. The degree and distribution of the atrophy probably depend on the extent of the injury. Fasciculation may be present, especially with associated ventral root or motor neuron changes, or both, as in Guillain-Barré syndrome, diabetic neuropathy, and porphyric neuropathy. Mild fatigue may be experienced. A few disorders, notably Guillain-Barré syndrome, produce a pattern of paresis and paralysis that involves all limbs, the trunk, and the neck. Peripheral bifacial and other cranial nerve palsies may be seen with a variety of disorders. Tenderness of the nerve trunks and associated sensory alterations help to distinguish neuropathy from amyotrophy. These include paresthesias and dysesthesias as well as decreased or absent primary sensations (e.g., of temperature, touch, light pain, position, or vibration). Ataxia of gait or limb may arise from the loss of position and vibratory sensations (i.e., proprioceptive sensory loss) and may be enhanced by motor weakness.

Reflexes may be altered. Reflex-mediated autonomic nervous system functions, such as sweating and pupillary size, may be affected. Neuropathies associated with autonomic disturbances include diabetes mellitus, alcoholism and related nutritional neuropathies, amyloidosis, porphyria, Guillain-Barré syndrome, Riley-Day syndrome, and familial sensory neuropathy. In many chronic polyneuropathies, the feet, hands, and spine become deformed. Metabolic changes may arise secondary to nerve dysfunction.

EVALUATION AND TREATMENT. The diagnostic workup to determine the cause of a neuropathy is often extensive. Early diagnosis and treatment before irreversible neuronal cell damage ensues are of paramount importance. Although axonal regrowth and recovery of function may take months, many neuropathies can be reversed. The therapeutic management is directed first at elimination of the cause, if possible. At least the primary disorder, such as diabetes mellitus, should be controlled. Further damage to the axon must be prevented by avoiding (1) trauma from premature demand for reuse of the nerve, (2) accidents that cause tissue damage, and (3) hypoxia and ischemia or other deprivation of essential substrates.

Guillain-Barré Syndrome. **Guillain-Barré syndrome (GBS) (Landry-Guillain-Barré syndrome, idiopathic polyneuritis, acute inflammatory demyelinating polyradiculopathy, acute autoimmune neuropathy)** is an acquired acute inflammatory demyelinating or axonal polyneuropathy with four subtypes. The subtypes and their clinical features are presented in Table 18-12. These subtypes occur throughout the world, affect children and adults of both genders and all age groups equally, and occur in all seasons of the year. The annual incidence rate is 1 to 2 per 100,000 with a 4% to 6% mortality, and a 5% to 10% morbidity rate (permanent disabling weakness, imbalance, or sensory loss).[157]

PATHOPHYSIOLOGY. GBS is considered to be an autoimmune disease triggered by a preceding bacterial or viral infection. Molecular mimicry (cross-activation of self-epitopes and pathogen-derived peptides by autoreactive T and B cells) is associated with the immune injury.[158] It has been recognized

that glycolipids, particularly gangliosides, are immune targets in the subtypes of GBS. Different gangliosides predominate in different locations in peripheral nerves and in different nerve fiber types. Table 18-12 presents the pathology and pathogenesis of the four axonal subtypes of GBS. The muscle innervated by the damaged peripheral nerves undergoes denervation and atrophy. If the cell body survives, regeneration of the peripheral nerve takes place and recovery of function is likely. If the cell body dies from intense root involvement in the inflammatory-degenerative process, no regeneration is possible. Collateral reinnervation from surviving axons and regenerating axons may take place. In this case, motor recovery is less complete and residual deficits persist.

CLINICAL MANIFESTATIONS. Clinical manifestations may vary depending on subtype. Typical first manifestations are numbness, pain, paresthesias, or weakness in the limbs. Motor signs manifest as an acute or subacute progressive paralysis. Proximal muscles may be involved earlier and more significantly than distal muscles. The paresis/paralysis may be present in an ascending pattern involving limbs, respiratory muscles, and bulbar muscles. Only bulbar muscles may be involved, resulting in dysphagia and dysarthria. Weakness usually plateaus or improves by the fourth week in 90% of cases. After weakness plateaus, strength improves over a period of days to months, with the majority of individuals reaching activity levels similar to their predisease state. If sensory symptoms are present in the subtype they may include paresthesias/dysthesias (tingling, burning, shocklike sensations, particularly in the limbs), pain (throbbing and aching, particularly in the lower back, buttocks, and legs), and numbness. Position and vibratory sensations are more affected than superficial sensation. Respiratory muscle weakness leads to the need for ventilatory support in 10% to 30% of individuals. Cranial nerve weakness manifests as facial weakness and bulbar weakness involving chewing, swallowing, and coughing. Autonomic dysfunction may manifest as tachycardia or, less frequently, bradycardia; hypotension or

TABLE 18-12 EXPANDED CLASSIFICATION OF GUILLAIN-BARRÉ SYNDROME (GBS)

SUBTYPES	CLINICAL FEATURES	PATHOLOGY	PATHOGENESIS
Acute inflammatory demyelinating polyneuropathy (AIDP accounts for most cases of GBS)	Ascending paralysis with typically distant start	Macrophages invade myelin sheaths and denude axons Lymphocytic inflammation Demyelination	T-cell–mediated lymphocytic infiltration into nerves is common
	Early sensory symptoms Loss of DTRs	Endoneurial edema Some degree of axon loss (all findings most prominent in the spinal roots and nerve terminals) CD4 and CD8 lymphocytes and macrophages are present Complement is deposited on the outermost Schwann cell plasmalemma	Antibody-mediated pathogenesis not yet demonstrated
Acute motor axonal neuropathy (AMAN)	Acute progressive weakness with no sensory impairment	Macrophages invade nodes of Ranvier, leaving the myelin sheath intact (absence of demyelination) Axonal degeneration in ventral root in severe cases	Selective antibody-mediated attack on axon (presence of IgG and complement deposits on axolemma along with macrophage recruitment) Associated with *Campylobacter jejuni* enteritis
		Lymphocyte infiltration sparse	GM1 autoantibodies play a direct pathogenic role through molecular mimicry
Acute motor and sensory axonal neuropathy (AMSAN)	Ascending paralysis Early sensory symptoms	Similar to AMAN Absence of demyelination Evidence of axonal loss in dorsal and ventral roots Lymphocytic infiltration sparse Extensive sensory nerve fiber degeneration	Undetermined
Fisher syndrome (FS) (5% of cases of GBS)	In purist form have ophthalmoparesis, areflexia, and ataxia	Pathologic features similar to those in AIDP, but are atypical FS	Antibodies to ganglioside GQ1b measured in serum in 90% of cases
	In atypical FS also have features of AIDP	Deposition of antiganglioside antibodies initially causes reversible conduction block followed by axonal degeneration	Anti-GQ1b antibodies cross-react with other gangliosides (typically GT1a, but in many cases with GD3, GD1b, and GT1b)
	Infections are common triggers for FS (*Campylobacter jejuni* enteritis)		

Data from Hardy TA et al: *Curr Allergy Asthma Rep* 11(3):197–204, 2011; Shahrizaila N, Yuki N: *Exp Rev Neurother* 11(9):1305–1313, 2011.

hypertension; and loss of or significant increase in sweating in those more severely affected. Persons may undergo a respiratory arrest or cardiovascular collapse, a cause of death. Hyponatremia caused by the syndrome of inappropriate antidiuretic hormone (SIADH) is common, especially in individuals whose lungs have been ventilated.

EVALUATION AND TREATMENT. Clinical history helps diagnose GBS and its subtypes. The major diagnostic tests are the examination of the CSF, nerve conduction studies, and EMG. The CSF findings include an unusually high protein level (500 mg/dl) without cellular abnormality. Nerve conduction studies help identify the subtype. Ventilatory support and management of the autonomic nervous system dysfunction are two dominant aspects of the therapeutic management. Intravenous immunoglobulin, plasmapheresis, or plasma exchanges or combination therapy within the first 2 weeks of onset of clinical manifestations may be indicated. After the disorder begins to remit, aggressive rehabilitation should be instituted.[159]

Radiculopathies. **Radiculopathies** are disorders of spinal nerve roots. As the spinal roots emerge from or enter the vertebral canal, they may be injured or damaged by compression, infection, inflammation, ischemia, or direct trauma whereby the roots are stretched or torn. **Radiculitis (radiculoneuritis)** refers to an inflammatory disorder of the spinal nerve roots. One or more roots may be affected.

PATHOPHYSIOLOGY. Many different pathologic conditions may cause tearing, compression, or inflammation of nerve roots.[160] Roots may be traumatized by a forceful tearing of a nerve, termed *avulsion,* often associated with injuries to the head and shoulders. An acute intervertebral disk prolapse (herniated disk), degenerative spondyloarthropathies, or a benign tumor may compress nerve roots. Metastatic tumors of the lung, breast, and gastrointestinal tract may produce a carcinomatous meningitis, causing compression and inflammatory changes in nerve roots. Other causes of inflammatory changes in nerve roots are chronic meningitis, neurosyphilis, sarcoidosis, and inflammatory arachnoiditis produced by myelography and lumbar punctures.

CLINICAL MANIFESTATIONS. The strength, tone, and bulk of the muscles innervated by the involved roots are affected. The pattern and distribution of weakness and atrophy are similar to those of the amyotrophies. Tone and deep tendon reflexes are decreased, but rarely absent, because the involved muscles are usually innervated by two or more spinal roots. Fasciculations often are present, and mild fatigue may be experienced. Because pathologic processes usually affect the ventral as well as the dorsal roots, sensory alterations are common.

Diseases that involve spinal roots typically produce local pain; pain on local percussion; pain and paresthesias in the sensory root distribution (called **radicular pain** and **radicular paresthesia**); increased pain with movement, stretching of the root, and maneuvers that transiently increase CSF pressure; sensory loss in a radicular pattern; and spasms of the muscles surrounding the vertebral column (i.e., paravertebral muscle spasms).

EVALUATION AND TREATMENT. Diagnostic measures may include physical examination, spinal films, nerve conduction studies, EMG, lumbar puncture with CSF examination, myelography, and biopsy of tumor masses.[161]

Treatment is directed at the cause of the injury and may take the form of surgical intervention, antibiotic administration, removal of the injurious agent, corticosteroid use, and radiation therapy and chemotherapy. Supportive management may include control of the discomfort, protection from further injury, prevention of complications, and rehabilitation when appropriate.

Plexus Injuries. **Plexus injuries** involve the nerve plexus distal to the spinal roots but proximal to the formation of the peripheral nerves. Such injuries may be caused by trauma, compression (entrapment), or infiltration, or they may be iatrogenic, caused by positioning during surgery or by an intramuscular injection. Clinical manifestations include motor weakness, muscle atrophy, and sensory loss in affected areas. Paralysis can occur with complete plexus lesions.[162]

The diagnosis is made on the basis of history and clinical manifestations. Therapeutic treatment is directed at removal of the cause, repair and approximation of nervous tissue, prevention of further injury, control of discomfort, prevention of complications, and rehabilitation when appropriate. Acetyl-L-carnitine (ALCAR) or *N*-acetylcysteine (NAC) can provide neuroprotection.[163]

Neuromuscular Junction Disorders

Transmission of the nerve impulse at the neuromuscular junction requires the release of adequate amounts of neurotransmitter from the presynaptic terminals of the axon and effective binding of the released transmitter to the receptors on the membranes of muscle cells (see Figure 15-14). Four neuromuscular junction disorders (NMJDs), whose pathogenesis is thought to be autoantibodies, are described: myasthenia gravis, muscle-specific kinase (MuSK) protein antibody–associated myasthenia gravis, Lambert-Eaton myasthenic syndrome, and acquired neuromyotonia. In addition, there are rare **inherited (congenital) myasthenic syndromes** that result from mutations in different key proteins for the acetylcholine receptor, ion channels, and motor end plates at the neuromuscular junction.[164] Nutritional deficits; certain drugs (e.g., reserpine or methyldopa [Aldomet]); certain toxins (e.g., botulism); some snake, scorpion, or spider venoms; certain plant extracts; and some insecticides also affect the neuromuscular junction. The most common autoimmune neuromuscular junction disorder (NMJD) is myasthenia gravis caused by the binding of autoantibodies to the acetylcholine receptor on the postsynaptic membrane. MuSK antibody–associated myasthenia gravis is also postsynaptic and is a severe form of the disease.[165] Presynaptic autoimmune diseases include **neurotonia** with autoantibodies to the potassium channels and the rare **Lambert-Eaton myasthenic syndrome** with autoantibodies to calcium channels on presynaptic nerve terminals, which presents with muscle weakness and is commonly associated with small-cell lung carcinoma.[166]

Myasthenia Gravis

Myasthenia gravis is a chronic autoimmune disease mediated by acetylcholine receptor (AchR) antibodies that act at the neuromuscular junction (Figure 18-30 and Table 18-13). About 20,000 to 70,000 people in the United States have the disease.

Myasthenia gravis is associated with an increased incidence of other autoimmune diseases, including systemic lupus erythematosus, rheumatoid arthritis, polymyositis, and thyrotoxicosis. (Autoimmune mechanisms are discussed in Chapter 9.) The etiology of myasthenia gravis is unknown. Some persons have genetic susceptibility related to variants in AchR genes, as well as the major histocompatibility genes, and they can present with varying clinical phenotypes.[167]

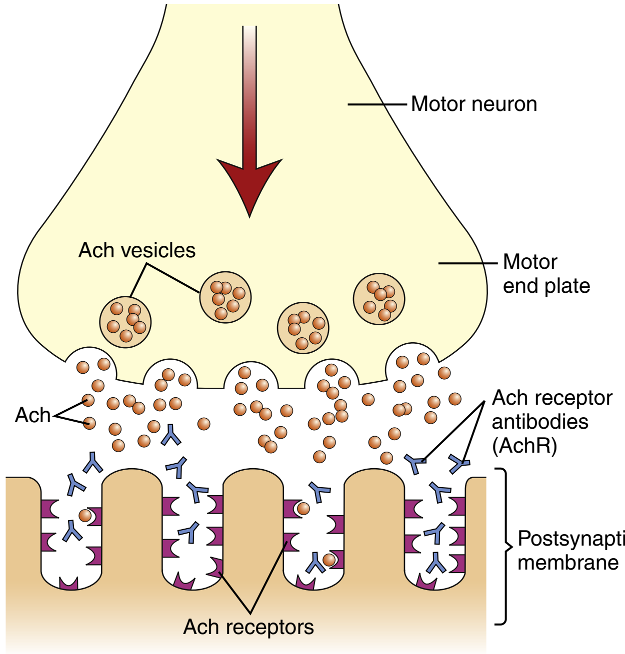

FIGURE 18-30 **Antibodies and Myasthenia Gravis.** Acetylcholine receptor antibodies block the acetylcholine receptor and inhibit the stimulating effect of acetylcholine on the postsynaptic membrane. *AchR,* Acetylcholine receptor. (Data from Juel VC, Massey JM: *Orphanet J Rare Dis* 2:44, 2007; Mahadeva B, Phillips LH 2nd, Juel VC: *Semin Neurol* 28[2]:212–227, 2008; Shigemoto K: *Acta Mycol* 26[3]:185–191, 2007.)

The subtypes of autoimmune myasthenia gravis are generalized AchR, ocular, and neonatal. Generalized AchR myasthenia gravis is further subdivided based on age and thymic pathology into the following categories:

1. Young persons, mostly female, with thymic hyperplasia
2. Older adults, both genders, with normal or involuted thymus glands
3. Persons of both genders with thymomas

Generalized AchR myasthenia involves the proximal musculature throughout the body and has several courses: (1) a course with periodic remissions, (2) a slowly progressive course, (3) a rapidly progressive course, or (4) a fulminating course. Classification by disease severity is as follows:

Grade I: ocular disease
Grade II: generalized mild weakness
Grade IIa: mild weakness
Grade IIb: moderate weakness
Grade III: severe generalized weakness
Grade IV: myasthenic "crisis" with respiratory failure[168]

About 10% to 15% of those with signs and symptoms of myasthenia gravis often involving severe swallowing and breathing (bulbar) problems do not have AchR antibodies on testing. Some of these have MuSK antibodies (an IgG4). This is now subtyped as MuSK antibody–associated myasthenia gravis.

In **neonatal myasthenia,** transitory signs of myasthenia gravis are present in 10% to 15% of infants born to mothers with myasthenia gravis. The signs appear 1 to 3 days after birth and persist for a few days to a few weeks. Myasthenia immunoglobulin is transferred from the mother to the neonate through the placenta. **Ocular myasthenia,** which is more common in males, involves weakness of the eye muscles and eyelids and may include swallowing difficulties and slurred speech as well.

PATHOPHYSIOLOGY. Myasthenia gravis results from a defect in nerve impulse transmission at the neuromuscular junction. The main defect is T-cell–dependent formation of autoantibodies (an IgG antibody) against receptors at the Ach-binding site on the postsynaptic membrane. The autoantibodies block the AchR or cause complement-mediated loss of AchRs from

TABLE 18-13 ANTIBODIES AND MECHANISMS OF ACTION AT NEUROMUSCULAR JUNCTION

FEATURES	MYASTHENIA GRAVIS (MG)	MUSCLE-SPECIFIC KINASE MG	LAMBERT-EATON MYASTHENIC SYNDROME	NEUROMYOTONIA
Target	AchR	MuSK	α1A VGCC	VGKC
Principal subclass of antibody	IgG1, IgG3 (autoantibodies against AchR)	IgG4 (autoantibody against MuSK)	Autoantibodies not known (possibly IgG4)	IgG4 (autoantibody against voltage-gated K^+ channels)
Principal mechanisms of action at NMJ	Complement-mediated destruction of folds (includes loss of AchR and sodium channels), increased turnover, direct block of function	Not clear yet; complement not activated; may involve mutations in end-plate protein Dok-7	Increased turnover	Increased turnover
Compensatory mechanisms identified	Increased presynaptic Ach release, increased postsynaptic AchR synthesis	Not clear yet	Involvement of other VGCCs in release process	Probable up-regulation of other VGKCs

Data from Farrugia ME, Vincent A: *Curr Opin Neurol* 23(5):489–495, 2010; Pal J et al: *J Neuroimmunol* 231(1-2):43–54, 2011.

the neuromuscular junction (see Figure 18-30).[169] The cause of this autosensitization is unknown. Destruction of receptor sites occurs, decreasing the number of receptors on the plasma membrane and causing diminished transmission of nerve impulses across the neuromuscular junction. Muscle depolarization is incomplete or unsuccessful.

CLINICAL MANIFESTATIONS. Myasthenia gravis typically has an insidious onset. Clinical manifestations may first appear during pregnancy, during the postpartum period, or in conjunction with the administration of certain anesthetic agents. Hallmark symptoms are exertional fatigue and weakness that worsens with activity, improves with rest, and recurs with resumption of activity. The individual often complains of fatigue after exercise and has a recent history of recurring upper respiratory tract infections. The muscles of the eyes, face, mouth, throat, and neck usually are affected first. The extraocular (eye) muscles and the levator muscles are most affected. Manifestations include diplopia, ptosis, and ocular palsies.

The muscles of facial expression, mastication, swallowing, and speech are the next most involved. The results are facial droop and an expressionless face; difficulty chewing and swallowing associated with dietary changes and weight loss; drooling; episodes of choking and aspiration; and a nasal, low-volume but high-pitched monotonous speech pattern.

The muscles of the neck, shoulder girdle, and hip flexors are affected less frequently. When these muscles do become involved, however, the person experiences fatigue requiring periods of rest, weakness of the arms and legs that improves with rest, and difficulty in maintaining head position. The respiratory muscles of the diaphragm and chest wall become weak, and ventilation is impaired. Impairment in deep breathing and coughing predisposes the individual to atelectasis and congestion. In the advanced stage of the disease, all the muscles are weak.

Myasthenic crisis occurs when severe muscle weakness causes extreme quadriparesis or quadriplegia, respiratory insufficiency with shortness of breath and a markedly decreased tidal volume and vital capacity, and extreme difficulty in swallowing. The individual in myasthenic crisis is in danger of respiratory arrest. Myasthenic crisis usually occurs 3 to 4 hours after the person takes medication.

Cholinergic crisis may develop secondary to drug overdose (anticholinesterase drug toxicity). The clinical picture resembles that of myasthenic crisis but the weakness occurs 30 to 60 minutes after taking anticholinergic medication. Other symptoms are also present. Intestinal motility increases and is associated with episodes of diarrhea and complaints of cramping; fasciculation, bradycardia, pupillary constriction, increased salivation, and increased sweating are present. These clinical manifestations are caused by the smooth muscle hyperactivity secondary to excessive accumulation of acetylcholine at the neuromuscular junctions and excessive parasympathetic-like activity. As in myasthenic crisis, the individual is in danger of respiratory arrest.

EVALUATION AND TREATMENT. The diagnosis of myasthenia gravis is made on the basis of a response to edrophonium chloride (Tensilon), results of repetitive single-fiber EMG, and detection of AchR and MuSK antibodies. The antibodies are found in 80% of generalized autoimmune myasthenia and 70% of individuals with ocular myasthenia. With intravenous administration of Tensilon, immediate improvement in muscle strength usually persists for 5 to 10 minutes. The EMG is diagnostic in that the muscle fiber weakens readily. Mediastinal CT and MRI are used to determine whether a thymoma is present. The progression of myasthenia gravis is highly variable. In some individuals it is mild and spontaneously remits. There is usually a series of relapses, with symptom-free intervals ranging from weeks to months. Over time the disease can progress, leading to death; however, current treatments have improved prognosis, including ocular myasthenia.

Treatment of myasthenia gravis is individualized. Anticholinesterase drugs, corticosteroids, immunosuppressant drugs (e.g., Rituximab, a chimeric monoclonal antibody against the protein CD20, primarily found on the surface of B cells), azathioprine, and cyclosporine are used to treat myasthenia gravis and myasthenic crisis. Plasmapheresis may be lifesaving during myasthenic crisis, before and after thymectomy, and at the start of immunosuppressant therapy. For individuals with cholinergic crisis, treatment is to withhold anticholinergic drugs until blood levels fall out of the toxic range while providing ventilatory support and preventing respiratory complications. Thymectomy is the treatment of choice for a thymoma.[170]

TUMORS OF THE CENTRAL NERVOUS SYSTEM

Central nervous system (CNS) tumors include brain and spinal cord tumors. No proven causative agents for CNS tumors have been established. Carcinogenesis is discussed in Chapter 12.

Cranial Tumors

Tumors within the cranium can be either primary or metastatic as follows:

- *Primary:* Intracerebral tumors originate from brain substance, including neuroglia, neurons, cells of blood vessels, and connective tissue (Table 18-14). Extracerebral tumors originate outside substances of the brain and include meningiomas, acoustic nerve tumors, and tumors of pituitary and pineal glands.
- *Metastatic (secondary):* These tumors arise in organ systems outside the brain and spread to the brain.

Sites of intracranial tumors are illustrated in Figure 18-31.

Primary brain tumors (both malignant and nonmalignant) had an estimated incidence rate of 23,130 with 14,080 deaths in the United States in 2013.[171] The incidence of CNS tumors increases to age 70 years and then decreases. CNS tumors are the second most common group of tumors occurring in children. Approximately 70% of all intracranial tumors in children are located infratentorially (see Chapter 20), and in adults 70% to 75% are located supratentorially. Peripheral nerve tumors are rare in children and common in adults.

Cranial tumors cause local and generalized clinical manifestations. The local effects are caused by the destructive action of the tumor itself on a particular site in the brain and compression causing decreased cerebral blood flow. The effects are

TABLE 18-14 BRAIN AND SPINAL CORD TUMORS

NEOPLASM	LOCATION	CHARACTERISTICS	CELL OF ORIGIN
Gliomas			
Pilocytic astrocytoma	Anywhere in brain or spinal cord	Slow growing, well circumscribed	Astrocytes
Diffuse astrocytoma	Anywhere in brain	Slow growing; marked cellular differentiation; infiltrative; undergoing malignant progression over time	Astrocytes
Oligodendroglioma	Most commonly in frontal lobes deep in white matter; may arise in brainstem, cerebellum, and spinal cord	Well differentiated; diffusely infiltrative; well-demarcated borders	Oligodendrocytes
Oligoastrocytoma	Same as with diffuse astrocytoma and oligodendroglioma	Most common mixed glioma	At least two distinct populations of neoplastic cell types—astrocytes and oligodendrocytes
Anaplastic astrocytoma	Anywhere in brain or spinal cord, but predominantly in cerebral hemispheres	Anaplastic features demonstrated	Astrocytes
Anaplastic oligoastrocytoma	Same as with anaplastic astrocytoma	Same as anaplastic astrocytoma or anaplastic oligodendroglioma	Astrocytes and oligodendrocytes
Glioblastoma multiforme	Predominantly in cerebral hemispheres	Poorly differentiated neoplastic cells; extensive cellular heterogeneity; well-developed microvascular proliferation; necrosis	Astrocytes
Ependymoma	Intramedullary: wall of ventricles, may arise in caudal tail of spinal cord	More common in children, variable growth rates; more malignant, invasive form is called *ependymoblastoma;* may extend into ventricle or invade brain tissue	Ependymal cells
Neuronal Cell			
Medulloblastoma	Posterior cerebellar vermis, roof of fourth ventricle	Well demarcated, rapid growing, fills fourth ventricle	Embryonic cells
Mesodermal Tissue			
Meningioma	Intradural, extramedullary: sylvian fissure region, superior parasagittal surface of frontal and parietal lobes, olfactory groove, wing of sphenoid bone, superior surface of cerebellum, cerebellopontine angle, spinal cord	Slow growing, circumscribed, encapsulated, sharply demarcated from normal tissues, compressive in nature	Arachnoid cells, may be from fibroblast
Choroid Plexus			
Papillomas	Choroid plexus of ventricular system, lateral ventricle in children, fourth ventricle in adults	Usually benign, slow expansion inducing hemorrhage and hydrocephalus; malignant tumor is rare	Epithelial cells
Cranial Nerves and Spinal Nerve Roots			
Schwannoma (neuroma, neurolemma)	Cranial nerves (most commonly vestibular division of cranial nerve VIII)	Slow growing	Sheath of Schwann cells
Neurofibroma (NF1 and NF2)	NF1 primarily PNS, occasionally CNS NF2 primarily CNS	Both types slow growing	Nerve sheath
Pituitary Tumors	Pituitary gland; may extend to or invade floor of third ventricle	Age linked, several types, slow growing, macroadenomas and microadenomas	Pituitary cells, pituitary chromophobes, basophils, eosinophils
Germ Cell Tumors	Neurohypophysis, hypothalamus, pineal region	Rare, 0.5% of all primary brain tumors; primarily in adolescents; male more common than female; variable prognosis	Several types: germinoma, embryonal carcinoma, yolk sac tumor, choriocarcinoma, teratoma, mixed germ cell tumor, with different cell origins
Blood Vessel Tumors			
Angioma	Predominantly in posterior cerebral hemispheres	Slow growing	Arising from congenitally malformed arteriovenous connections
Hemangioblastomas	Predominantly in cerebellum	Slow growing	Embryonic vascular tissue

CNS, Central nervous system; *PNS,* Peripheral nervous system.

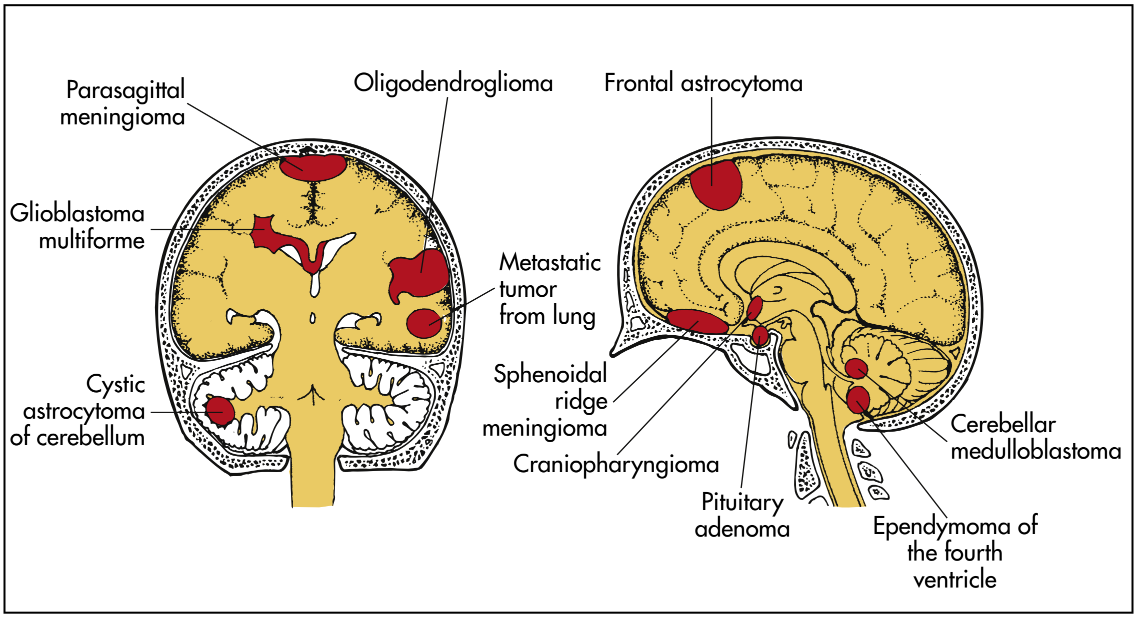

FIGURE 18-31 Common Sites of Intracranial Tumors.

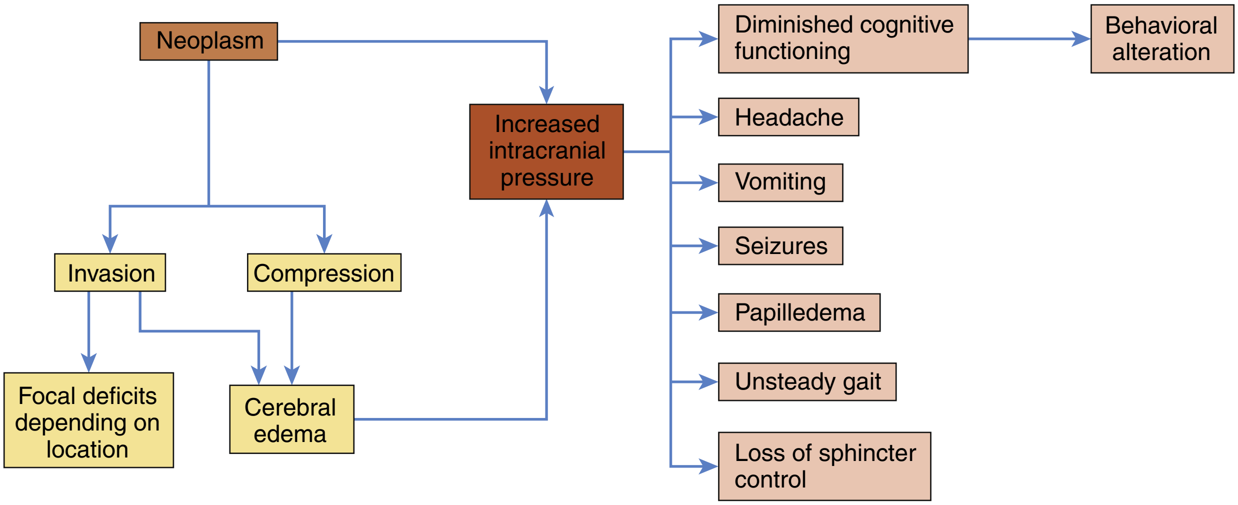

FIGURE 18-32 Origin of Clinical Manifestations Associated with an Intracranial Neoplasm.

varied and include seizures, visual disturbances, unstable gait, and cranial nerve dysfunction. The generalized effects result from increased ICP (Figure 18-32). Increased ICP may occur because of obstruction of the ventricular system, hemorrhages occurring in and around the tumor, cerebral edema caused by tumors or expansion of the tumor mass.

Intracranial brain tumors do not metastasize as readily as tumors in other organs because there are no lymphatic channels within the brain substance. If metastasis does occur, it is usually through seeding of cerebral blood, through CSF, during cranial surgery, or through artificial shunts.

Primary Brain (Intracerebral) Tumors

Primary brain tumors constitute about 2% of all cancers in the United States. **Gliomas** comprise 50% to 60% of all adult primary brain tumors and include astrocytomas, oligodendrogliomas, mixed oligoastrocytomas, and glioblastoma multiforme. Gliomas are divided into four grades based on histopathologic features, cellular density, atypia, mitotic activity, microvascular proliferation, and necrosis (Table 18-15). Other CNS tumors include meningiomas, ependymomas, nerve sheath tumors (schwannomas), and neurofibromas.

Pilocytic astrocytomas are more common in children and most often present with a median age of 12 years.[172] All other gliomas generally present after age 30 with secondary glioblastomas occurring more frequently in younger adults and primary glioblastomas usually presenting in older adults.[173]

Etiology for primary brain tumors is unclear and ionizing radiation is the only known environmental risk factor. Exposure to radiofrequency electromagnetic fields (cell phones) is under investigation.[174]

Mutation of the isocitrate dehydrogenase 1 *(IDH1)* gene, or less commonly mutation of the related *IDH2* gene, has been identified in the vast majority of World Health Organization

TABLE 18-15 **CLASSIFICATION OF GLIOMAS**

GRADE*	TYPE	DESCRIPTION	CHARACTERISTICS
I	Pilocytic astrocytoma	Common in children and young adults and people with neurofibromatosis type 1; common in cerebellum	Least malignant, well differentiated; grows slowly; near-normal microscopic appearance, noninfiltrating
II	Diffuse, low-grade astrocytoma (fibrillary, gemistocytic, protoplasmic) Oligodendroglioma	Common in young adults; more common in cerebrum but can occur in any part of brain	Abnormal microscopic appearance; grows slowly; infiltrates to adjacent tissue; may recur at higher grade
III	Anaplastic (malignant) astrocytoma Anaplastic oligodendroglioma	Common in young adults	Malignant; many cells undergoing mitosis; infiltrates adjacent tissue; frequently recurs at higher grade
IV	Glioblastoma (glioblastoma multiforme)	Common in older adults, particularly men Predominant in cerebral hemispheres	Poorly differentiated; increased number of cells undergoing mitosis; bizarre microscopic appearance; widely infiltrates; neovascularization; central necrosis

Data from American Brain Tumor Association: *Brain tumor primer,* ed 9, Chicago, IL, 2010, Author. Available at http://neurosurgery.mgh.harvard.edu/abta/; Louis DN et al: *Acta Neuropathol* 114(2):97–109, 2007.
*World Health Organization Grading of Central Nervous System Tumors.

(WHO) grades II and III astrocytic, oligodendroglial, and oligoastrocytic gliomas. Silencing of the *MGMT* gene (methylated-DNA-protein-cysteine methyltransferase) is found in astrocytomas. Chromosome 1p and 19q deletions are associated with oligodendrogliomas. Alterations in tumor-suppressor genes (e.g., mutations, *TP53*) are common. Alterations also occur in growth factor signaling[175] and gliomas may arise from cancer-initiating resident stem cells.[176]

The principal treatment for cerebral tumors is surgical or radiosurgical excision or surgical decompression if total excision is not possible. Chemotherapy, radiation therapy, or their combination may be used. The blood-brain barrier is an obstacle to the delivery of chemotherapeutic agents. New methods are in progress for penetration of this barrier.[177] Specificity of treatment is advancing with the development of immunotherapy techniques.[178] (Cancer treatment is discussed in Chapter 12.)

Astrocytoma. Astrocytomas are a type of glioma and the most common primary CNS tumor (50% of all brain and spinal cord tumors). Astrocytomas develop from astrocytes and grow by expansion and infiltration into the normal surrounding brain tissues. These tumor cells are believed to have lost normal growth restraint, and thus they proliferate uncontrollably.

One third of astrocytomas are classified at diagnosis as grade I or grade II. These slow-growing but infiltrative gliomas tend to form cavities (pseudocysts); however, some are firm, noncavitating, avascular, gray-white masses that are difficult to distinguish from normal white matter of the brain. Although these tumors may occur anywhere in the brain or spinal cord, they are located most commonly in the cerebrum, hypothalamus, or pons. Low-grade astrocytomas in adults tend to have a lateral or supratentorial location, and they tend to be midline or near midline in position in children, often in the posterior fossa.

Headache and subtle neurobehavioral changes may be an early symptom. Approximately half of persons with low-grade astrocytomas experience a focal or generalized seizure. Onset of a focal seizure disorder between the second and sixth decades of life is suggestive of an astrocytoma. Other general or focal neurologic manifestations develop gradually. Increased ICP is usually a late clinical manifestation.

Grade I astrocytomas are treated with surgery and follow-up CT scans. Grade II astrocytomas are treated surgically if they are accessible or by conventional external radiation, local radiation, or stereotactic radiosurgery. Following surgery alone, the 5-year survival rate is 25%; with surgery followed by radiotherapy, the 5-year survival rate is 50%.

Grades III and IV astrocytomas are found predominantly in the frontal lobes and cerebral hemispheres (Figures 18-33 and 18-34). These tumors also may be located in the brainstem. They are found twice as frequently in men as in women. Grades III and IV astrocytomas are the third most common cancer in the 15- to 34-year-old age group and the fourth most common in the 35- to 54-year-old age group.[179] Grades III and IV astrocytomas are often large and well circumscribed with a variegated pattern. The peripheral rim is pinkish gray and solid with a soft, yellow necrotic center and points of hemorrhage. Microscopically, there is increased cellularity, vascular proliferation, cellular pleomorphism, and necrosis. Necrosis is the main histologic difference between an anaplastic grade III tumor and a grade IV glioblastoma multiforme.

Grade IV astrocytomas (glioblastoma multiforme) account for about 55% of all gliomas. They are highly vascular and extensively infiltrative with heterogeneity in their molecular pathology. They may become large enough to extend from the meningeal surface through the ventricular wall. Fifty percent of glioblastomas are bilateral or at least occupy more than one lobe at the time of death. There are reports of grade IV astrocytomas found outside the central nervous system.[180,181]

The typical clinical presentation for a glioblastoma multiforme is that of diffuse, nonspecific clinical manifestations, such as headache, irritability, and personality changes, that progress to more clear-cut manifestations of increased ICP, such as headache on position change; papilledema; or vomiting. Of those affected, 30% to 40% experience seizure activity. Symptoms may progress to definite focal signs, such as hemiparesis, dysphasia, dyspraxia, cranial nerve palsies, and visual field deficits, in addition to the generalized signs from increased ICP.

Diagnosis of high-grade astrocytomas most commonly takes 3 to 6 months from onset of the first clinical manifestations

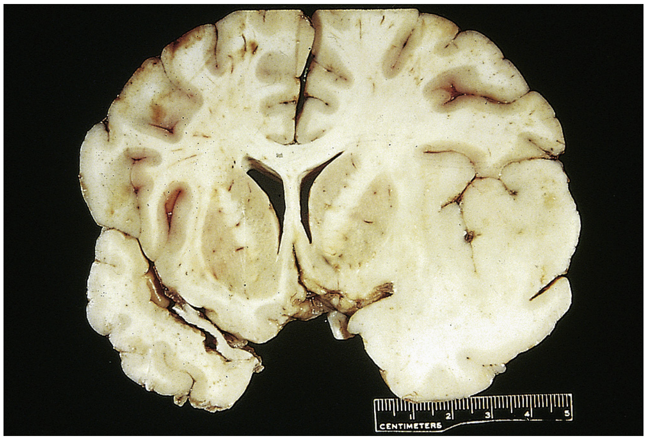

FIGURE 18-33 **Well-Differentiated Infiltrating Astrocytoma.** The right temporal lobe contains an infiltrative, homogeneous lesion that has expanded the lobe and obscured the normal boundaries between gray and white matter (compare to left temporal lobe). Because of the ill-defined borders, surgical resection rarely removes all of the tumor in such cases. (From Kumar V, Cotran RS, Robbins SL: *Robbins basic pathology,* ed 7, Philadelphia, 2003, Saunders.)

FIGURE 18-34 **Glioblastoma Multiforme.** In contrast to the well-differentiated infiltrating astrocytoma in Figure 18-33, this glioblastoma contains irregular areas of discoloration and cystic change, reflecting the presence of necrosis and hemorrhage. These lesions are widely infiltrative and associated with considerable mass effect. Note the shift of midline structures to the right. (From Kumar V, Cotran RS, Robbins SL: *Robbins basic pathology,* ed 7, Philadelphia, 2003, Saunders.)

because the person does not recognize the need to consult a healthcare provider. Survival at 5 years for grades III and IV astrocytomas is about 5% to 10%.

Oligodendroglioma. A far less commonly occurring glioma is **oligodendroglioma,** comprising 2% of all brain tumors and 10% to 15% of all gliomas. Oligodendrogliomas are typically slow-growing well-differentiated tumors, often with cysts and calcification present. Most are macroscopically indistinguishable from other gliomas. They occur most often from 30 to 50 years of age and are more common in males than females. Their etiology is unknown. Most oligodendrogliomas are in the frontal and temporal lobes, often in deep white matter; 20% are in both hemispheres. They may be found also in other parts of the cerebrum, third ventricle, brainstem, cerebellum, and spinal cord. A high incidence of this tumor occurs in young adults with a history of temporal lobe epilepsy. Approximately half of these tumors generally classified as oligodendrogliomas (a grade II tumor) are actually oligoastrocytomas (a grade III tumor).[182] Malignant degeneration occurs in approximately one third of persons with oligodendrogliomas. If there is extension to the pia mater (see Figure 15-15) or ependymal wall (epithelial layer surrounding choroid plexus and separating brain tissue from cerebrospinal fluid), oligodendrogliomas may metastasize to distant CNS sites through the ventriculoarachnoid spaces.

More than 50% of individuals experience a focal or generalized seizure as the first clinical manifestation; approximately half have experienced increased ICP at the time of diagnosis and surgery, and only one third develop any focal manifestations. The time from first clinical manifestation to surgical intervention often ranges from 2 to 6 years. Median survival, when surgery and radiotherapy are both used, is 5 to 10 years and prognosis is better than for other astrocytomas.[179]

FIGURE 18-35 **Ependymoma.** These tumors may arise in both the intracranial compartment and the spine. Intracranial tumors typically originate from a ventricular surface, as in the case of this large lesion arising in the fourth ventricle *(arrow).* (From Kumar V, Cotran RS, Robbins SL: *Robbins basic pathology,* ed 7, Philadelphia, 2003, Saunders)

Ependymoma. **Ependymomas** are rare gliomas that arise from ependymal cells that form the walls of the ventricles or the spinal canal. They are not encapsulated (Figure 18-35 and see Table 18-14). They comprise 6% of all primary brain tumors in adults and 10% in children and adolescents. Intracranial locations are more common among children and spinal cord location is more common among adults. The clinical presentation of spinal ependymoma is neurologic deficit (e.g., pain and dysthesias) corresponding to the level of the lesion. Lateral and third ventricle ependymomas that involve the cerebral hemispheres present with seizures, visual changes, and contralateral weakness of a body part on one side of the body. Etiology for these tumors is unknown.[183]

Clinical manifestations and progression of dysfunction associated with ependymomas may follow a short or long course. The interval between first manifestations and surgery may be as short as 4 weeks with some ependymoblastomas to as long as 7 to 8 years with others.

Ependymomas are treated surgically and with radiotherapy of the tumor region and operative site (possibly of the entire brain and spine). The 5-year survival rate is between 20% and

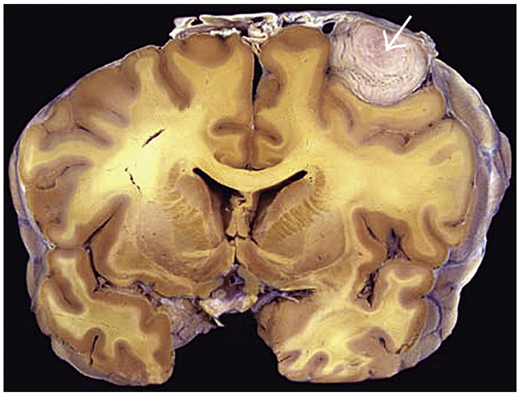

FIGURE 18-36 Meningioma, Gross. Meningioma beneath the dura with compression of underlying cerebral hemisphere. (From Klatt EC: *Robbins and Cotran atlas of pathology,* Philadelphia, 2006, Saunders.)

50%. Some persons benefit from a shunting procedure when the ependymoma has caused a noncommunicating hydrocephalus (see Chapter 17 and Chapter 20).

Primary Extracerebral Tumors

Meningioma. **Meningioma** constitutes about 30% of all intracranial tumors. The annual incidence is 6 cases per 100,000, with a peak incidence in the sixth and seventh decades, and this tumor is more common in women.[184] Predisposing factors to developing a meningioma are having neurofibromatosis (NF) type 2 (NF2, see Nerve Sheath Tumors at right) and undergoing ionizing radiation after a several-decade latency period. Genetically, formation of benign meningiomas has been linked to *NF2* gene mutation and chromosome 22q loss along with *DAL-1* loss on chromosome 18. Atypical and anaplastic meningiomas have been linked to additional gene alterations involving other multiple chromosomes.[185]

A meningioma is a sharply circumscribed mass that derives its shape from the space it occupies; the cause is unknown. These slow-growing, often encapsulated tumors arise from arachnoidal (meningeal) cap cells in the dural coverings of the brain. Rarely do meningiomas arise from arachnoid cells of the choroid plexus of the ventricles. Most are attached to the dura mater and arise within the intracranial cavity, the spinal cavity, or, rarely, the orbit (Figure 18-36). A meningioma may extend to the dural surface and erode the cranial bones or produce an osteoblastic reaction. Small meningiomas (less than 2 cm in diameter) are often found on postmortem examination in middle-aged and older adults who had experienced no clinical manifestations and died of totally unrelated causes. A few meningiomas exhibit malignant, invasive qualities.

Only when meningiomas reach a certain size—at which time they begin to indent the brain parenchyma—do they begin to produce clinical manifestations. Focal seizures are frequently the first manifestation. Other clinical manifestations depend on the tumor's location. Clinical features based on site of origin are as follows:

1. *Sphenoidal wing:* ophthalmoplegia, mild proptosis, and involvement of the ophthalmic division of the trigeminal nerve
2. *Olfactory groove:* anosmia, personality change, and visual failure
3. *Parasagittal:* focal seizures of a focal motor or sensory deficit
4. *Parasellar:* evidence of chiasmatic compression; urinary incontinence; dementia; gradual paraparesis, hormonal failure; optic atrophy; bitemporal hemianopia
5. *Lateral convexity:* variable depending on structures compressed, including slow hemiparesis, speech abnormalities[179]

Because of the extremely slow-growing nature of most meningiomas, increased ICP is less common than with gliomas. The most common symptom is seizures (40%). Diagnosis is made using contrast-enhanced CT, MRI, or both. The primary treatment is surgical resection. Stereotactic radiotherapy is used with incomplete resection or recurrence (20% rate). Conventional radiotherapy also is used. Hydroxyurea and somatostatin are used in cases of tumor recurrence.[186]

Nerve Sheath Tumors. Nerve sheath tumors are either neurofibromas or schwannomas (neuroma, neurolemma). Neurofibromatosis (NF) is an inherited autosomal dominant disorder accounting for 5% of all neuromas and is divided into two types: NF1 and NF2, which are clinically and genetically distinct disorders. The gene products are neurofibromin and merlin (schwannomin), both of which are thought to be tumor suppressors.[187]

Alterations in chromosomes 17 (17q11.2 for NF1) and 22 (NF2) are associated with both neurofibromas and schwannomas. NF1 is associated with cutaneous manifestations, iris hamartomas, and tumors primarily involving the peripheral nervous system and, occasionally, the CNS.[188] NF2 is associated with cataracts, hearing loss, and tumors primarily in the CNS, most commonly vestibular schwannoma and meningioma.[189] Criteria for the diagnosis of neurofibromatosis types 1 and 2 are presented in Box 18-4. The remaining neuromas are benign tumors that arise from the sheath of Schwann cells surrounding the axons of the cranial nerves. The tumors most commonly affect people older than 50 years, women more often than men. The vestibular division of cranial nerve VIII is most commonly affected, although neuromas of the acoustic division of cranial nerves V, VII, VIII, and IX are found (Figure 18-37).

The tumor originates most commonly just distal to the junction between the nerve root and the brainstem. As the tumor grows, it extends into the posterior fossa to occupy the cerebropontine angle and compress adjacent nerves. Eventually the brainstem is displaced, and the CSF flow is obstructed.

Initial clinical manifestations may include headache, tinnitus, hearing loss, impaired balance, unsteady gait, facial pain, and loss of facial sensations. Later, vertigo with nausea and vomiting, a sense of pressure in the ear, and moderate to severe unsteadiness with rapid position changes may appear. CT or MRI can establish the diagnosis. Posterior fossa dye studies may be required. Treatment is by surgical excision and radiotherapy of the neuroma. Pituitary tumors are discussed in Chapter 22, and cerebral tumors in children are discussed in Chapter 20.

Brain Metastases. Brain metastases are approximately 10 times more common than primary brain tumors and the incidence is increasing with improved local control of systemic

BOX 18-4 NIH DIAGNOSTIC CRITERIA FOR NEUROFIBROMATOSIS

Criteria for the Diagnosis of NF1

Two of the following eight criteria:

- Six or more café-au-lait macules greater than 5 mm in greatest diameter in prepubertal individuals and greater than 15 mm in greatest diameter in postpubertal individuals (adults)
- Multiple axillary or inguinal freckles
- One plexiform neurofibroma or two or more neurofibromas of any types
- Optic glioma
- Two or more Lisch nodules (iris hamartomas)
- A distinctive osseous lesion such as sphenoid dysplasia or thinning of the cortex of long bones with or without pseudoarthrosis
- A first-degree relative with NF1 by the above criteria

Criteria for the Diagnosis of NF2

Either one of the following criteria:

- Bilateral masses of the eighth cranial nerve seen with appropriate imaging techniques (e.g., CT or MRI)
- A first-degree relative with NF2 and either:
  - a. Unilateral mass of the eighth cranial nerve or
  - b. Two of the following:
    1. Neurofibroma
    2. Meningioma
    3. Glioma
    4. Schwannoma
    5. Juvenile posterior subcapsular lenticular opacity

From *NIH diagnostic criteria for neurofibromatosis.* Available at www.medicalcriteria.com/criteria.neuro_nf.htm. Last modified October 23, 2010. Accessed April 1, 2013.

CT, Computed tomography; *MRI,* magnetic resonance imaging; *NF,* neurofibromatosis.

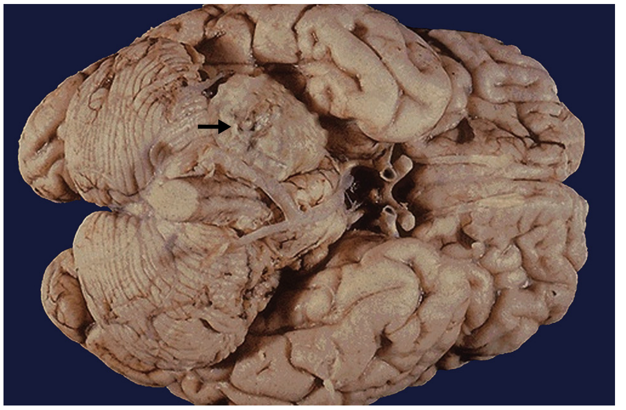

FIGURE 18-37 Acoustic Neuroma (Schwannoma), Gross. A mass lesion arising in the right vestibular branch of the eighth cranial nerve at the cerebellopontine angle *(arrow).* (From Klatt EC: *Robbins and Cotran atlas of pathology,* Philadelphia, 2006, Saunders.)

tumors. The incidence is estimated at up to 250,000 new cases per year. At autopsy, about 25% of persons with metastases have brain metastases. Lung and breast cancer are the most common tumors to have brain metastases within 1 to 3 years, followed by renal cell carcinoma, gastrointestinal cancer, and malignant melanomas. Carcinoma of the gallbladder, liver, thyroid, testes, uterus, ovary, and pancreas also may metastasize to the brain. Other tumors, besides carcinomas, that metastasize only occasionally are rhabdomyosarcomas, Ewing tumors, chorioepithelioma, and lymphoma.[190]

Metastasis of a cancer to the brain parenchyma or the meninges is a late occurrence in the disease process and is believed to be hematogenous in origin. Two thirds of metastatic tumors are located within the brain and one third are located in extradural spaces. The cerebral hemispheres are the site of 75% of metastases, most predominantly in the frontal lobes followed by the parietal, occipital, and temporal lobes in order of frequency of location. Tumors of the pelvis or retroperitoneal space have a predilection to metastasize to the cerebellum, pons, or their coverings.[191] In more than three fourths of persons with metastasis, the metastases are multiple and found in both the cerebrum and the cerebellum in a scattered distribution. The metastatic tumors often are located in the meninges and near the brain surface in the gray matter and subcortical white matter. These tumors produce little glial cell reaction in the brain tissue but do cause vasogenic, peritumoral edema in the surrounding brain tissue attributable to blood-brain barrier incompetence.[192]

The brain metastatic process requires a series of sequential events, called the "metastatic cascade," as follows:

1. Invasion of primary tumor border
2. Extravasation of the circulatory system
3. Survival and persistence/quiescence in the circulation
4. Extravasation at the distant CNS site
5. Formation of micrometastasis
6. Progressive colonization and growth

Hematogenous metastasis to the CNS is an inherently inefficient process depending on an interaction between tumor cells with host defenses and the microenvironment. To produce brain metastasis, tumor cells must reach the brain vasculature by attaching themselves to the endothelial cells of the brain microvessels in the blood-brain barrier, extravasate into the brain parenchyma, induce blood vessel development (angiogenesis), and proliferate in response to growth factors. Local brain invasion, in itself, is a process requiring mechanisms for cell motility, cell adhesion, enzymatic remodeling of the extracellular components, tumor cell survival, and proliferation. Cytokines, chemokines, and growth factors have been demonstrated to participate in the process.[193]

The clinical manifestations of parenchymal brain metastasis are headache, seizures, or alteration in cognition, mental status, and behavior,[192] although several unusual syndromes do exist. Carcinomatous encephalopathy causes headache, nervousness, depressed mood, trembling, confusion, and forgetfulness. In carcinomatosis of the cerebellum, headache, dizziness, and ataxia are found. Carcinomatosis of the craniospinal meninges (carcinomatous meningitis) manifests with headache, confusion, and manifestations of cranial or spinal nerve root dysfunction.

Contrast-enhanced imaging is the most sensitive imaging procedure for metastatic brain tumors. Prognosis is poor. If one to three tumors are found, surgical excision is indicated. Radiotherapy is commonly used to treat solitary as well as multiple tumors and may be combined with whole brain radiation.[194]

BOX 18-5 MOST COMMON PRIMARY SPINE TUMORS

Benign Tumors	Malignant Tumors
Osteoid osteoma/osteoblastoma	Chondrosarcoma
Giant cell tumors	Chordoma
Hemangiomas	Ewing sarcoma
Aneurysmal bone cyst	Osteosarcoma

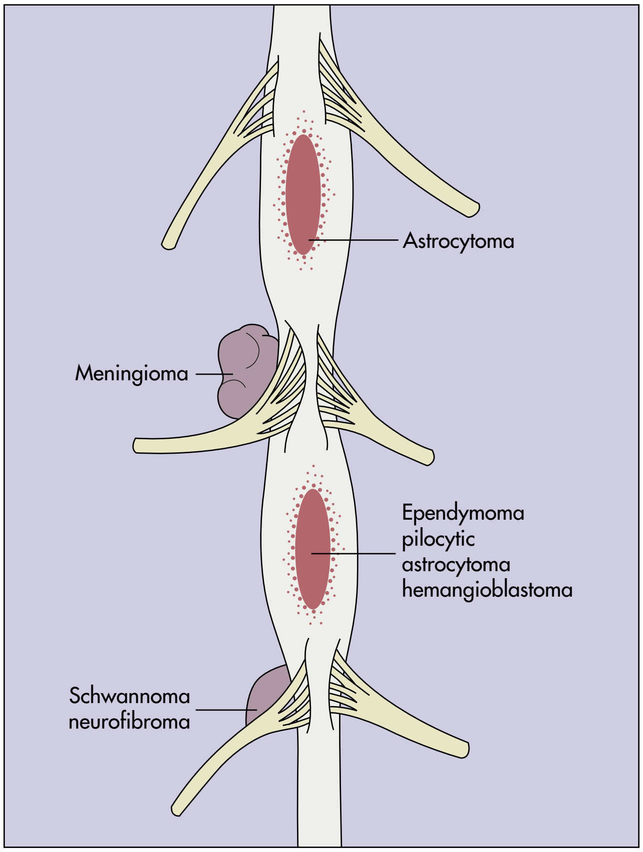

FIGURE 18-38 Distribution of Some Spinal Tumors. (From Perkin DG: *Mosby's color atlas and text of neurology,* London, 1998, Mosby-Wolfe.)

Spinal Cord Tumors

Primary spinal cord tumors are relatively rare, about 2% to 4% of CNS neoplasms. The most common primary spinal cord tumors are listed in Box 18-5 and shown in Figure 18-38. Spinal cord tumors are named to reflect their cell type, growth rate, and structure of origin. They are classified as **intramedullary tumors** (originating within the neural tissues) or **extramedullary tumors** (originating from tissues outside the spinal cord). Extramedullary tumors arise from the meninges or roots (forming **intradural tumors**) or from epidural tissue or vertebral structures (forming **extradural tumors**). About 5% of spinal cord tumors seen in general hospital settings are intramedullary, 40% are intradural-extramedullary, and 55% are extradural.

Metastatic spinal cord tumors are three to four times more common than primary spinal cord tumors. They are usually carcinomas from breast, lung, and prostate; lymphomas; or myelomas; 25% to 70% involve the vertebral body and are asymptomatic. Metastatic spinal cord tumors are extradural in location. Of extradural tumors, 50% are metastatic and have spread to the spine through direct extension from tumors of the vertebral structures or from extraspinal sources extending through the interventricular foramen or through the bloodstream.

The most common primary extramedullary spinal cord tumors are neurofibromas and meningiomas. These tumors are intradural more often than extradural. Neurofibromas are found most commonly in the thoracic and lumbar regions. Meningiomas are more evenly distributed throughout the spine. Other extramedullary tumors in order of frequency of occurrence are sarcomas, vascular tumors, chordomas, and epidermoid and similar tumors. Of intradural-extramedullary tumors, 70% are meningiomas, neurofibromas, or sarcomas.

Intramedullary tumors have the same cellular origins as brain tumors. Ependymomas are the most common intramedullary tumors. Astrocytomas, glioblastomas, oligodendrogliomas, ganglioneuromas, medulloblastomas, hemangiomas, and hemangioblastomas are more or less equally distributed in frequency of occurrence.[195]

PATHOPHYSIOLOGY. Extramedullary spinal cord tumors produce dysfunction by compression of adjacent tissue, not by direct invasion. The spinal cord is compressed by the tumor from without, and destruction of the white matter tracts occurs. The spinal canal around the cord becomes filled by tumor.

Intramedullary spinal cord tumors produce dysfunction by invasion and compression. The cord enlarges as a result of the tumor that is enlarging inside the cord. In addition, distortion of adjacent white matter tracts occurs. Metastases from spinal cord tumors occur from seeding through the CSF; medulloblastomas and ependymomas establish distant implants in this manner.

CLINICAL MANIFESTATIONS. The acute onset of clinical manifestations suggests a vascular insult caused by thrombosis of vessels supplying the spinal cord. Clinical manifestations that are gradual and progressive suggest compression. The clinical manifestations associated with spinal cord tumors fall into three major categories: (1) a compressive syndrome (sensorimotor syndrome), (2) an irritative syndrome (radicular syndrome), and rarely (3) a syringomyelic syndrome.

The **compressive syndrome (sensorimotor syndrome)** is associated with compression and is caused less frequently by invasion and destruction of the spinal cord tracts. Symptoms are usually gradual and progressive, and initial manifestations may be asymmetric. With tumors located in the cervical area, the motor dysfunction usually has the following pattern: ipsilateral arm involvement, followed by ipsilateral and contralateral leg involvement, and finally involvement of the opposite arm. With thoracic tumors the pattern of motor involvement is paresis and spasticity of one leg, followed by involvement of the opposite leg. The sensory clinical manifestations of tingling paresthesias have a pattern similar to that of the motor signs. Pain and temperature dysfunctions are found more commonly than touch, vibration, and proprioceptive changes, although posterior column signs also are found frequently. Pain is less

well localized than with an irritative syndrome caused by root involvement. Initially the pain and temperature changes are contralateral to the motor deficit (Brown-Séquard syndrome, see Table 18-4, pp. 592-593). Bladder and bowel deficits usually appear when paresis develops in the legs.

The **irritative syndrome (radicular syndrome)** combines the clinical manifestations of a cord compression with radicular pain, which is pain in the sensory root distribution and indicates root irritation. The segmental manifestations associated with root irritation include segmental sensory changes that include paresthesias and impaired pain and touch perception; motor disturbances, including cramps, atrophy, fasciculations, and decreased or absent deep tendon reflexes; and ache in the spine. Tenderness of the spinous processes over the tumor is present in about half of extramedullary tumors. The segmental changes may appear months and sometimes years before the clinical manifestations of compression in benign tumors. The compressive clinical manifestations include an asymmetric spastic paresis of the lower extremities with tumors in the thoracic or lumbar region, paresis of the arms and legs with tumors in the cervical area, decreased or absent pain and temperature perception below the tumor site, posterior column signs, and spastic bladder.

Because they involve the central gray matter of the cord, intramedullary spinal cord tumors (notably ependymomas) may produce a **syringomyelic syndrome,** or inflammation of the spinal cord. Inflammation results in the development of tubular (syrinx) cavities in the spinal cord. Occasionally an extramedullary tumor may produce the same effect, although the mechanisms are unknown.

EVALUATION AND TREATMENT. The diagnosis of a spinal cord tumor is made through bone scan, needle biopsy guided by CT and positron-emission tomography (PET), or open biopsy. Involvement of specific cord segments is established. Spinal tumors are not staged but can be classified as slow growing (low-grade) or rapidly growing (high-grade).

Treatment varies, depending on the nature of the tumor and the person's clinical status. Indications for surgery include establishment of a tissue diagnosis, neurologic palliation, spinal stabilization, pain relief, and cancer therapy. Surgical resection may involve curettage (piecemeal removal of the tumor) or may be performed en bloc (removal of tumor in one piece). Surgical approaches to the spine include the posterior approach (decompression laminectomy), lateral approach, anterior approach (most favored), and combined approaches. Posterior and anterior reconstructive surgery may be necessary. Oncologic surgical procedures are classified as intralesional, marginal, wide excision, or radical excision. Indications for external radiation vs. surgery are a radiosensitive tumor (e.g., lymphoma), soft tissue compression without instability, a person who is a poor surgical candidate, paraplegia or advanced paraparesis of greater than 24 hours' duration, and an expected survival of less than 3 to 4 months. Chemotherapy, hormonal therapy, and pain management protocols may be appropriate.

SUMMARY REVIEW

Central Nervous System Disorders

1. Traumatic brain injury (TBI) is an alteration in brain function or other evidence of brain pathology caused by an external force.
2. MVAs are the major cause of traumatic CNS injury. Traumatic injuries are classified as closed-head trauma (blunt) or open-head trauma (penetrating). Closed-head trauma is the more common type of trauma.
3. Primary brain injury is caused by an impact and can be classified as focal or diffuse.
4. Focal brain injury includes coup and contrecoup, contusion (bruising of the brain), laceration (tearing of brain tissue), extradural hematoma (accumulation of blood above the dura mater), subdural hematoma (blood between the dura mater and arachnoid membrane), intracerebral hematoma (bleeding into the brain), and open-head trauma.
5. Open-head trauma involves a skull fracture with exposure of the cranial vault to the environment. The types of open-head trauma (compound fracture, perforated fracture) are linear, comminuted, compound, and basilar skull fracture (in the cranial vault or at the base of the skull).
6. Diffuse axonal injury (DAI) results from the effects of head rotation. The brain experiences shearing stresses resulting in axonal damage ranging from concussion to a severe DAI state. Categories of diffuse brain injury include mild concussion; classic cerebral concussion; and mild, moderate, and severe DAI.
7. Secondary neuronal injury occurs as an indirect result of primary brain injury and is the result of both systemic and intracranial processes. Secondary injury results from ischemia, excitotoxicity, inflammation, cerebral edema, increased intracranial pressure, and brain herniation.
8. Spinal cord injuries occur most often in young men who sustain various kinds of injuries (recreational or travel related) and older adults because of preexisting degenerative vertebral disorders.
9. Primary spinal cord injury involves damage to vertebral or neural tissues from compression, traction, or shearing forces.
10. Secondary spinal cord injury is related to ischemia, excitotoxicity, inflammation, edema, oxidative damage, and activation of necrotic and apoptotic cell death, and begins within minutes after injury and continues for weeks.
11. Spinal cord injury often causes spinal shock with cessation of all motor, sensory, reflex, and autonomic functions below any transected area. Loss of motor and sensory function depends on the level of injury.
12. Paralysis of the lower half of the body with both legs involved is called paraplegia. Paralysis involving all four extremities is called quadriplegia.
13. Return of spinal neuron excitability occurs slowly. Reflex activity can return in 1 to 2 weeks in most people with acute spinal cord injury. A pattern of flexion reflexes emerges, involving first the toes and then the feet and legs. Eventually

SUMMARY REVIEW—cont'd

reflex voiding and bowel elimination appear, and mass reflex (flexor spasms accompanied by profuse sweating, piloerection, and automatic bladder emptying) may develop.

14. Autonomic hyperreflexia (dysreflexia) is a syndrome of sudden massive reflex sympathetic discharge associated with spinal cord injury at level T5-T6 or above and can cause life-threatening hypertension.
15. Immobilization of the spine is the immediate intervention for a suggested or confirmed vertebral fracture.
16. The pathologic findings in degenerative disk disease (DDD) include disk protrusion, spondylosis and/or subluxation, degeneration of the vertebrae (spondylolisthesis), and spinal stenosis.
17. Low back pain is pain between the lower rib cage and gluteal muscles and often radiates into the thigh.
18. Low back pain has a high prevalence, affecting 75% to 90% of the population at some time. Sciatica affects about 1% of those with low back pain.
19. Most causes of low back pain are unknown; however, some secondary causes are disk prolapse, tumor, bursitis, synovitis, DDD, osteoporosis, fracture, inflammation, and sprain.
20. Diagnosis of injury to the lower back is made on the basis of physical examination, EMG results, and imaging procedures.
21. Treatment for low back pain includes use of analgesics and NSAIDs, exercise, physical therapy, education, and surgery.
22. Herniation of an intervertebral disk is a protrusion of part of the nucleus pulposus. Herniation most commonly affects the lumbosacral disks (L5-S1 and L4-L5). The extruded pulposus compresses the nerve root, causing pain that radiates along the sciatic nerve.
23. Clinical improvement occurs in most cases; only 10% have sufficient pain after 6 weeks to consider surgery. There is little evidence that drug treatments are effective.
24. Cerebrovascular disease is the most frequently occurring neurologic disorder. Any abnormality of the blood vessels of the brain is referred to as a cerebrovascular disease.
25. Cerebrovascular disease is associated with two types of brain abnormalities: (a) ischemia with or without infarction and (b) hemorrhage.
26. The most common clinical manifestation of cerebrovascular disease is a CVA (stroke syndrome), and the most common risk factor is hypertension.
27. CVAs are classified according to pathophysiology and include ischemic (thrombotic, embolic, and global hypoperfusion), lacunar, and hemorrhagic strokes.
28. A transient ischemic attack is a transient episode of neurologic dysfunction resulting from focal cerebral ischemia.
29. Aspirin, systemic anticoagulation, and thrombolysis improve outcomes with ischemic stroke. Antiplatelet therapy and statins decrease recurrence. Endarterectomy is effective if carotid stenosis is greater than 50%.
30. Treatment of hemorrhagic stroke includes control of bleeding, prevention of increased intracranial pressure, and prevention of cerebral edema and seizures.
31. Intracranial aneurysms result from defects in the vascular wall and are classified on the basis of form and shape. They are commonly asymptomatic, but the signs vary according to the location and size of the aneurysm.
32. Surgical intervention is the treatment of choice before a cerebral aneurysm ruptures.
33. An AVM is a tangled mass of dilated blood vessels. Although sometimes present at birth, AVM exhibits a delayed age of onset with symptoms ranging from headache and dementia to seizures and ICH or SAH. Vasospasm and delayed cerebral ischemia are serious complications.
34. Migraine is an episodic disorder whose marker is headache. Migraine is classified as a headache with and without aura and is precipitated by a triggering event.
35. The clinical phases of a migraine attack are the premonitory phase, the migraine aura, the headache phase, and the recovery phase.
36. Migraine is associated with activation of the peripheral and central arms of the trigeminal system, cortical spreading depression, and distinct activity of brainstem nuclei.
37. Cluster headaches occur in episodes several times during a day for a period of days at different times of the year. The pain is unilateral, intense, tearing, and burning. Associated symptoms include ptosis, lacrimation, reddening of the eye, and nausea. The cause of trigeminal activation is unknown. There is sympathetic nervous system underactivity and parasympathetic overactivity. The two forms are acute and chronic.
38. Chronic paroxysmal hemicrania is a cluster headache with more frequent daily attacks; it occurs primarily in women. It responds to treatment with indomethacin.
39. Tension-type headache is the most common type of headache. Both a central mechanism and a peripheral mechanism are associated with the etiology. The headache is bilateral, with the sensation of a tight band around the head. The pain may last for hours or days. There are acute and chronic forms.
40. Infection and inflammation of the CNS can occur by bacteria, viruses, fungi, parasites, and mycobacteria. The resulting infection by bacteria is pus producing, or pyogenic.
41. Meningitis is inflammation of the brain or spinal cord. Bacterial meningitis is primarily an infection of the pia mater and arachnoid villi and of the fluid of the subarachnoid space. Viral meningitis is believed to be limited to the meninges. Fungal and tubercular meningitis are less common and occur in immunosuppressed individuals in particular.
42. The meningeal vessels become hyperemic, and neutrophils migrate into the subarachnoid space with bacterial meningitis. An inflammatory reaction occurs, and exudation ensues and increases rapidly.
43. The variety of clinical manifestations depends on the type of meningitis and ranges from throbbing headache to neck stiffness and rigidity and decreasing responsiveness. Specific cranial nerve dysfunction is a common occurrence.
44. Bacterial meningitis and fungal meningitis are treated with appropriate antibiotic therapy; viral meningitis is treated with antiviral drugs or corticosteroids and supportive care.
45. Brain abscesses often originate from infections outside the CNS. Microorganisms gain access to the CNS from adjacent sites or spread along the wall of a vein. A localized

SUMMARY REVIEW—cont'd

inflammatory process develops with exudate formation, vessel thrombosis, and leukocyte degeneration. After a few days the infection becomes delimited, with a center of pus and a wall of granular tissue.

46. Clinical manifestations of brain abscesses include headache, nuchal rigidity, confusion, drowsiness, and sensory and communication deficits. Treatment includes antibiotic therapy and surgical excision or aspiration.
47. Encephalitis is an acute febrile illness of viral origin with nervous system involvement. The most common encephalitides are caused by arthropod-borne viruses and herpes simplex virus. Meningeal involvement appears in all encephalitides.
48. Clinical manifestations of encephalitis include fever, delirium, confusion, seizures, abnormal and involuntary movement, and increased intracranial pressure.
49. Most encephalitides are treated by administration of an antiviral agent or an immune globulin and by control of intracranial pressure.
50. The common neurologic complications of AIDS are HIV-associated neurocognitive disorder (HAND), HIV neuropathy, HIV myelopathy, opportunistic infections, cytomegalovirus infection, parasitic infection, and neoplasms. Pathologically, there may be diffuse CNS involvement, focal pathologic findings, and obstructive hydrocephalus. Neurologic involvement associated with HIV has declined with HAART.
51. Lyme disease is a tick-borne spirochete bacterial infection involving the peripheral and central nervous systems that progresses through three stages of symptoms with acute and chronic manifestations.
52. MS is a chronic inflammatory disease involving degeneration of CNS myelin. The cause is unknown and an immune system dysfunction produces the pathology. The demyelination is thought to result from a previous viral insult to the nervous system in a genetically susceptible individual with a subsequent abnormal immune response in the CNS.
53. The clinical manifestations of MS involve different types: relapsing-remitting, primary progressive, secondary progressive, and progressive-relapsing. Optico-spinal MS involves the optic nerve and cranial nerves III through XII. Spinal MS primarily involves the spinal tracts and dorsal column with spastic paresis and bowel and bladder dysfunction. Cerebellar MS manifests with motor ataxia and weakness.
54. There is no cure for MS. Corticosteroid and immune therapy is used to acutely manage relapses or reduce frequency of relapses.

Peripheral Nervous System and Neuromuscular Junction Disorders

1. Neuropathies are the syndromes that result when the peripheral nerves are affected. Axon and myelin degeneration may be present. Neuropathies are classified as generalized symmetric polyneuropathies, generalized neuropathy, and focal or multifocal neuropathies.
2. Therapy for the neuropathies is directed at the primary cause, such as diabetes mellitus. Axonal regrowth and recovery of function may take months, but many neuropathies can be reversed.
3. Guillain-Barré syndrome is an acquired, acute inflammatory demyelinating or axonal disorder caused by a humoral or cell-mediated immunologic response, or both, directed at peripheral nerves. Four subtypes have been identified and clinical manifestations depend on the subtype.
4. Radiculopathies are disorders of the roots of spinal cord nerves. The roots may be compressed, inflamed, or torn. Clinical manifestations include local pain or paresthesias in the sensory root distribution. Treatment may involve surgery, antibiotics, corticosteroids, radiation therapy, and chemotherapy.
5. Myasthenia gravis results from a defect in nerve impulse transmission at the neuromuscular junction. Autoantibodies, complement deposits, and membrane attack complex destroy the acetylcholine receptor (AchR) sites, causing decreased transmission of the nerve impulse.
6. Clinical manifestations of myasthenia gravis include weakness of voluntary muscles, including muscles of the face and throat, and may involve muscles of the diaphragm and chest wall.
7. Treatment of myasthenia gravis involves symptom relief and immunotherapy. The progression of the disease is highly variable; in some individuals it is mild and spontaneously remits.

Tumors of the Central Nervous System

1. Tumors that occur within the cranium are either primary or metastatic (secondary). Primary tumors arise from brain tissue and are classified as intracerebral or extracerebral. Metastatic tumors to the brain arise in organs outside the brain and are much more common than primary brain tumors.
2. CNS tumors cause local and generalized manifestations. Gliomas are the most common primary tumor in adults. The effects are varied; local manifestations include seizures, visual disturbances, loss of equilibrium, and cranial nerve dysfunction.
3. The principal treatment for brain tumors is surgical or radiosurgical excision or decompression if total excision is not possible. Chemotherapy and radiation therapy also are used.
4. Spinal cord tumors are classified as intramedullary (within the neural tissues) or extramedullary (outside the spinal cord). Metastatic spinal cord tumors are usually carcinomas, lymphomas, or myelomas.
5. Extramedullary spinal cord tumors produce dysfunction by compression of adjacent tissue, not by direct invasion. Intramedullary spinal cord tumors produce dysfunction by invasion and compression.
6. The onset of clinical manifestations of spinal cord tumors is gradual and progressive, suggesting compression. Specific manifestations depend on the location of the tumor; for example, there may be paresis and spasticity of one leg with thoracic tumors, followed by involvement of the opposite leg.
7. Spinal cord tumors are treated by surgery, radiation therapy, chemotherapy, and hormonal therapy.

KEY TERMS

Arteriovenous malformation (AVM), 604
Aseptic meningitis, 609
Autonomic hyperreflexia (dysreflexia), 593
Bacterial meningitis, 609
Brain abscess, 613
Capillary telangiectasis, 605
Cavernous angioma (malformation), 605
Cerebral vasospasm (CVS), 606
Cholinergic crisis, 626
Chronic migraine, 607
Chronic paroxysmal hemicrania (CPH), 609
Classic cerebral concussion (Grade IV), 588
Closed (blunt) trauma, 582
Cluster headache, 608
Compressive syndrome (sensorimotor syndrome), 633
Contrecoup injury, 583
Contusion, 583
Coup injury, 583
Degenerative disk disease (DDD), 594
Delayed cerebral ischemia (DCI), 606
Demyelinating polyneuropathy, 621
Diffuse brain injury (diffuse axonal injury [DAI]), 587
Distal axonal polyneuropathy, 621
Embolic stroke, 599
Encephalitis, 614
Ependymoma, 630
Extradural brain abscess (empyema), 613
Extradural hematoma, 584
Extradural tumor, 633
Extramedullary tumor, 633
Focal brain injury, 582
Focal neuropathy, 622
Fungal meningitis, 611
Fusiform aneurysm (giant aneurysm), 604
Generalized AchR myasthenia, 625
Generalized neuropathy, 622
Generalized symmetric polyneuropathy, 621
Glioma, 628
Guillain-Barré syndrome (GBS) (Landry-Guillain-Barré syndrome, idiopathic polyneuritis, acute inflammatory polyradiculopathy, acute autoimmune neuropathy), 622
Hemorrhagic stroke (spontaneous intracranial hemorrhage [ICH]), 602
HIV-associated peripheral neuropathy, 617
HIV myelopathy, 617
HIV neuropathy, 617
Human immunodeficiency virus–associated neurocognitive disorder (HAND), 615
Inherited (congenital) myasthenic syndrome, 624
Intracerebral brain abscess, 613
Intracerebral hematoma, 586
Intradural tumor, 633
Intramedullary tumor, 633

- Review Questions and Answers

CHAPTER OUTLINE

Mental illnesses are common and found in different cultures and across the socioeconomic spectrum. When left untreated, the consequences can be devastating. This chapter provides an introduction to the neurobiology of schizophrenia, mood disorders, and some anxiety disorders. The etiology and pathophysiology of mental illnesses are diverse and complex. Diagnostic criteria are constantly being updated to more precisely diagnose and effectively treat the disorders. Every mental disorder manifests a range of symptoms that vary in intensity. Symptom variations likely reflect individual differences in neural pathologic brain structures or functions, or both, which affect treatment. Risk factors, such as exposure to uncontrollable psychosocial stress, may precipitate the onset of mental disorders and point to the challenge in understanding how diseased genes and environmental factors interact.

The development of visual and quantitative structural and functional neuroimaging techniques provides insight into the pathophysiologic basis of mental disorders. In schizophrenia, neuroanatomic, functional, and neurochemical alterations associated with this debilitating illness have uncovered abnormal brain regions along with a host of candidate genes that confer risk. Similarly, in mood and anxiety disorders, brain scans are revealing structural and functional abnormalities. Notably, many brain regions implicated in normal cognitive and emotional processing are found in schizophrenia, mood, and anxiety disorders. The future lies in unraveling how the highly interconnected brain structures modulated by neurotransmitters, neuropeptides, and hormones operate in normal to abnormal mental states.

Knowledge of the pathophysiology associated with a specific mental illness has guided the development of pharmacologic medications. Although second- and third-generation drugs with fewer side effects are now available, many individuals continue to suffer; and to complicate diagnosis and treatment, psychiatric disorders, such as depression and anxiety, often coexist. Identifying and characterizing diseased genes and environmental triggers in mental illness will offer hope in developing effective therapies that alleviate symptoms and lessen or reverse the pathophysiologic alterations.

SCHIZOPHRENIA

Schizophrenia is a serious psychiatric illness that strikes 1% of the world's population. The illness is equally prevalent in males and females and emerges in young adults during the late teens and early twenties, with a slightly earlier onset in males than in females. **Schizophrenia** is the term coined originally by Eugen Bleuler in 1911 to describe a collection of illnesses characterized by **thought disorders,** which reflect a break in reality or splitting of the cognitive from the emotional side of one's personality. A schizophrenic individual may exhibit a feeling of happiness when recollecting a terrible event or emotional indifference when describing a joyful occasion. Today, disorganized thought in schizophrenia is characterized by positive and negative symptoms including auditory hallucinations, paranoid delusions, and cognitive deficits that have devastating effects on the individual and the individual's family.

Etiology and Pathophysiology

Genetic Predisposition

Schizophrenia is a heritable disorder. In monozygotic twins, the concordance rate varies from 30% to 50%. This variability may stem from different diagnostic criteria and methodologic or sampling differences across studies. In dizygotic twins and siblings the concordance rate decreases to 12%, which is still considerably higher than the 1% figure found in the general population.

Nonetheless, schizophrenia is not a simple genetic disorder in which inherited disease alleles will always lead to illness. Schizophrenia likely involves several genes located on different chromosomes and differs from mendelian disorders, in which genes are fully penetrant and recognized as the primary cause of disease (e.g., genes for Huntington disease). As indicated by the 50% concordance rate in monozygotic twins, the genes for schizophrenia show reduced penetrance, resulting in individuals who carry the disease genes without manifesting the illness. Further complicating the search for the specific genes that confer risk of schizophrenia is the variability in biologic and phenotypic traits among individuals who manifest the illness (see What's New? Copy Number Variations Increase in Schizophrenia and in Offspring of Older Fathers).

Prenatal and Perinatal Vulnerability Factors. Because the concordance rate of schizophrenia in monozygotic twins is never 100% as in mendelian disorders, environmental factors likely play an important role in increasing the risk of developing the disorder. A leading hypothesis suggests that early environmental factors interfere with genetically programmed neural developmental alterations that eventually compromise normal brain structures and functions.[1] An early brain defect may remain silent and not dramatically affect the individual until subsequent development requires adaptive use of brain structures.[2] Several hypothesized early environmental factors that may alter brain development and increase the risk of developing schizophrenia include exposure to prenatal infection, prenatal nutritional deficiencies, perinatal complications (such as birth defects and neonatal hypoxia), and upbringing in an urban environment.[3]

WHAT'S NEW?

Copy Number Variations Increase in Schizophrenia and in Offspring of Older Fathers

Copy number variations (CNVs) involving deletions or duplications of several million base pairs of DNA sequence of the genome are increasingly recognized to elevate the risk of serious neurodevelopmental disorders including schizophrenia, autism, epilepsy, and mental retardation. Concerning schizophrenia, large CNV deletions involving multiple genes show increased penetrance accompanied with severe phenotypic symptoms of the disease. For example, CNV deletion at 22q11.2, which consists of 1.5 to 3.0 megabases of DNA, is reported to increase the risk of schizophrenia by 20- to 30-fold in comparison to the general population. Research linking 22q11.2 deletion to schizophrenia as well as other recently identified CNV deletions occurring at distinct loci will accelerate our genetic understanding of the pathogenesis of the disease and have implications for genetic counseling and clinical management.

Of further potential clinical relevance of the role of CNVs in schizophrenia, offspring of fathers who are age 50 or more have a twofold to threefold increased risk of the disease when compared to fathers who are in their twenties. Although the causal mechanisms remain unclear, a recent study using a mouse model reported that offspring sired by older male mice exhibited an increase in spontaneously occurring (de novo) CNVs. Six de novo CNVs were found in the offspring of aged male mice and none from the younger control group. When the CNVs in the mouse brain were then mapped to the human genome, three de novo CNVs were found to have genes on human chromosomes linked to brain development and schizophrenia. These results suggest that paternal-age–related mutations in the germline contribute to offspring de novo CNVs that may underlie schizophrenia.

Data from Bassett AS et al: *Am J Psychiatry* 167:899–914, 2010; Flatscher-Bader T et al: *Transl Psychiatry* 1:e34, 2011; Moreno-DeLuca D, Cubells JF: *Curr Psychiatry Rep* 13:129–137, 2011.

Neuroanatomic and Functional Abnormalities

Neuroanatomic Alterations. Advanced neuroimaging techniques have revealed evidence of structural brain abnormalities in schizophrenia.[4,5] A consistent finding is the enlargement of the lateral and third ventricles and the widening of frontocortical fissures and sulci (Figure 19-1). Schizophrenics with cerebral ventricular enlargement often exhibit cognitive impairments and negative symptoms, and respond poorly to treatment. Other studies reported a reduction in the thalamus and temporal lobe areas (e.g., amygdala, hippocampus, and parahippocampal gyrus).[6] A reduction in thalamus size may disrupt neurotransmission between the cortex and primary sensory and motor areas. Temporal lobe alterations may contribute to the production of positive schizophrenic symptoms, such as hallucinations, delusions, and thought disorder.

Brain imaging studies in adolescents with early onset schizophrenia reveal progressive loss of cortical gray matter in temporal lobes, somatosensory and motor cortices, and the dorsolateral cortex (Figure 19-2). Of clinical concern is the loss of cortical tissue, which is evident by the time the individual seeks treatment and continues throughout the course of the illness despite the use of antipsychotic medication.[7] The progressive loss in frontal lobe volume is accompanied by increased severity of negative symptoms and further reductions in cognitive functioning. These results highlight the ineffectiveness of

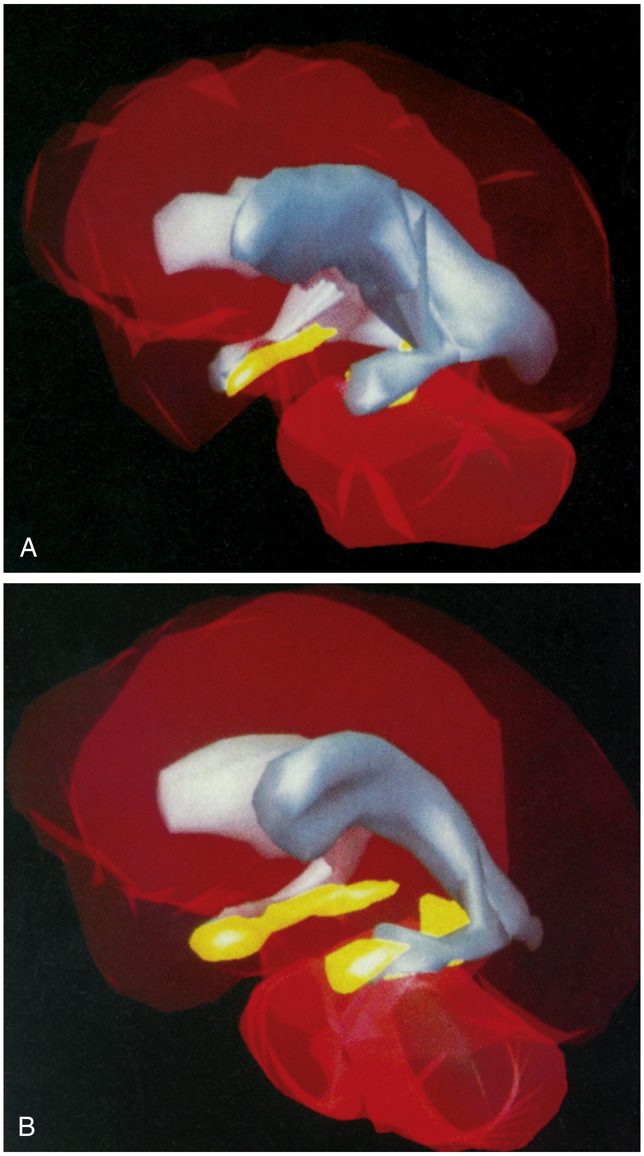

FIGURE 19-1 **Magnetic Resonance Imaging (MRI) Comparison of Normal Brain and Brain with Schizophrenia.** Three-dimensional MRI reconstructions showing **A,** the cerebroventricles *(gray regions)* and hippocampus *(yellow regions)* of a schizophrenic patient, and **B,** those of a healthy individual. Note the enlarged cerebroventricles and reduced hippocampal volume of the brain of the schizophrenic individual. (From Gershon ES, Rieder RO: *Sci Am* 267:128, 1992. Original illustrations by Nancy C. Andreason, University of Iowa.)

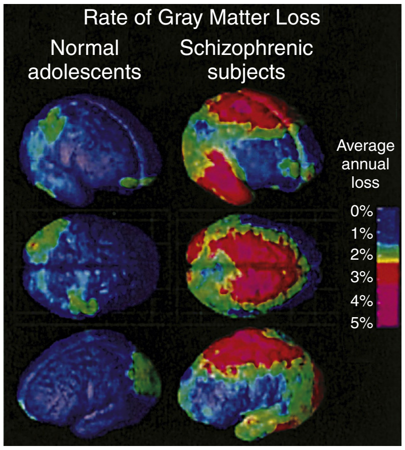

FIGURE 19-2 **Accelerated Gray Matter Loss in Brains of Early Onset Schizophrenic Adolescents.** Annual gray matter loss ranging from 2% to 5% was found in 13- to 18-year-old schizophrenics—compared with age-matched healthy adolescents. (From Thompson PM et al: *Proc Natl Acad Sci U S A* 98:11650, 2001.)

current medications for schizophrenia to attenuate or reverse the loss of frontal brain tissue.

Brain abnormalities in schizophrenia are believed to originate in the prenatal period of cell proliferation and migration. Reelin, an extracellular matrix protein involved in neuronal migration during development and in synaptic function during adulthood, is reduced in the prefrontal cortex and hippocampus of schizophrenic individuals.[8,9] Reelin is concentrated in interneurons that contain **gamma-aminobutyric acid (GABA),** the most widespread inhibitory neurotransmitter. Furthermore, in the dorsal prefrontal cortex of schizophrenic brains, the level of glutamic acid decarboxylase, the major enzyme in GABA biosynthesis, is reduced, which likely impairs normal cognitive/emotional functions.

Pathophysiologic changes in the dorsal prefrontal cortex are believed to contribute to the production of negative symptoms in schizophrenia (Figure 19-3). In particular, the **dorsolateral prefrontal cortex (DLPFC)** (Brodmann areas 9, 10, 46, 47) is intricately involved in the initiation and maintenance of goal-directed activities and in solving cognitive problems related to working memory. **Working memory** involves the brief storage and use of information to complete cognitive tasks such as language comprehension, learning, and reasoning. Blood flow and metabolism normally increase in the DLPFC during working memory processing but not in schizophrenics, who also perform poorly in tests of working memory. Thus the dorsolateral prefrontal cortex appears to be hypoactive in schizophrenia.

Neurotransmitter Alterations. The onset of schizophrenia was initially hypothesized to stem from abnormally high concentrations of the brain neurotransmitter dopamine. This **dopamine hypothesis** of schizophrenia was proposed on the basis of pharmacologic studies showing that antipsychotic drugs were potent blockers of brain dopamine receptors. A strong positive correlation was found between the clinical potencies of first-generation antipsychotic drugs (e.g., chlorpromazine, fluphenazine, and haloperidol) and their affinity for the dopamine D_2 receptor. In addition, drugs at high doses that dramatically increased dopaminergic transmission—such as levodopa (L-dopa), cocaine, and amphetamine—produced schizophrenic-like psychosis, which was reversed by dopamine blockers.

A current view of the dopamine hypothesis of schizophrenia is that brain dopamine pathways are altered in different ways (Figure 19-4). For example, the negative symptoms and cognitive alterations in schizophrenia are proposed to result from reduced dopaminergic neurotransmission in the mesocortical dopamine pathway.[10] This hypodopaminergic transmission in the prefrontal cortex contrasts with the hypothesized hyperdopaminergic secretion, in mesolimbic brain regions, which may

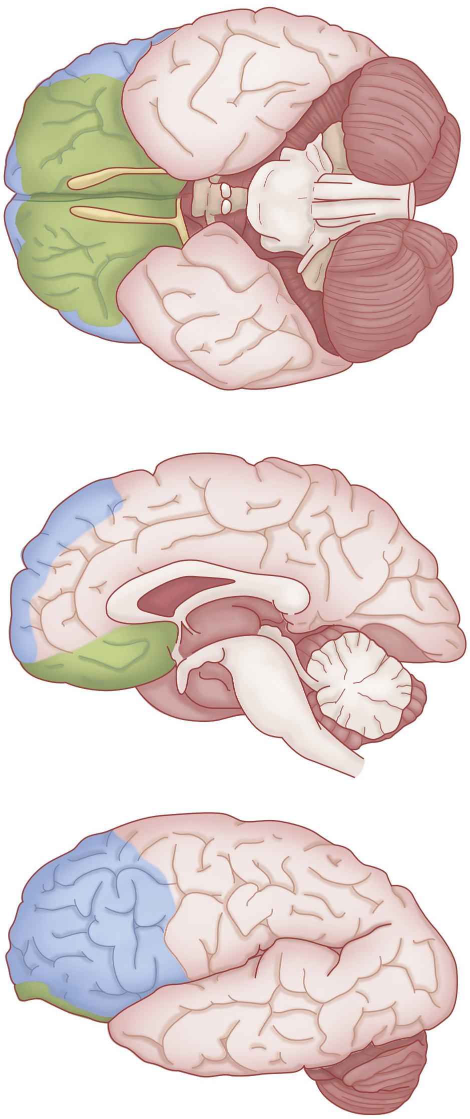

FIGURE 19-3 **The Prefrontal Cortex.** The prefrontal cortex consists of a dorsolateral *(blue)* and an orbitofrontal *(green)* region.

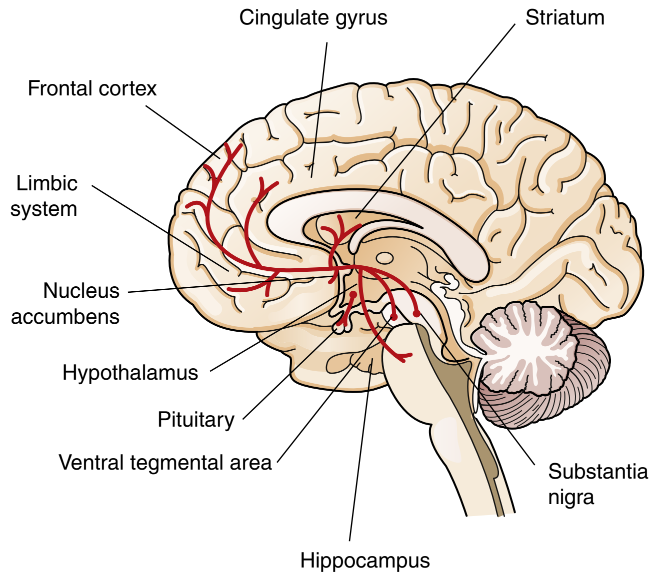

FIGURE 19-4 **The Dopamine System.** Dopamine cell bodies are located in the substantia nigra, where they project to the stratum (nigrostriatal pathway); and in the ventral tegmental area, where they project to the frontal and cingulate cortex (mesocortical pathway), the striatum, the hippocampus, and other limbic structures (mesolimbic pathway). Dopamine nuclei are also located in the hypothalamus and project to the pituitary.

contribute to the production of positive schizophrenic symptoms. The mesolimbic dopamine pathway innervates temporal lobe structures including the hippocampal formation and amygdala, as well as the nucleus accumbens and anterior cingulate cortex.

Another neurotransmitter system that may underlie the pathogenesis of schizophrenia is the excitatory neurotransmitter glutamate and its actions on the *N*-methyl-D-aspartate (NMDA) receptor subtype. The **glutamate hypothesis** of schizophrenia proposes that underactivation of glutamate receptors contributes to schizophrenia.[11] In schizophrenia, glutamate concentrations in the cerebrospinal fluid (CSF) are reduced along with a decrease in cortical glutamate synthesis. Furthermore, in unaffected individuals, blocking the glutamate NMDA receptor with antagonists, such as phencyclidine (PCP) and ketamine, facilitates the positive and negative symptoms of schizophrenia. PCP users report auditory hallucinations and disorientation, and may become violent from their delusions. In monkeys, chronic PCP treatment impairs cognitive performance in a test associated with prefrontal cortical damage.[12]

Clinical Manifestations

The symptoms of schizophrenia are currently divided into three broad categories of positive, negative, and cognitive symptoms (Box 19-1). *Positive symptoms* frequently occur during a **psychotic episode,** when an individual loses touch with reality and experiences something that should be absent (e.g., hallucinations). *Negative symptoms* are characterized by disruptions in normal emotional states and expressions. Cognitive symptoms are fairly common and involve problems with thought processes that severely impair the ability to perform routine daily tasks that involve attention, planning, and social skills. According to the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)*,[13] schizophrenia is diagnosed when an individual exhibits delusions, hallucinations, negative symptoms, or social/occupational dysfunctions for at least 6 months and at least two of the common symptoms of the disorder—delusions, hallucinations, disorganized speech, disorganized or catatonic behavior, or presence of negative symptoms—must occur for 1 month (or less if successfully treated).

Psychotic Dimension

Psychotic dimension refers to hallucinations and delusions and reflects a person's confusion or loss of touch with the external world. Hallucinations and delusions are classified as positive symptoms and are the most common in schizophrenia.

Hallucinations. A **hallucination** is a perception experienced without external stimulation of the sense organs. Sensory hallucinations can be auditory, tactile, visual, gustatory, and olfactory. For example, the schizophrenic individual may hear

BOX 19-1 MAJOR SYMPTOMS OF SCHIZOPHRENIA

Positive Symptoms

Hallucinations

Auditory
Olfactory
Somatic-tactile
Visual
Voices commenting
Voices conversing

Delusions

Delusions of being controlled
Delusions of mind reading
Delusions of reference
Grandiosity
Guilt
Persecutory
Religious
Somatic
Thought broadcasting
Thought insertion
Thought withdrawal

Positive Formal Thought Disorder

Circumstantiality
Derailment
Distractible speech
Illogicality
Incoherence
Pressure of speech
Tangentiality

Bizarre Behavior

Aggressive, agitated
Clothing, appearance
Repetitive, stereotyped
Social, sexual behavior

Negative Symptoms

Affective Flattening

Affective nonresponsivity
Decreased spontaneous movements
Inappropriate affect
Lack of vocal inflections
Paucity of expressive gestures
Poor eye contact
Unchanging facial expression

Alogia

Blocking
Increase in response latency
Poverty of speech
Poverty of speech content

Anhedonia-Asociality

Few recreational interests
Few social relationships
Impaired intimacy
Little sexual interest

Attention

Social inattentiveness
Inattentiveness during testing

Avolition-Apathy

Impaired personal hygiene
Lack of persistence
Physical anergia

Cognitive Symptoms

Inability to understand information and make proper decision to complete a task
Difficulty paying attention
Problems with working memory or the inability to use recently learned information
Lack of insight

WHAT'S NEW?

Controversies in Mental Health Research

The *Diagnostic and Statistical Manual of Mental Disorders*—or *"DSM"* —is published by the American Psychiatric Association, and has been considered the authoritative guide to diagnosing mental disorders. First published in 1952, the *DSM* has undergone several revisions, and not until the 1980 publication of the *DSM-III* did the manual dramatically impact mental health professionals, including psychiatrists, clinical psychologists, social workers, and nurses. The *DSM-III* became known as the "bible of psychiatry" because it introduced a new set of criteria to standardize the diagnoses of mental disorders by categorizing symptoms presumably unique to each mental illness, such as schizophrenia and bipolar disorder. This categorical symptom approach stimulated research on the etiology and pathophysiology of diverse mental disorders and began to impact public health policy, education, and reimbursement decisions made by insurance companies. Modest categorical changes were subsequently made in the 1994 edition of *DSM-IV* and a text revision of *DSM-IV*, called *DSM-IV-TR*, was published in 2000.

The highly anticipated *DSM-5* published in 2013 and represents the culmination of more than 10 years of revision work involving more than 1500 experts in the psychiatric, psychologic, psychiatric nursing, pediatric, neurologic, social work, and related disciplines from 39 countries. Users familiar with earlier *DSM* versions will encounter two major changes in *DMS-5*. One major change includes reordering the chapters based on the relatedness of disorders in terms of similar underlying vulnerabilities and symptoms. This change in each chapter is intended to align the *DMS-5* with the *World Health Organization's International Classification of Diseases*, ed 11, in order to further facilitate communication and diagnosis of disorders.

The second major change is to replace the multiaxial system of diagnosis with a nonaxial documentation by combining the former Axes I, II, and III with separate notations for psychosocial and contextual factors (formerly Axis IV) and disability (formerly Axis V). Notably, the *DSM-5* will not increase the number of mental disorders; instead, fewer disorders will be found in *DSM-5* than in *DSM-IV*. However, any change by *DSM* in the diagnosis of mental health that defines "normal" behavior will be of concern, especially by advocacy groups and insurance companies. For example, one controversial change in the *DSM-5* will be to potentially diagnose any child over the age of 6 who displays irritability or frequent angry outbursts with "disruptive mood dysregulation disorder." This new diagnosis was included to provide parents or caregivers the opportunity to plan interventions for children who exhibit problems controlling their emotions. However, advocacy groups questioned whether such a diagnosis would stigmatize children and may lead to unnecessary drug prescriptions. Another change is a grief and depression diagnosis. Whereas previous *DSM* versions prevented a diagnosis of depression in a person grieving the death of a loved one, the *DMS-5* will allow depression diagnoses in the bereaved. The rationale was to provide those with chronic grief to be diagnosed with, and obtain treatment for, depression. However, some healthcare professionals questioned whether diagnosing normal grieving as depression is necessary at all, as in the previous *DSM*.

Although the new *DSM-5* is expected to be used by many clinicians for diagnosing and treating mental disorders, some prominent researchers and clinicians have begun to question the way mental illnesses are currently viewed by categorizing and diagnosing symptoms. In particular, the current categorical symptom diagnoses guide to mental disorders does not guarantee effective treatment. A patient may exhibit multiple symptoms that overlap with a diagnosis for different disorders and that may explain why specific clinical treatment will not always relieve or temper mental illness. What appears to be missing in our present understanding of mental disorders are the causes and underlying brain mechanisms that trigger the onset of the illness.

To address this issue, Dr. Thomas Insel, Director of the National Institute of Mental Health, and other prominent scientists are hoping to steer psychiatric research away from classifying symptoms to a fundamental approach of identifying the genes, molecules, and pathophysiologic brain circuits that cause mental disorders. To do so, Dr. Insel started a federal project called Research Domain Criteria to fund research that investigates the biologic basis, and not the symptom categories, of mental disorders. Research projects are beginning to unravel brain functions that broadly implicate neural systems linked to memory, fear, anhedonia, and stress, which affect many people with mental illness. Future treatments that target pathophysiologic neural systems with new drugs or with cognitive-behavioral methods may be more beneficial to psychiatric patients than currently available treatments for psychiatric symptoms.

Data from Adam D: *Nature* 496:416–418, 2013; American Psychiatric Association: www.dsm5.org; Halter MJ et al: *J Psychosoc Nurs* 51:30–39, 2013; Insel TR et al: *Neurosci Biobehav Rev* (in press); Stringaris A: *J Child Psychol Psychiatr* 54:501, 2013.

voices, experience touch or electrical sensations, report images of animate and inanimate objects, or complain of unpleasant tastes and odors. These hallucinations may occur alone or together.

Delusions. A **delusion** is a persistent belief contrary to the educational and cultural background of the individual. Delusions may involve grandiose, nihilistic, persecutory, somatic, sexual, and religious themes. Paranoid beliefs are common and may involve spying, conspiracy, persecution, and ridicule. Delusions also may be referential in that particular stimuli or events become highly personalized, such as believing a television talk show host is directing information specifically at them.

Disorganized Behavior

Disorganized behavior includes disorganized speech and disorganized or bizarre behavior. Incongruity of affect is another dimension of disorganized behavior.

Disorganized Speech. A common form of disorganized speech is **formal thought disorder,** which involves fluent speech that is difficult to comprehend. The speech often moves from one topic to another unexpectedly (loose associations) and illogically and the person becomes easily distracted when talking.

Another form of disorganized speech is called **poverty of content.** Here, the use of vocabularies to convey information is severely retarded despite a fair amount of spoken words. For instance, the same phrases are used repeatedly throughout a conversation.

Disorganized Behavior. Disorganized (or bizarre) behavior is the conceptual equivalent of disorganized speech. The individual has difficulty engaging in goal-directed activities. Repetitive (e.g., stereotyped rocking) or aimless behavior and poor personal hygiene are exhibited. Another feature is the incongruity of affect or the manifestation of inappropriate situational affect as exemplified by hostility without provocation or childlike silliness in sober situations.

Negative Dimensions

Negative dimensions reflect a deficit in normal functioning and are characterized by affective flattening, anhedonia, alogia (poverty of speech), and avolition. **Affective flattening** is the near absence of emotional or facial expressions throughout a conversation or in different situations. In **anhedonia,** individuals are unable to experience emotions such as pleasure or pain and report a sense of detachment from the environment. **Alogia** is the absence of spontaneous speech production for the purpose of answering questions or expressing oneself. **Avolition** is a deficit in spontaneous or goal-directed behavior, such as completing simple daily tasks.

Treatment

The use of chlorpromazine in the mid-1950s dramatically altered the treatment of schizophrenia, which previously required extensive institutional hospitalization. The drug was especially effective in reducing positive symptoms such as hallucinations and delusions as well as thought disorders and hyperactivity. The beneficial effects of chlorpromazine and similar first-generation antipsychotic drugs like haloperidol on positive symptoms were believed to stem from their ability to block the dopamine D_2-receptor subtype, especially in the overly active mesolimbic dopamine pathways.

However, D_2-receptor blockade, such as in the striatum, produces a notable neurologic side effect resembling Parkinson disease—a disorder associated with degeneration of dopamine cell bodies in the substantia nigra that project to the striatum. A related side effect of conventional antipsychotics that develops in 15% to 20% of schizophrenics after several years of treatment is a condition called **tardive dyskinesia.** This condition is characterized by tic-like jerky movements, such as smacking the lips or flicking the tongue, unsteady gait, or rocking back and forth when seated. Other side effects may include sedation, hypotension, akathisia (motor restlessness), constipation, weight gain, amenorrhea, and, less frequently, hepatotoxicity and electrocardiographic changes.

Although the majority of schizophrenic individuals obtained some positive symptom relief from the first-generation or conventional antipsychotics, approximately 20% failed to respond to D_2-blocking drugs (Box 19-2), especially those with pronounced symptoms of apathy, disorientation, and social withdrawal. However, some of these treatment-resistant individuals responded to a second generation of drugs that became known as atypical antipsychotic drugs.[14] Atypical antipsychotics also were shown to have superior efficacy in reducing not only the positive but also the negative symptoms in comparison with conventional antipsychotics. For example, clozapine improve some cognitive functions (such as verbal fluency, verbal learning, and memory) and some physical functions (such as psychomotor speed). In

BOX 19-2 MEDICATIONS USED IN THE TREATMENT OF SCHIZOPHRENIA

GENERIC NAME	BRAND NAME
Conventional Antipsychotics	
Chlorpromazine	Thorazine
Fluphenazine	Prolixin
Haloperidol	Haldol
Perphenazine	Trilafon
Pimozide	Orap
Prochlorperazine	Compazine
Thioridazine	Mellaril
Thiothixene	Navane
Trifluoperazine	Stelazine
Second-Generation Atypical Antipsychotics	
Aripiprazole	Abilify
Clozapine	Clozaril
Loxapine	Loxitane
Molindone	Moban
Olanzapine	Zyprexa
Paliperidone	Invega
Quetiapine	Seroquel
Risperidone	Risperdal
Ziprasidone	Geodon

addition, the notable neurologic side effects that accompany the use of the conventional antipsychotics were diminished.

Unlike conventional antipsychotics, atypical drugs appear to work by blocking a range of neurotransmitter receptors. For example, clozapine blocks not only D_2 receptors but also D_1, D_3, D_4, and D_5 receptors and serotonin (5-hydroxytryptamine, i.e., HT_2, 5-HT_6, 5-HT_7); norepinephrine; and cholinergic and histamine receptors. Risperidone and ziprasidone have higher affinity for blocking 5-HT_2 than D_2 receptors. The higher 5-HT_2/D_2-receptor–binding ratio of atypical antipsychotics in comparison with conventional drugs may reflect a normalization of serotonin-dopamine interactions leading to clinical efficacy not observed with D_2-receptor blockade alone.

Atypical antipsychotics are not without adverse effects, most notably metabolic abnormalities including regulation of glucose and lipid levels and weight gain. For example, long-term clozapine or olazapine treatment increases body weight gain, which becomes a risk factor for diabetes and cardiovascular disease. Schizophrenics treated with clozapine also are at risk of developing **agranulocytosis,** a potentially lethal blood disorder involving the loss of white blood cells and a compromised immune system.

In conjunction with antipsychotic medication, psychosocial therapy can facilitate the management of schizophrenia. Psychosocial relationships assist the individual in developing coping strategies and in identifying stressors and relapse symptoms. Cognitive-behavioral therapy (CBT), a talking therapy that initiates cognitive and behavioral change based on an individualized reappraisal of the person's faulty beliefs, is effective in treating schizophrenics with stabilized antipsychotic medications.[15] An important benefit of psychosocial and family support is the encouragement of compliance with antipsychotic medication that requires a period before the emergence of clinical efficacy.

MOOD DISORDERS: DEPRESSION AND BIPOLAR DISORDER

Mood refers to a sustained emotional state as opposed to brief emotional feelings, which are termed *affective states.* Healthy individuals are normally capable of experiencing a variety of affective states including euphoria, joy, surprise, fear, sadness, anxiety, and depression. When emotional states, such as sadness, become chronic and uncontrollable, individuals may be diagnosed with a mood disorder called *depression.* The two major classifications of mood disorder are: (1) unipolar or major depressive disorder, also known as *major depression* or *clinical depression,* which consists of episodes of depression; and (2) **bipolar disorder,** which is further classified into bipolar I and bipolar II disorders. Bipolar I disorder features manic episodes and at least one major depressive episode and bipolar II disorder is characterized by recurrent major depressive episodes with one or more hypomanic (milder than manic) episodes. Box 19-3 presents the major criteria of depression and bipolar disorder according to the American Psychiatric Association's *DSM-IV-TR.*[13]

Major (unipolar) depression is the most common mood disorder and the leading cause of disability in the United States and throughout the world. Unipolar depression appears in all age groups including young children. In the United States, the lifetime prevalence rate of depression is 16.2% of the population with a twofold greater risk in women than men after adolescence. In children and adolescents, 2% to 6% suffer from depression. The prevalence of bipolar disorder ranges from 3% to 5% in the general population. Bipolar I disorder occurs equally in men and women in comparison with bipolar II disorder, which afflicts more women than men. When left untreated, a number of depressed and bipolar individuals are at risk of developing a host of medical illnesses, including cardiovascular disease, obesity, diabetes, and thyroid disease.

BOX 19-3 MAJOR SYMPTOMS OF DEPRESSION AND MANIA

Symptoms of Depression*

Depressed or irritable mood
Loss of interests and pleasure
Significant (>5%) weight gain or loss in a month
Insomnia or hypersomnia
Psychomotor agitation or retardation
Fatigue or loss of energy
Feelings of worthlessness or excessive guilt
Poor concentration or indecisiveness
Recent thoughts of death or suicide

Symptoms of Manic Episode†

Elevated mood
Irritable mood
Inflated self-esteem
Decreased need for sleep
Excessive talking
Racing/crowded thoughts
Distractibility
Increase in goal-directed activity
Excessive risky activities

*Five or more of the symptoms are present in a 2-week period and at least one of the symptoms is either depressed mood or loss of interests or pleasure.
†Three or more symptoms (four if the mood is only irritable) during a distinct period of abnormally and persistently elevated, expansive, or irritable mood occurring for at least 1 week.

Etiology and Pathophysiology

Genetic Predisposition and Environmental Influences

Family and twin studies indicate a strong basis for mood disorders. Using *DSM-III* or *DSM-III-R* criteria, concordance rates for bipolar disorder ranged up to 62% and 42% for monozygotic and dizygotic twins, respectively.[16] For unipolar disorder, concordance rates of 62% and 28% were reported in monozygotic and dizygotic twins, respectively. Even among adoptees with a biologic family history of mood disorders, the incidence of developing major depression or manic-depressive illness is higher than among control adoptees. The strong tendency for mood disorders to run in families has encouraged a search for the abnormal gene or genes. Interestingly, loci on chromosomes 18 and 22 have been linked to both bipolar disorder and schizophrenia. Bipolar individuals, who may exhibit psychotic behavior, have deficits in reelin expression linked to genetic

loci, located on chromosome 22, which confers susceptibility to schizophrenia (see preceding section on schizophrenia, p. 642). However, the large variation in clinical symptoms suggests that developmental and environmental factors are as important as genetic factors in contributing to the etiology of mood disorders.

A current view of mood disorders is that the illness stems from a complex interplay between susceptible genes and environmental influences. For example, the interplay between life stressors and a potentially dysfunctional serotonin (5-HT) system appears to elevate the risk of depression.[17] Researchers have identified a polymorphic variant of the serotonin transporter (5-HT-T) that exists either as a short *(s)* allele or as a long *(l)* allele. The serotonin transporter serves in the reuptake of serotonin at the synapse and may moderate the serotonergic response to stress. However, individuals with two copies of the *s* allele were more likely to develop major depression and have suicidal thoughts in response to stressful events than individuals homozygous for the *l* allele. In addition, among individuals who carry two *s* alleles, the risk of a major depressive episode increased twofold after experiencing four or more stressful events. This work[17] suggests that exposure to both adverse life events and a genetic alteration in 5-HT function increases the risk of developing major depression.

Neurochemical Dysregulation

Modern theories of mood disorders began with the important observations that drugs such as imipramine that elevated norepinephrine levels within the synapse reduced depression whereas drugs that depleted monoamine levels (e.g., reserpine) increased depression. These studies led to the dominant **monoamine hypothesis of depression,** in which a deficit in the concentration of brain norepinephrine, dopamine, and/or serotonin is the underlying cause of depression, in contrast to mania, which results from elevated concentrations of monoamines. Three major classes of antidepressant drugs were initially developed and included monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants (TCAs), and selective serotonin reuptake inhibitors (SSRIs). These antidepressants shared the common property, albeit through different mechanisms, that increasing monoamine neurotransmitter levels within the synapse is the basis for their antidepressant effects (Figure 19-5).

Additional support for the monoamine hypothesis of depression came from studies showing a reduction of monoamine metabolites in the cerebral spinal fluid (CSF) of depressed people. Other work demonstrated that dietary depletion of tryptophan, the precursor of serotonin synthesis, or alpha-methylparatyrosine (AMPT), a drug that inhibits dopamine and norepinephrine synthesis, produced a rapid return to depression in individuals successfully treated with antidepressants.[18]

Neuroendocrine Dysregulation

Stress and Hypothalamic-Pituitary-Adrenal System Dysregulation. The hypothalamic-pituitary-adrenal (HPA) system plays an essential role in an individual's ability to cope with stress (see Chapter 11). However, chronic activation of the HPA system and elevated glucocorticoid secretion are found in a large percentage (30% to 70%) of people with major depression, suggesting that mechanisms responsible for increased HPA hormone secretion contribute to the pathophysiology of depression.[19] Notably, antidepressant drugs effective in normalizing the HPA system are associated with a good clinical response, whereas persistent dysregulation of the HPA system is related to continued depression or relapse.

Uncontrollable stress activates not only the HPA system but also the immune system, which may further contribute to the development of depression. Psychosocial stress-induced activation of the immune system increases secretion of proinflammatory cytokines, such as interleukin-1α (IL-1α) and IL-β, tumor necrosis factor-alpha (TNF-α), and IL-6, which modulates signaling pathways throughout the periphery and brain and augments further secretion of HPA hormones and monoamine metabolism. A potential consequence of prolonged cytokine-induced activation is dysregulation in feedback and feed-forward control mechanisms of the HPA system, leading to chronic elevations in cortisol level, as observed in major depression. Persistent elevations in cortisol level also may induce immunosuppression that compromises the body's immune systems to control inflammation and infectious diseases. Increasing evidence suggests that inflammation is another risk factor that triggers the onset of depression. For example, inflammation is a significant contributor to coronary heart disease and the prevalence of comorbid depression in people with heart disease is threefold higher than that in the general population.[20]

Increasing evidence from animal models of stress-induced depression shows that depression-like behavior is accompanied by atrophy of neurons in the hippocampus, a reduction in the development of new hippocampal neurons (i.e., **neurogenesis**), and a deficit in hippocampal **brain-derived neurotrophic factor (BDNF)** levels.[21,22] Consistent with animal studies, human postmortem work indicates low hippocampal BDNF levels in depression. Because the growth factor BDNF supports the survival of neurons and facilitates neurogenesis from hippocampal stem cells, a neurotrophic hypothesis of depression has been proposed as an extension of the monoamine hypothesis of depression to broadly account for the pathophysiologic basis of depression. That is, stress-induced depression and the accompanying reduction in levels of monoamines are caused by deficits in neurogenesis and BDNF levels. Of clinical relevance, administration of antidepressants to animals reverses the depression-like state and increases the development of neurogenesis and BDNF levels (see What's New? Hippocampal Neurogenesis and the Glucocorticoid Receptor Play Essential Roles in Deterring Depression).

Hypothalamic-Pituitary-Thyroid System Dysregulation. Approximately 20% to 30% of persons with major depression have an altered hypothalamic-pituitary-thyroid (HPT) system. These individuals exhibit increased CSF levels of thyrotropin-releasing hormone (TRH), blunted thyroid-stimulating hormone (TSH) response to TRH challenge, and decreased nocturnal rise in TSH level that normally occurs between midnight and the early morning hours.[23] Persistent blunting of the TSH response to TRH is associated with an increased

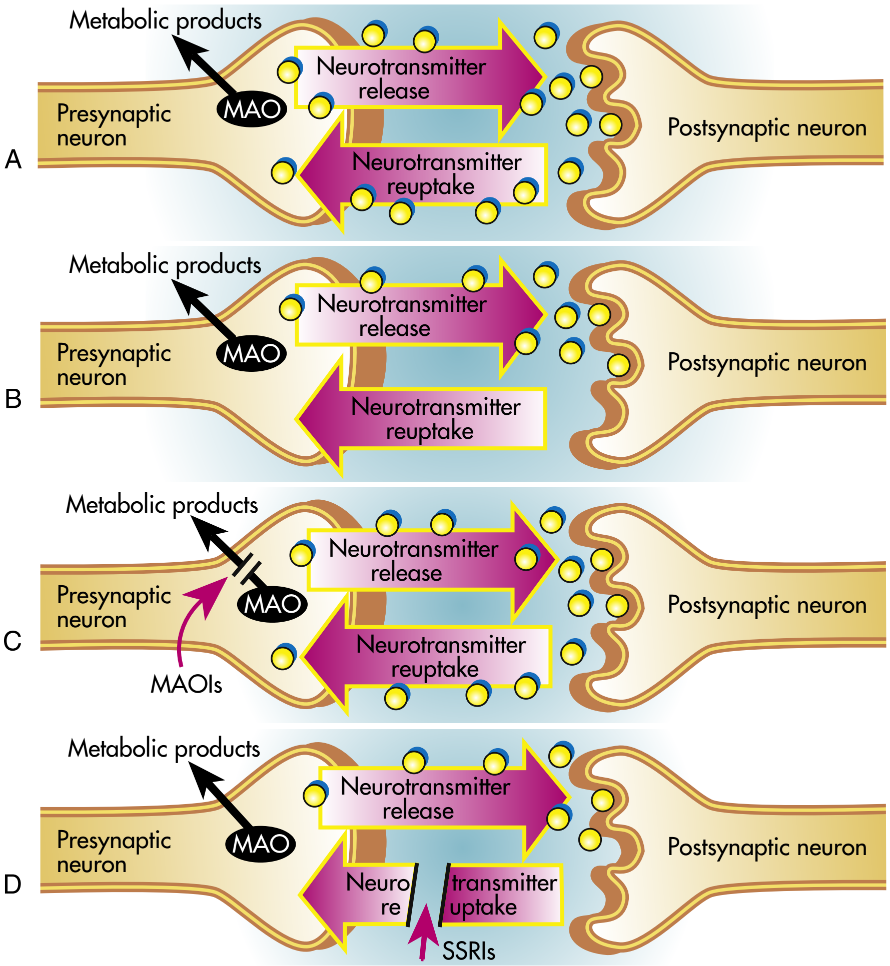

FIGURE 19-5 Schematic Diagrams Showing the Sites of Actions of Antidepressants and Their Effects on Neurotransmitter Levels. **A,** In healthy individuals an action potential generated in the presynaptic neuron results in neurotransmitter release into the synapse. Some neurotransmitters bind to receptors on the postsynaptic neuron that leads to activation of second messenger systems (not shown). Neurotransmitters are also removed from the synapse by reuptake into the presynaptic neuron and deaminated by monoamine oxidase *(MAO)*. **B,** In depressed individuals, neurotransmitter levels are hypothesized to be reduced. The mechanisms responsible for this reduction are not understood. **C,** MAO inhibitors act by preventing the degradation of neurotransmitters, such as norepinephrine and serotonin. As a result, neurotransmitter levels are elevated. **D,** The tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors *(SSRIs)* act by reducing the uptake of neurotransmitters from the synapse, leading to increased neurotransmitter levels. TCAs, such as nortriptyline and desipramine, tend to block norepinephrine reuptake, whereas amitriptyline and imipramine also have effects on serotonin reuptake. SSRIs are highly effective in blocking serotonin reuptake.

WHAT'S NEW?

Hippocampal Neurogenesis and the Glucocorticoid Receptor Play Essential Roles in Deterring Depression

The hippocampus contains glucocorticoid receptors that play a negative feedback role in modulating the inhibition of the HPA hormone system. Chronic stress induces a persistent elevation in secretion of the glucocorticoid cortisol and may precipitate depression as well as a reduction in hippocampal neurogenesis. However, the specific effects of hippocampal neurogenesis on depression are not well understood. Two recent studies examined the role of hippocampal neurogenesis in depression. One study reported that hippocampal neurogenesis–deficient mice were more likely to exhibit increases in depression-like behavior and deficits in glucocorticoid negative feedback in comparison to control mice. The results suggest an essential role of hippocampal neurogenesis in dampening stress-induced HPA hormone secretion and buffering the effects of stress on depression. The other study examined whether hippocampal glucocorticoid receptors are involved in antidepressant-induced stimulation of neurogenesis. Using human hippocampal progenitor cells, the antidepressant sertraline was found to increase neuronal differentiation via a glucocorticoid receptor–dependent mechanism. Furthermore, drugs that block the actions of the glucocorticoid receptor reduced the effects of sertraline on progenitor cell proliferation. The results of this study highlight a role of the glucocorticoid receptor in the antidepressant-induced facilitation of hippocampal neurogenesis in humans.

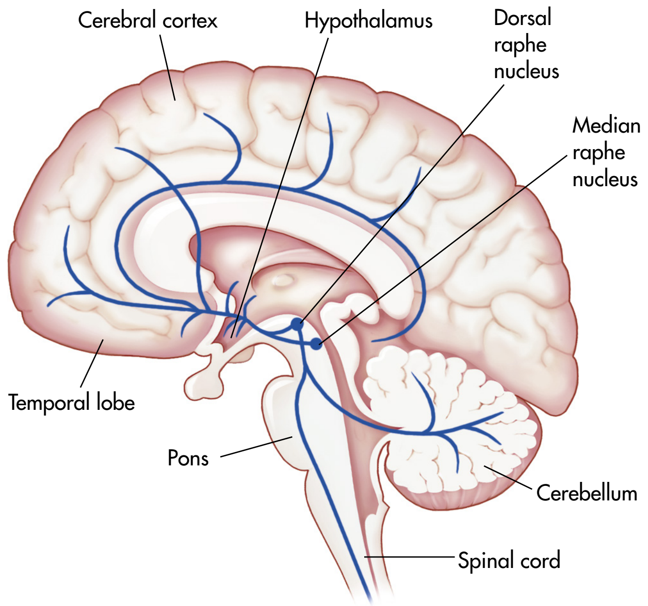

FIGURE 19-6 The Serotonin System. Serotonin neurons are located in the brainstem raphe nuclei. They project diffusely to all regions of the cortex, temporolimbic regions, hypothalamus, basal ganglia, cerebellum, the brainstem, and spinal cord.

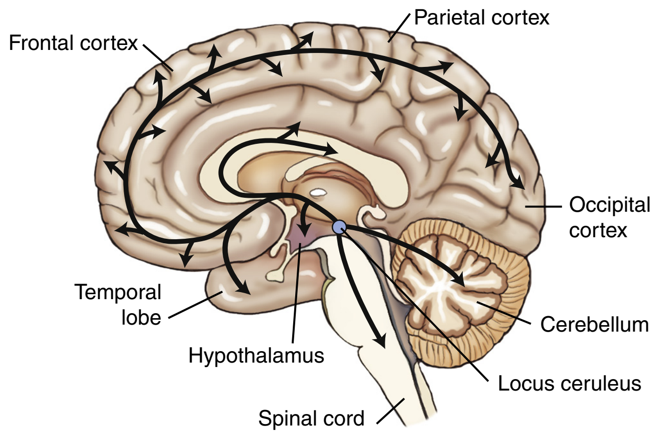

FIGURE 19-7 The Norepinephrine System. The norepinephrine cell bodies originate in the locus ceruleus and project throughout the brain, including the hypothalamus, the temporal lobe, the entire cortex, the cerebellum, and spinal cord.

probability of relapse. Abnormalities in thyroid function, such as increased basal TSH concentrations with normal thyroxine levels, also are observed in bipolar disorder, especially among individuals with rapid cycling.

Neuroanatomic and Functional Abnormalities

The dorsal and median raphe nuclei, located in the central gray of the caudal mesencephalon and rostral pons, contain a large group of serotonin-synthesizing neurons that project extensively to all regions of the cortex, basal ganglia, limbic system, hypothalamus, cerebellum, and brainstem (Figure 19-6). Postmortem and/or brain imaging studies of depressed individuals revealed a widespread decrease in serotonin 5-HT_{1A} receptor subtype binding in the frontal, temporal, and limbic cortex as well as serotonin transporter binding in the cerebral cortex and hippocampus. Mood disorders in some people may reflect a dysfunctional raphe-serotonin system, which normally modulates homeostasis, emotionality, and tolerance to aversive experiences.

A group of norepinephrine-containing cells located in the locus ceruleus of the rostral pons project to vast areas of the forebrain, brainstem, and spinal cord (Figure 19-7). The locus ceruleus–norepinephrine system is implicated in global psychologic processes including attention, vigilance, and orientation to novel, aversive, or threatening stimuli. Activation of the locus ceruleus–norepinephrine system is also capable of inhibiting the raphe-serotonin system, suggesting an indirect role in modulating serotonin functions. Norepinephrine receptor alterations (e.g., α- and β-adrenergic receptor subtypes) are found in the frontal cortex of some suicide victims with major depression. Alterations in norepinephrine systems may be linked to attention or concentration difficulties as well as sleep and arousal disturbances in depression.

Postmortem and brain imaging studies further reveal structural and functional abnormalities associated with mood disorders, especially in frontal and limbic regions such as the amygdala.[24,25] Postmortem studies report a reduction in glial cell numbers in people with unipolar and bipolar disorders. There are also reports of reduced frontal lobe volume in depressed individuals and decreased or asymmetric temporal lobe volume in individuals with bipolar illness and depression. One study showed increased volume of the amygdala in bipolar illness. In some cases, specific brain abnormalities are associated with a subtype of depression. For example, late onset depressed older adults more often exhibit enlarged lateral ventricles than midlife depressed individuals, depressed older adults with an early age of illness, or bipolar individuals.

Functional neuroimaging studies indicate decreased cerebral blood flow and glucose metabolism in the dorsolateral and dorsomedial prefrontal cortex of individuals affected by major depression or bipolar disorder. Dorsolateral prefrontal abnormalities in depression may be responsible for the retardation in cognitive processing and speech deficits similar to those found in schizophrenia. Dorsomedial frontal dysfunction may be associated with mnemonic and attentional impairments that accompany mood disorders. Other frontocortical regions, including the ventrolateral, ventromedial, and orbital areas, exhibit increased blood flow and metabolism in unipolar depression (Figure 19-8). These frontal brain areas have extensive interconnections with the amygdala, and increased blood flow and metabolism, especially in the right amygdala, is positively related to negative affect in depressed individuals. These functional changes in brain activity begin to normalize with successful antidepressant treatments, suggesting they are state rather than trait related.

Clinical Manifestations

Depression

Major **depression** is characterized by unremitting feelings of sadness and despair (see Box 19-3). The **dysphoric mood** or intensely painful mood is accompanied frequently by insomnia, loss of appetite and body weight, and reduced interest in

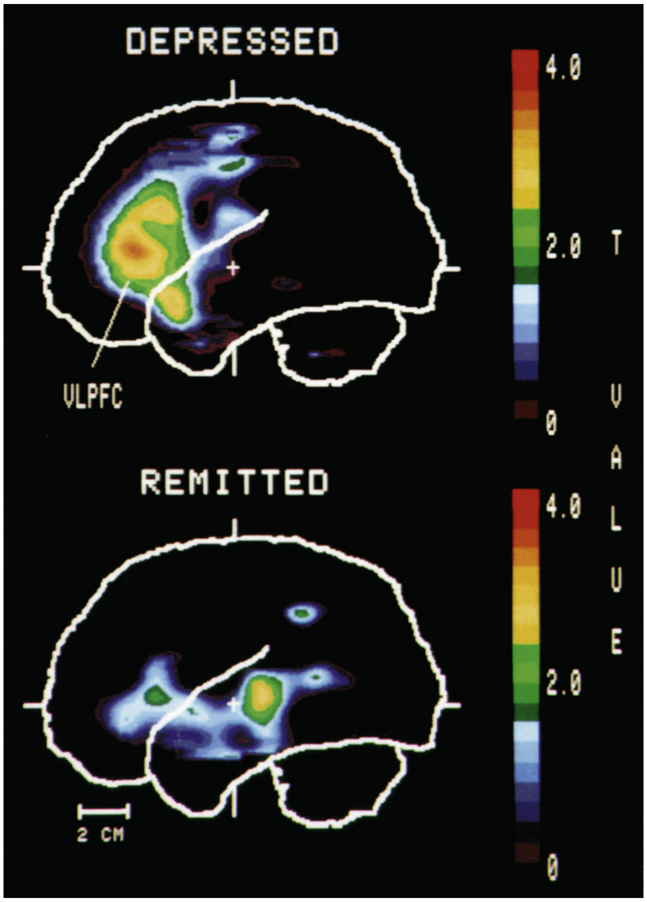

FIGURE 19-8 Positron-Emission Tomography (PET) Comparison of Brain Activity in Depression and in Remittance. PET scan showing increased activity in the left prefrontal cortex in a depressed person but not in the remitted person. *VLPFC*, Ventrolateral prefrontal cortex. (From Drevets WC et al: *J Neurosci* 12:3628, 1992. Copyright ©1992 by the Society for Neuroscience.)

pleasurable activities and interpersonal relationships. Sleep disturbances may include difficulty in initially falling asleep and awakening in the middle of the night, lying awake for several hours with an inability to subsequently fall asleep. Individuals may have reduced motor activity and suffer marked fatigue. Others complain of restlessness and agitation. Feelings of worthlessness and guilt are common, and pessimistic or negative outcomes are often perceived even in routine situations. The ability to function (e.g., work) and concentrate is greatly diminished. Depressive episodes may occur or recur suddenly or gradually and continue from a few weeks to months, and 20% may exhibit a chronic form of depression.

Suicidal risk increases in depression. Factors such as living alone or being divorced, having a prior history of drug abuse or suicide attempt, or having depression at midlife or older ages contribute to suicide in 10% to 15% of depressed individuals.

Bipolar Disorder: Mania

Manic individuals experience elevated levels of euphoria and self-esteem and feelings of grandiosity. Energy levels are greatly enhanced even after only a few hours of sleep each night. The increased energy, however, does not lead to organized plans and thoughts. The individual may show poor judgment in spending money, may become hypersexual, or may make poor business commitments. Other hallmarks of mania are excessive, rapid, loud, and pressured speech. The manic person frequently skips from one topic of conversation to another and is easily distracted both when speaking and when performing tasks. Approximately 50% of manic individuals develop psychotic symptoms, such as delusions or hallucinations, which require hospitalization. The onset and termination of manic symptoms (see Box 19-3) are usually abrupt and may last for a few days or months followed by depression. The risk of recurrence of bipolar disorder is high, especially without immediate treatment.

Treatment

Depression

Approximately 80% of depressed persons will respond to antidepressant drugs such as MAOIs, TCAs, and SSRIs (Box 19-4); psychotherapy; or a combination of both treatment modalities. Although SSRIs have become the standard first-line treatment for major depression, initial selection of an antidepressant often includes an assessment of the person's symptoms and age as well as the side effects, safety, cost, and convenience of the prescribed medication. For example, medications that produce sedation may be helpful for the treatment of sleep disturbances. Approximately 50% of depressed individuals may not show a favorable response during initial treatment to an antidepressant drug, and 10% to 20% may continue to exhibit symptoms after 2 years. Individuals who are nonresponsive to a specific antidepressant during a 2-month period may be given another antidepressant medication. Atypical antidepressants, such as nefazodone, trazodone, and mirtazapine, presumably produce their clinical effects by blocking specific receptors (e.g., 5-HT_{2A}). A new generation of antidepressants that selectively block serotonin and norepinephrine reuptake is available in the United States (e.g., venlafaxine) and Europe (i.e., milnacipran, reboxetine). At present, there are no criteria to determine whether selection of the next antidepressant will be efficacious. Among children and adolescents, only fluoxetine is currently approved for use in children by the U.S. Food and Drug Administration (FDA)[26] (see What's New? Comprehensive Treatment of Risk Factors May Promote Resilience and Rapid Recovery from Depression).

In bipolar depression, antidepressant medications may lead to cycle acceleration or induction of mania. However, SSRIs and bupropion may be less likely to induce these effects than MAOIs or TCAs.

A number of side effects are reported with MAOIs, TCAs, and SSRIs. Commonly reported side effects of MAOIs include sedation or agitation, insomnia, dry mouth, impotence, and weight gain. MAOIs also may induce acute and heightened elevations in blood pressure (e.g., hypertensive crisis) after intake of tyramine-rich foods, such as aged cheeses, sour cream, pods of broad beans, pickled herring, liver, canned figs, raisins, and avocados. In addition, MAOI interactions with TCAs, SSRIs, stimulants, and over-the-counter flu medications are dangerous and should be avoided. Because of these adverse side effect issues, MAOIs are used less often than other antidepressants.

BOX 19-4 FDA-APPROVED MEDICATIONS USED IN THE TREATMENT OF DEPRESSION AND ANXIETY DISORDERS

GENERIC NAME	BRAND NAME
Monoamine Oxidase Inhibitors	
Isocarboxazid	Marplan
Phenelzine	Nardil
Tranylcypromine	Parnate
Selegiline	Emsam
Tricyclics	
Amitriptyline	Elavil
Amoxapine	Asendin
Clomipramine	Anafranil
Desipramine	Norpramin, Pertofrane
Doxepin	Adapin, Sinequan
Imipramine	Tofranil
Maprotiline	Ludiomil
Nortriptyline	Aventyl, Pamelor
Protriptyline	Vivactil
Trimipramine	Surmontil
Selective Serotonin Reuptake Inhibitors	
Citalopram	Celexa
Escitalopram	Lexapro
Fluoxetine	Prozac
Fluvoxamine	Luvox
Paroxetine	Paxil
Sertraline	Zoloft
Serotonin and Norepinephrine Reuptake Inhibitors	
Desvenlafaxine	Pristiq
Duloxetine	Cymbalta
Venlafaxine	Effexor
Serotonin Reuptake Inhibitor and 5-HT$_{1A}$ Receptor Partial Agonist	
Vilazodone	Viibryd
Norepinephrine and Specific Serotonergic Modulator	
Mirtazapine	Remeron
Norepinephrine–Dopamine Reuptake Inhibitor	
Bupropion	Wellbutrin
Serotonin Modulator	
Nefazodone	Serzone
Trazodone	Desyrel

TCAs may produce sedation, insomnia, orthostatic hypotension, seizures, and weight gain. Some TCAs have moderate anticholinergic side effects, including constipation, urinary hesitancy or retention, dry mouth, blurred vision, and memory impairment. These side effects may be an issue when considering TCA treatment of older adults, in which case the TCAs desipramine and nortriptyline may be preferred because of their reduced anticholinergic, cardiovascular, and sedating effects.

Common side effects of SSRIs include sleep disturbances (e.g., insomnia) and nausea. However, agitation, allergic skin reactions, dry mouth, anxiety, altered appetite, and sexual dysfunction have been reported. Unlike MAOIs and TCAs, SSRIs do not have pronounced effects on the cardiovascular or cholinergic systems. SSRIs are potent inhibitors of cytochrome P-450 isoenzymes, which are involved in drug metabolism. Therefore, SSRIs may lead to dangerous elevations in blood concentrations of other psychiatric medications when taken together. SSRIs should not be taken with MAOIs or immediately after discontinuing MAOI treatment. A serotonin syndrome characterized by excitement or autonomic hyperactivity, abdominal pain, rigidity, and hyperthermia may develop, leading to coma or death.

Side effects of atypical antidepressants may include sedation, dry mouth, weight gain, and constipation. Nefazodone and trazodone have been associated with hepatic toxicity. Venlafaxine and reboxetine lack many of the serious side effects associated with TCAs; however, sweating, dry mouth, and some sedation may occur.

Electroconvulsive therapy (ECT) is used when individuals fail to respond to antidepressants or when they are severely depressed, pregnant, suicidal, or psychotic. ECT effectively alleviates depressive symptoms in about 50% to 80% of people, who may then begin to respond to antidepressant medications. Although the mechanism of action of ECT is not clear, the procedure is known to produce alterations in monoamine systems. Deep brain stimulation (DBS) is another treatment showing promise to alleviate major depression in people resistant to current antidepressant medications, ECT, and psychotherapy.[27,28] The treatment involves implanting electrodes during neurosurgery into the subcallosal cingulate gyrus (SCG [Brodmann area 25 and parts of 24 and 32]) and attaching them to an implanted pulse generator through subcutaneous extension wires. This SCG region is targeted because abnormal SCG brain activity, a suggested pathophysiologic cause of major depression, is reversed by effective antidepressant treatment. A 3- to 6-year follow-up study of 20 treatment-resistant depressed individuals who received DBS in the SCG found that more than half eventually returned to work and improved their quality of life.[29]

Bipolar Disorder

FDA-approved treatments are available for bipolar disorders.[30] Individuals with bipolar I disorder are usually treated with lithium, the first choice of treatment to control mania and rapid cycling and to reduce the risk of suicide. In some cases, lithium in combination with SSRIs is used to treat bipolar disorder. In addition to lithium, several medications are used including anticonvulsants (e.g., carbamazepine, valproate, gabapentin, lamotrigine, topiramate) or atypical antipsychotics (e.g., clozapine, risperidone, ziprasidone, quetiapine, and a combination of olanzapine with the SSRI fluoxetine). Some bipolar individuals benefit from thyroid augmentation (levothyroxine). As in depression, ECT is administered when manic individuals fail to respond to medication, are pregnant, or have cardiovascular disease.

Frequently reported side effects of lithium treatment include increased thirst, tremors, diarrhea, and weight gain, which diminish over time. A potentially serious side effect is lithium

WHAT'S NEW?

Comprehensive Treatment of Risk Factors May Promote Resilience and Rapid Recovery from Depression

Environmental stressors and genetic predisposition

	Depression risk factors	Therapeutic intervention	Resilience protective factors
Cognitive/behavioral	Weak executive function: weak coping self-efficiency; negative attention bias; cognitive inflexibility	Cognitive behavioral therapy with cognitive reappraisal; positive emotion exercises, coping skill development, and training; well-being therapy	Strong executive function; high coping self-efficacy; positive emotions; realistic optimism; cognitive flexibility
Emotion regulation	Weak regulation (e.g., anhedonia; slow stress recovery)	Mindfulness; training; antidepressant medications	Strong regulation (e.g., delay gratification; rapid stress recovery)
Social	Weak social skills; minimal social network; no resilient role models	Social emotional training; network support treatment	Strong social skills; diverse social network; resilient role models
Physical health	Sleep deprivation; poor cardiovascular fitness; poor nutrition; obesity	Teach sleep hygiene; exercise regimen; improve diet	Strong sleep habits; physically fit; good nutrition
Neurobiology	Dysregulated HPA axis and SNS in response to stress; attenuated prefontal cortical executive function and stress-induced limbic system hyperactivity	Neural circuit training; novel medications (corticotropin-releasing factor, NPY, GABA, glutamate)	Effective regulation of HPA axis and SNS in response to stress; robust prefrontal cortical executive function and capacity to regulate limbic reactivity to stress

Genetic and environmental factors, such as uncontrollable stress, interact to increase the risk of developing major depression. These factors interact in complex ways that are not fully understood to dysregulate neurobiologic systems that compromise adaptive cognitive, emotional, social, and physiologic/health functions. For example, exaggerated stress-induced arousal of sympathetic and neuroendocrine systems may be due, in part, to genetic polymorphisms in serotonin, endocrine, and neuropeptide systems. However, the extent to which a genetic predisposition contributes to severe depression also may arise from the individual's inability to cope with stressors, inexperience in exhibiting flexible psychosocial and emotional skills, and lack of physical health, among others. Identifying and addressing these varied genetic and cognitive/behavioral/socioemotional/health risk factors of depression may open new doors to effective treatment. In particular, combined treatments or behavioral programs that promote resilience, the ability to recover from adversity—such as cognitive-behavioral therapy; social support; and improved diet, sleep, and exercise used in conjunction with current or novel drug medications that lessen or reverse the neuropathophysiology associated with heightened activation of stress systems—may quickly lead to remission. Although, at its early stages, the development of comprehensive resilience programs holds promise not only for treating depressed individuals but also for proactively serving to diminish or prevent the risk of acquiring stress-related disorders.

Data from Karatsoreos IN, McEwen BS: *Trends Cogn Neurosci* 15(12):576–584, 2011; Southwick SM, Charney DS: *Science* 338(6103):79–82, 2012. Figure from Southwick SM, Charney DS: *Science* 338(6103):79–82, 2012.

toxicity. Lithium is normally removed from the kidneys; however, when the body is sodium depleted, the kidneys will reabsorb sodium along with lithium. Individuals receiving lithium treatment are advised to avoid physically demanding activities that may dehydrate the body and to seek medical attention during fever or other conditions that may increase sweating. Anticonvulsant treatment may produce unsteadiness, dizziness, tremors, nausea, and blurry vision.

In addition to pharmacotherapy, psychotherapy can be beneficial for those who have difficulty with psychosocial stressors, such as low self-esteem, legal problems, fear of recurrence, and interpersonal conflicts. Treatment is effective when the individual becomes aware of the bipolar disorder, copes with psychosocial stressors, engages in drug compliance, and monitors symptom recurrences.

Unlike treatment of mania in bipolar I disorder, a major focus in the treatment of bipolar II disorder, the less severe form of mania, is on the recurrent depressive symptoms. Here, antidepressants alone (e.g., escitalopram, fluoxetine, venlafaxine) are reported to be effective in treating bipolar II disorder.

The treatment of bipolar II in children has raised concerns because of complications with its diagnosis. For example, bipolar II and attention-deficit/hyperactivity disorder (ADHD) share the common features of elevated behavioral activity levels, excessive talking, restlessness, and distractibility. Misdiagnosing bipolar II for ADHD has negative consequences for treatment because the stimulant drugs Ritalin and Adderall, which are frequently used to treat ADHD, will potentially exacerbate the symptoms of a child with bipolar II disorder. On the other hand, when ADHD is misdiagnosed with bipolar disorder, the child may begin an ineffective treatment regimen. To reduce misdiagnosis of children with bipolar and other similar symptomatic characteristics, such as ADHD as well as conduct disorder and oppositional defiant disorder, the upcoming *DSM-5*[31]

includes a new category called *disruptive mood dysregulation disorder*. This new disorder diagnosis will be used to describe a young child (6 to 10 years of age) who exhibits only some of the symptoms of bipolar II, such as frequent temper outbursts, irritability, and bad moods. This category is hoped to exclude children from being diagnosed with bipolar disorder and reduce possible unwarranted treatment with strong medications.[32]

ANXIETY DISORDERS

Fear and anxiety are normal feelings expressed in threatening or harmful situations. The symptoms may include arousal, tenseness, and increased autonomic activity such as heart rate, blood pressure, and respiration. In addition, individuals often engage in protective behavioral responses such as flight or avoidance. These physiologic and behavioral responses allowed humans to adapt and cope under a variety of situational challenges. However, when fear and anxiety become too intense and undermine the ability to function on a daily basis, the individual may develop an anxiety disorder. **Anxiety disorders** are the most prevalent psychiatric illness, occurring in approximately 10% to 30% of the general population. Notably, many individuals with anxiety disorders develop major depression, and the high comorbidity of anxiety disorders and depression suggests a common neural pathophysiologic basis linking these two mental illnesses.

The *DMS-IV-TR* lists eight recognized anxiety disorders: panic disorder, agoraphobia, generalized anxiety disorder, social phobia, specific phobia, obsessive-compulsive disorder, posttraumatic stress disorder, and acute stress disorder. This section presents an overview of panic disorder, generalized anxiety disorder, posttraumatic stress disorder, and obsessive-compulsive disorder.

Panic Disorder

Panic disorder consists of multiple disabling panic attacks and is characterized by intense autonomic arousal involving a wide variety of symptoms, including lightheadedness, a rapid heart rate (tachycardia), difficulty breathing, chest discomfort, generalized sweating, general weakness, trembling, abdominal distress, and chills or hot flashes. Between panic attacks the individual often worries about future panic attacks and fear of losing control and dying. Symptoms originally occur spontaneously and vary in length from several minutes to an hour.

A notable complication of panic disorder is the development of **agoraphobia** or phobic avoidance of places or situations where escape or help is not readily available. The agoraphobic individual will avoid being away from home, standing in line or in a crowd, or traveling in a train, plane, or automobile. Severe agoraphobic individuals become housebound.

ETIOLOGY AND PATHOPHYSIOLOGY. Genetic factors play a major role in panic disorder. The risk is nearly 20% among first-degree relatives and the prevalence of panic disorder is about 1.5% in men and up to 3.0% in women with no family history of the illness. Some studies suggest that the cholecystokinin (CCK) receptor gene on chromosome 11p may be linked to panic disorder.[33]

The etiology of panic disorder is not known but the ability to elicit physical symptoms of panic attacks by chemicals, called panicogens, provides insight into its pathophysiology. Panic-prone individuals respond to panicogens that include carbon dioxide, caffeine, cholecystokinin, sodium lactate, and adrenergic receptor agonists, such as yohimbine. Carbon dioxide and sodium lactate, two well-studied panicogens, alter brain pH balance that panic-prone people are sensitive in detecting. Brain pH chemosensors are located in the brainstem medulla and pons, the midbrain serotonergic raphe neurons, the hypothalamus, and the amygdala. Heightened pH sensitivity in the amygdala may play a key role in generating fearful perceptions and activating the cerebral cortex and neural circuits in the temporal lobe and brainstem, which further facilitate the production of panic symptoms (see Figures 19-7 and 19-9).[34] Exaggerated activation of physiologic and behavioral arousal stemming from the noradrenergic locus ceruleus neurons also may enhance the symptoms of panic. Thus, panic-prone people appear especially sensitive in detecting pH alterations in brain sites that modulate fear and arousal.

Panic disorder also may involve the GABA-benzodiazepine (BZ) receptor system. BZ increases the $GABA_A$ ion channel response to GABA, thereby elevating chloride ion influx and producing a neuronal inhibitory effect. Brain imaging work reveals a reduction in BZ receptor binding in brain regions including the hippocampus, insular, and prefrontal cortex.[35] Drugs that block the benzodiazepine receptor are reported to increase panic attacks and feelings of anxiety, suggesting an alteration in inhibitory neuromodulation contributes to panic disorder.

TREATMENT. Up to 80% of individuals affected by panic disorder respond to CBT and antidepressant drugs, either separately or in combination. In CBT, the individual learns that the physical symptoms are not fatal and attempts to exert control over the anxiety and panic. For example, breathing exercises to

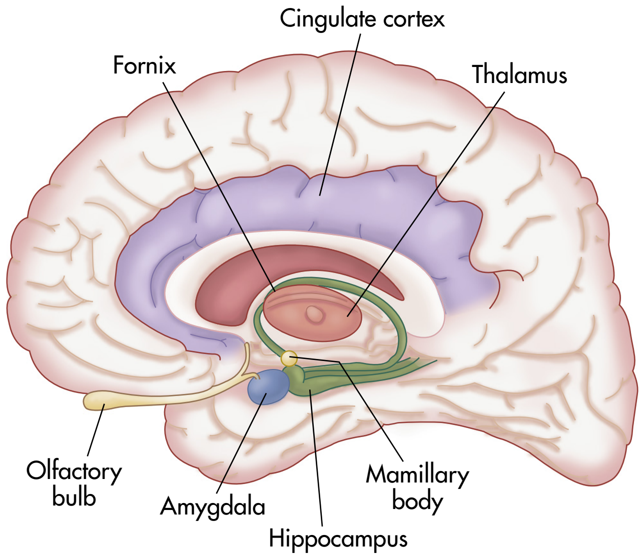

FIGURE 19-9 The Limbic System. Structures of the limbic system play important roles in emotion, learning, and memory. Pathophysiology in limbic structures is frequently found in mental disorders.

control hyperventilation serve to lessen the intense physiologic symptoms of panic, such as elevated heart and respiration rates. Another benefit of CBT is awareness of compliance with drug medications. However, for individuals with mild agoraphobia, CBT alone may be effective.

Antidepressants such as SSRIs are considered first-line medications for panic disorder. Among the SSRIs, paroxetine and sertraline have received FDA approval specifically for panic disorder. Venlafaxine, a serotonin-norepinephrine reuptake blocker, also is effective.

BZs, such as alprazolam and clonazepam, are other medications for treating panic disorder. These drugs also serve as an adjunct or augmentation therapy for individuals who do not fully respond to SSRIs. Short-term effects of BZs include sedation, ataxia, and cognitive impairments. Long-term BZ treatment may lead to physiologic and psychologic dependence. Abrupt BZ withdrawal induces a withdrawal syndrome of heightened reemergence of anxiety, insomnia, photophobia, and diarrhea. A gradual reduction in BZ medication or adjunct CBT may reduce the reliance and withdrawal symptoms of BZs.

Generalized Anxiety Disorder

Excessive and persistent worries are the hallmarks of **generalized anxiety disorder (GAD).** The individual worries about life events such as marital relationships, job performance, health, money, or social status. The lifetime prevalence rates of GAD range from 4.1% to 6.6%, with somewhat higher rates in women than in men. GAD usually emerges in the early twenties, but can occur in childhood. Six major symptoms of GAD have been identified and include restlessness, muscle tension, irritability, being easily fatigued, difficulty concentrating, and difficulty sleeping. The individual startles easily and frequently suffers from depression and panic attacks. The severity of symptoms fluctuates over time and may be linked to the changing nature of stress. Although GAD tends to be chronic, the symptoms may lessen with age. A frequent complication of GAD is substance abuse, which may result from self-medication with alcohol or drugs to relieve anxiety symptoms.

ETIOLOGY AND PATHOPHYSIOLOGY. Female twin studies suggest a concordance rate of 30%, but disease genes linked to specific chromosomes have yet to be identified. Abnormalities in the norepinephrine and serotonin systems were reported in GAD.[36] For example, there is a reduction in α_2-adrenergic receptor binding, a decrease in serotonin levels in CSF, and reduced platelet binding of paroxetine, an SSRI. Another reported alteration in GAD is a reduction of BZ binding in the left temporal hemisphere.[37]

Two functional magnetic resonance imaging (fMRI) studies have revealed alterations in specific brain regions in adults and adolescents with GAD. One study in GAD adults showed increased anticipatory anxiety was associated with elevated cingulate cortex activity and both the heightened anxiety and cingulate cortex activation were reduced after 8 weeks of treatment with venlafaxine, a serotonin and norepinephrine reuptake inhibitor.[38] This study suggests that a decrease in pathophysiologic cingulate cortex activity is a predictor of GAD treatment efficacy. In children and adolescents with GAD, brief exposure to masked angry faces induced heightened right amygdala activation, which correlated positively with severity of anxiety.[39] This study underscores the role of abnormal amygdala activity in attentional bias or vigilance to threats in GAD.

TREATMENT. GAD is diagnosed when a person spends at least 6 months worrying excessively and engages in at least three of the six major symptoms.[12] 5-HT/norepinephrine (NE) reuptake inhibitors, such as venlafaxine or the SSRIs paroxetine and escitalopram, have become first-line therapeutics for managing GAD. These medications may produce relief of GAD symptoms within 1 week and are effective in treating comorbid symptoms of depression. Buspirone, which has an affinity for serotonin receptors (5-HT_{1A}), is another treatment option, although the onset of clinical efficacy may take 2 weeks. The primary side effects of buspirone, which lessen over time, include dizziness, headaches, nausea, and mild nervousness. GAD nonresponders to 5-HT/NE reuptake inhibitors or buspirone may be treated with BZs. However, because GAD tends to be chronic, and comorbid with depression or other anxiety disorders,[40] BZs are usually limited to uncomplicated cases of GAD. In addition to drug therapy, behavioral therapy is used to acquire relaxation techniques that control anxiety.

Posttraumatic Stress Disorder

Exposure to a terrifying or life-threatening event may produce **posttraumatic stress disorder (PTSD).**[41, 42] Although the disorder was initially described in combat situations and called “shell shock,” “war neurosis,” or “traumatic neurosis,” PTSD does not develop only from exposure to traumatic experiences in the battlefield. Any horrific experience involving intense fear, threat of death, or helplessness, including serious accidents, natural disasters (such as earthquakes), child abuse, kidnapping, and violent attacks (such as rape or assault), may induce PTSD. The disorder may develop within hours of the traumatic experience or after several months or years. In PTSD, the individual reexperiences the traumatic event with intrusive flashbacks and persistent nightmares. During a flashback, images, odors, sounds, and negative emotions are recalled and lead to marked distress. The duration of the flashback varies from seconds to hours or, in rare cases, several days. Nightmares of the traumatic experiences often prevent further sleep. Exposure to cues associated with the life-threatening event triggers psychologic distress, intense autonomic arousal, and avoidance behavior. The individual shows emotional numbing or detachment from others and often avoids activities that may lead to a recollection of thoughts, feelings, or contact to places or people involved in the trauma. Additional characteristics of PTSD include irritability, lack of concentration, hypervigilance, and exaggerated startle response.

The lifetime prevalence rate of PTSD is 7% to 8%. In men, PTSD is usually found among combat veterans, whereas PTSD in women is often related to rape or assault. Abused children also may develop PTSD. Individuals with a history of psychiatric illness (major depression, panic disorder) or those lacking strong social support appear more sensitive to the effects of traumatic stress.

ETIOLOGY AND PATHOPHYSIOLOGY. The primary etiology of PTSD is exposure to a terrifying life-threatening event and likely

involves stress-induced alterations in several neural structures and neurotransmitter systems. The amygdala and prefrontal cortex are highly involved in the pathophysiology of PTSD because these brain structures normally play important roles in how fearful memories are stored, retrieved, and extinguished. Individuals with PTSD who are exposed to trauma-related stimuli generally exhibit increased activity in the amygdala and diminished activity in prefrontal cortical areas. Persistent dysregulation of this fear-based memory system may underlie chronic PTSD—that is, the failure of prefrontal cortical inhibition to control amygdala-induced activation of fear compromises the extinction of fear memory.[43] Structural brain imaging studies show that combat-exposed PTSD victims also have a smaller hippocampus, a brain structure involved in endocrine functions and memory formation. Pediatric PTSD studies reveal a more generalized effect of trauma on reducing total brain volume. Other brain sites exhibiting increased activity in PTSD are the dorsal anterior cingulate cortex and insula, albeit similar findings were reported in other anxiety disorders (e.g., GAD, obsessive-compulsive disorder [OCD]).[44]

As in panic disorder, BZ binding is altered in PTSD as indicated by a reduced distribution of BZ receptor binding in the prefrontal cortex compared with healthy controls.[45] This reduction in prefrontal BZ receptor distribution was not found in other brain regions.

TREATMENT. PTSD is diagnosed according to the duration and timing of symptoms *(DSM-IV-TR)*. When the duration of symptoms is less than 3 months, PTSD is diagnosed as acute whereas a chronic diagnosis is made when symptoms persist for 3 months or longer or when the delay of onset is longer than 6 months after the trauma. As in GAD, the severity of symptoms fluctuates over time. Among war veterans, financial coverage for group or family therapy is supported by the Veterans Administration. CBT is another therapy used for the individual to learn to control their anxiety symptoms and the emotionally distressing memories of the traumatic event.

Chronic PTSD lasting for years may occur in 30% of diagnosed individuals. Paroxetine and sertraline are considered first-line SSRI medications for chronic PTSD because of their tendency to lessen the recurrent nightmares and flashbacks and to treat the high accompanied prevalence of depression and substance abuse. Other antidepressants, such as the TCAs (amitriptyline and imipramine), have moderate effects and are second-line drugs; drugs such as nefazodone and bupropion may provide benefits. BZs may be used in the aftermath of a traumatic event to control hyperarousal symptoms such as irritability, insomnia, and muscle tension. However, there is no clear evidence that BZs have clinical efficacy or provide prophylaxis against the development of chronic PTSD, and BZs should be carefully monitored among individuals with a history of drug abuse.

Obsessive-Compulsive Disorder

Repetitive, intrusive thoughts and/or compulsions are the hallmarks of **obsessive-compulsive disorder (OCD)**. These thoughts and acts impair normal functioning and cause marked distress. Obsessions may involve a preoccupation with contamination, doubting, religious or sexual themes, or the belief that a negative outcome will occur if a specific act is not performed. Compulsions are physical and mental ritualized acts such as washing, cleaning, checking, counting, organizing, hoarding, and repeating specific thoughts or prayers. The lifetime prevalence rates of OCD range from 1.2% to 3.3% with an age of onset between 20 and 25 years. OCD occurs equally in adult men and women; however, many begin to experience symptoms during childhood or adolescence.

OCD is diagnosed when obsessions or compulsions cause severe distress, consume time, or interfere with normal daily activities.[13] In many cases the OCD individual also is diagnosed with major depression, panic disorder, or GAD.[46] Among children, tic disorders, attention-deficit/hyperactivity disorder, and depression coexist with OCD.

ETIOLOGY AND PATHOPHYSIOLOGY. The risk of developing OCD is about 10% to 12% among first-degree relatives. These first-degree relatives are also at increased risk (4.6%) of Tourette syndrome and tics in comparison with control relatives (1%). Thus OCD and Tourette syndrome may share common genes and pathophysiology.

Abnormalities of the basal ganglia–frontocortical circuitry are found in OCD.[47] Some studies have shown increased orbitofrontal and thalamic volumes in OCD but not in the caudate nucleus of the basal ganglia (Figure 19-10). More consistent data report an increase in orbitofrontal and anterior cingulate cortical activity, which may be responsible for intrusive thoughts, obsessions, and anxiety, which drive the basal ganglia to engage in compulsive ritualized acts as a means to alleviate the anxious obsessions. Furthermore, when provoked, OCD individuals consistently show increased activity in the orbitofrontal, anterior cingulate, and caudate nucleus areas of the brain. Of relevance to prognosis, OCD individuals with very high frontocortical activity are likely to respond poorly to treatment.

Abnormalities in serotonin and dopamine functions may further contribute to the pathophysiology of OCD. Serotonin

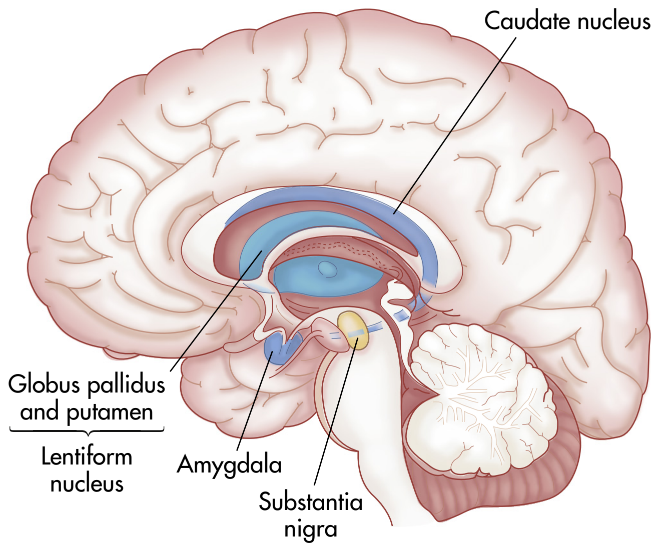

FIGURE 19-10 Basal Ganglion. Structures of the basal ganglion, which include the caudate nucleus, putamen, globus pallidus, and substantia nigra, are important in movement.

agonists exacerbate the symptoms of OCD, and serotonin synthesis is decreased in the prefrontal cortex and caudate nucleus. Stimulation of the dopamine system also increases repetitive acts, which may be blocked by dopamine antagonists. However, the dopamine stimulant–induced compulsions are not accompanied by anxiety and, therefore, suggest that lack of serotonin control over the dopamine system may be a primary defect in OCD.

TREATMENT. Because of the chronic nature of OCD, long-term treatment often involves a combination of pharmacotherapy and CBT. SSRIs, including citalopram, fluvoxamine, paroxetine, and sertraline, are the first drugs of choice for OCD.[48] Approximately 70% to 80% of OCD individuals show a partial positive response that may be further improved by other medications. For example, clonazepam, a BZ, is found to improve the effects of fluoxetine and clomipramine therapy. Antipsychotic drugs (e.g., haloperidol and risperidone) in combination with SSRIs are also effective especially in comorbid OCD and tic disorders. Normalization of dysfunctional serotonin and dopamine systems in OCD may be the basis for the therapeutic effects of SSRIs and dopamine receptor–related drugs.

CBT and response prevention therapy involve exposure to cues that elicit distress followed by preventing the individual from engaging in compulsive rituals for at least an hour or until the anxiety subsides. Both therapies can produce long-term symptom remission in adults and children who are able to tolerate the exposure-induced anxiety component.

For individuals with severe treatment-resistant OCD, neurosurgery is used to disconnect the basal ganglia from the frontal cortex.[49] This lesioning procedure results in significant relief of obsessions and compulsions in nearly 50% of individuals and provides further evidence of pathophysiology in the basal ganglia–frontocortical circuitry in OCD. An alternative treatment to ablative neurosurgery is deep brain stimulation, which also is used for intractable depression.[27] Deep brain stimulation in the anterior limb of internal capsule, striatum/ventral capsule, nucleus accumbens, subthalamic nucleus, and inferior thalamic peduncle is effective in alleviating some OCD symptoms.[50,51] Stimulating these brain regions may be reducing abnormal neuronal firing in the neuroanatomic circuitry linked to OCD.

SUMMARY REVIEW

Schizophrenia

1. Schizophrenia is characterized by thought disorders that reflect a break between the cognitive and the emotional sides of one's personality.
2. Schizophrenic symptoms are classified into positive, negative, and cognitive categories. Positive symptoms include hallucinations, delusions, formal thought disorder, and bizarre behavior. Negative symptoms include flattened affect, alogia, anhedonia, attention deficits, and apathy. Cognitive symptoms are the inability to perform daily tasks requiring attention and planning.
3. Schizophrenia has a strong genetic predisposition and environmental factors (e.g., viral infection, nutritional deficiencies, prenatal birth complications, urban upbringing) may interfere with genetically programmed neural development to alter brain structure and function.
4. Brain imaging studies reveal structural brain abnormalities including an enlargement of the cerebroventricles and widening of the fissures and sulci in the frontal cortex. In addition, there is a reduction in the volumes of both the thalamus, which may disrupt communication among cortical brain regions, and the temporal lobe, which may be responsible for the manifestations of positive symptoms.
5. In schizophrenia the frontal lobe shows a progressive loss in volume and a worsening of negative symptoms despite the use of antipsychotic medications. Blood flow and metabolism are reduced in the dorsolateral prefrontal cortex, which compromise the ability to engage in goal-directed and cognitive problem-solving behavior.
6. Neurochemical abnormalities in dopamine and glutamate systems are found in schizophrenia.
7. The first generation of antipsychotic drugs block the dopamine D_2 receptor. The second generation, called atypical antipsychotics, block not only D_2 receptors but also dopamine, serotonin, and other neurotransmitter receptors. Antipsychotic medications, however, are not always effective in treating schizophrenic individuals with severe negative symptoms. Talk therapies are used to increase drug compliance and to encourage coping strategies.

Mood Disorders: Depression and Bipolar Disorder

1. Major depression and bipolar disorder are two common mood disorders. Major depression is characterized by an intense and sustained unpleasant state of sadness and hopelessness. In bipolar disorder, individuals show recurrent patterns of depression and mania, the latter characterized by extreme levels of energy and euphoria.
2. Environmental triggers such as psychosocial stress appear to facilitate the onset of depression in individuals with a genetic vulnerability.
3. A reduction in brain monoamine neurotransmission is linked to depression, whereas an elevated monoamine level is associated with mania.
4. Exposure to uncontrollable stress elevates secretion of the stress hormone cortisol, which increases both the secretion of proinflammatory cytokines and the risk of developing depression. Abnormalities involving thyroid hormones also are found in depression.
5. Stress-induced depression is accompanied by deficits in brain-derived neurotrophic factor (BDNF) and neurogenesis in the hippocampus. In animal models, stress-induced depression-like behavior and the accompanying deficits in hippocampal BDNF and neurogenesis are reversed by antidepressant treatment.
6. The frontal lobe and limbic system volumes are reduced in major depression and bipolar illness. In addition, blood flow is altered in prefrontal and limbic brain regions that include the amygdala, a structure implicated in emotional behavior.

SUMMARY REVIEW—cont'd

7. Pharmacotherapy involves the use of MAOIs, TCAs, SSRIs, and atypical antidepressants. Manic and bipolar individuals are treated with lithium or mood stabilizers. Severely depressed and manic people may be administered ECT. Deep brain stimulation is another promising treatment for intractable depression.

Anxiety Disorders

1. When normal fear and anxiety mental states persist and become uncontrollable, an individual may develop an anxiety disorder. PD, GAD, PTSD, and OCD are examples of uncontrollable fear and anxiety states that require medical attention.
2. Panic disorder consists of panic attacks characterized by intense autonomic arousal that occurs spontaneously and is accompanied by symptoms including lightheadedness, tachycardia, and difficulty breathing. In addition, the intense occurrence of autonomic responses is accompanied by heightened fear and anxiety that often continue between panic attacks.
3. Panic-prone people are sensitive in detecting pH alterations in the amygdala, a brain structure that modulates fear. An activated amygdala recruits the cerebral cortex and neural circuits in the temporal lobe and brainstem, which may further exacerbate symptoms of panic.
4. A reduction in BZ receptor binding in brain regions, including the hippocampus, insular, and prefrontal cortex, also may contribute to the pathophysiology of panic disorder.
5. Panic disorder is generally treatable with CBT and antidepressants such as TCAs and SSRIs. BZs are used as an adjunct or augmentation therapy for individuals who are nonresponsive to SSRIs or TCAs.
6. GAD is characterized by excessive and persistent worries about life events. Individuals exhibit varying levels of motor disturbances, irritability, and fatigue that may be linked to fluctuations in psychosocial stress. Many GAD individuals manifest symptoms of depression.
7. Pathophysiologic changes in the cingulate cortex and amygdala may have prominent roles in stimulating anticipatory anxiety and attentional bias to threats in people with GAD.
8. Treatment of GAD usually involves a combination of behavioral therapy and drug medications, especially serotonin/norepinephrine reuptake inhibitors.
9. PTSD develops after exposure to a life-threatening or traumatic experience. Individuals experience recurring thoughts and flashbacks and nightmares of the terrifying event.
10. In PTSD structural and/or functional alterations exist in the amygdala, prefrontal cortex, and hippocampus, which likely contribute to dysfunction in an emotional fear memory system.
11. Treatment of chronic PTSD is difficult and involves psychotherapy and SSRI pharmacotherapy.
12. OCD is a chronic illness characterized by irrational obsessions and ritualized acts that impair normal functioning and cause severe distress.
13. Pathophysiologic alterations in the basal ganglia–frontocortical circuitry and serotonin and dopamine functions are linked to OCD.
14. OCD requires long-term treatment consisting of CBT and drug medication, such as SSRIs and talk therapies. Severe OCD may require neurosurgery to disconnect the basal ganglia from the frontal cortex. Deep brain stimulation may be another option for uncontrollable OCD.

- Review Questions and Answers

CHAPTER OUTLINE

Neurologic disorders in children can occur before birth through adolescence and include congenital malformations, genetic defects in metabolism, brain injuries, infection, tumors, and other disorders that affect neurologic structure and function. The symptoms, diagnosis, and management of neurologic disorders in children are often different than those of adults. It is important to note that with better proactive care and advances in treatment, many of the children with these disorders will live into adulthood and physicians who care for adults will be seeing these disorders in adults in increasing numbers.

STRUCTURE AND FUNCTION OF THE NERVOUS SYSTEM IN CHILDREN

Embryology is a highly complex and often difficult science to understand fully. A basic knowledge of this science is essential because it is the process of embryonic development that explains many of the malformations that occur in children.

Both genetics and environment shape nervous system development. The proper proportions of essential nutrients are necessary for growth and proliferation of the nervous system tissue (see Nutrition & Disease: Iron and Cognitive Function). Maternal lifestyle, nutrition, exposure to potential toxins, and state of health also have a crucial effect on nervous system development at critical periods of fetal maturation.

The central nervous system (CNS) develops from a dorsal thickening of the ectoderm known as the **neural plate.** This plate appears around the middle of the third gestational week and unfolds to form a **neural groove** and **neural folds.** During the fourth gestational week the neural groove deepens, its folds develop laterally, and it closes dorsally to form the **neural tube,** epithelial tissue that ultimately becomes the CNS. The neural tube closes first in the cervical region and then "zippers" in two directions—cranially and caudally (Figure 20-1).

In the developmental process, some neuroectodermal cells separate from the neural tube but remain between the tube and the surface ectoderm, creating the **neural crest.** This cellular band develops into the cranial and spinal ganglia, more commonly referred to as the *peripheral nervous system.* Other structures associated with the nervous system arise from mesoderm (**somite**) and include blood vessels, microglial cells, dural and arachnoid layers of the meninges, the capsule of

NUTRITION & DISEASE

Iron and Cognitive Function

Iron deficiency (ID) is the single most significant nutrient deficiency, affecting 15% of the world population and causing anemia in 40% to 50% of children. Iron is essential for neurologic activity, including synthesis of dopamine, serotonin, and catecholamine and, possibly, formation of myelin. Children with ID have decreased attentiveness, short attention span, and perceptual restrictions. ID also may contribute to attention-deficit/hyperactivity disorder. In some studies, cognitive deficits in iron can be reversed with iron supplements. In one randomized study, supplementation with iron or zinc, or both, during infancy did not lead to long-term cognitive improvement in 9-year-old children. Research is in progress to determine the effects of acute vs. chronic ID and the relationships between severity of deficiency and cognitive functioning. Alterations in the hippocampus and the brain striatal dopaminergic-opiate system function have been found in ID.

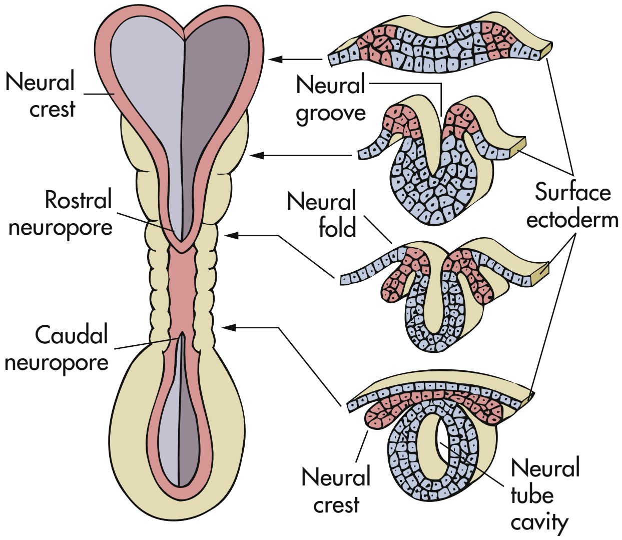

FIGURE 20-1 Neural Tube at 3 Weeks of Gestation. Neural folds have begun to fuse at the cervical level of the future spinal cord. *Right,* Cross sections of the neural tube at four different levels; at any given level the embryonic central nervous system (CNS) goes through a series of stages resembling these four cross sections. Total length of neural tube at this time is about 2.5 mm.

some peripheral sensory nerve endings, and peripheral nerve coverings.

The cranial end of the neural tube forms the brain, and the remainder develops into the spinal cord. The lumen of the neural tube becomes the ventricles of the brain and the central canal of the spinal cord (Figure 20-2). On either side of the neural tube's inner surface is a longitudinal groove (**sulcus limitans**). Anterior to this region (**basal plate**) the gray matter differentiates into the nuclei of the lower motor neurons. The region posterior to the sulcus (**alar plate**) differentiates into the sensory nuclei of the spinal cord.

Embryonic development of the nervous system occurs in six stages: (1) dorsal (posterior) induction, (2) ventral (anterior)

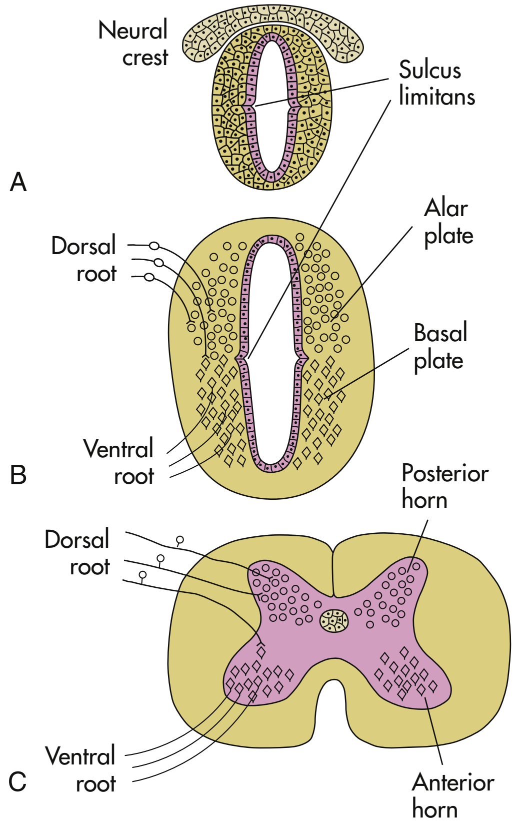

FIGURE 20-2 Sulcus Limitans and Alar and Basal Plates. **A,** Neural tube during the fourth week of gestation. **B,** Embryonic spinal cord during the sixth week of gestation; dorsal root ganglion cells, derived from the neural crest, send their central processes into the spinal cord to terminate mainly in alar plate cells; basal plate cells become motor neurons, whose axons exit in the ventral roots. **C,** Adult spinal cord.

induction, (3) proliferation, (4) migration, (5) organization, and (6) myelination. Figure 20-3 summarizes the embryonic development of the nervous system and identifies disorders associated with interference in any of these stages. Many different events happen simultaneously, and critical periods must pass uninterrupted if the vulnerable fetus is to develop normally.

Brain Development

When an infant is born, the bones of the skull are separated at the suture lines, thus forming two fontanels or "soft spots": one diamond-shaped anterior fontanel and one triangular-shaped posterior fontanel. The posterior fontanel may be open until 2 to 3 months of age; the anterior fontanel normally closes by 18 months (Figure 20-4). The fact that the sutures are not closed allows for increases in head circumference as part of normal growth for 5 to 8 years after birth; in fact, the head is the fastest growing body part during infancy. Although basically all of the neurons that an individual will ever have are present at birth, the development of skills, such as walking, talking, and thinking, depends on these cells making correct connections with other cells and on myelination of the axons making those connections. This leads to brain and then to skull growth. Increased intracranial pressure may result in an increased head circumference in excess of that expected with normal growth.

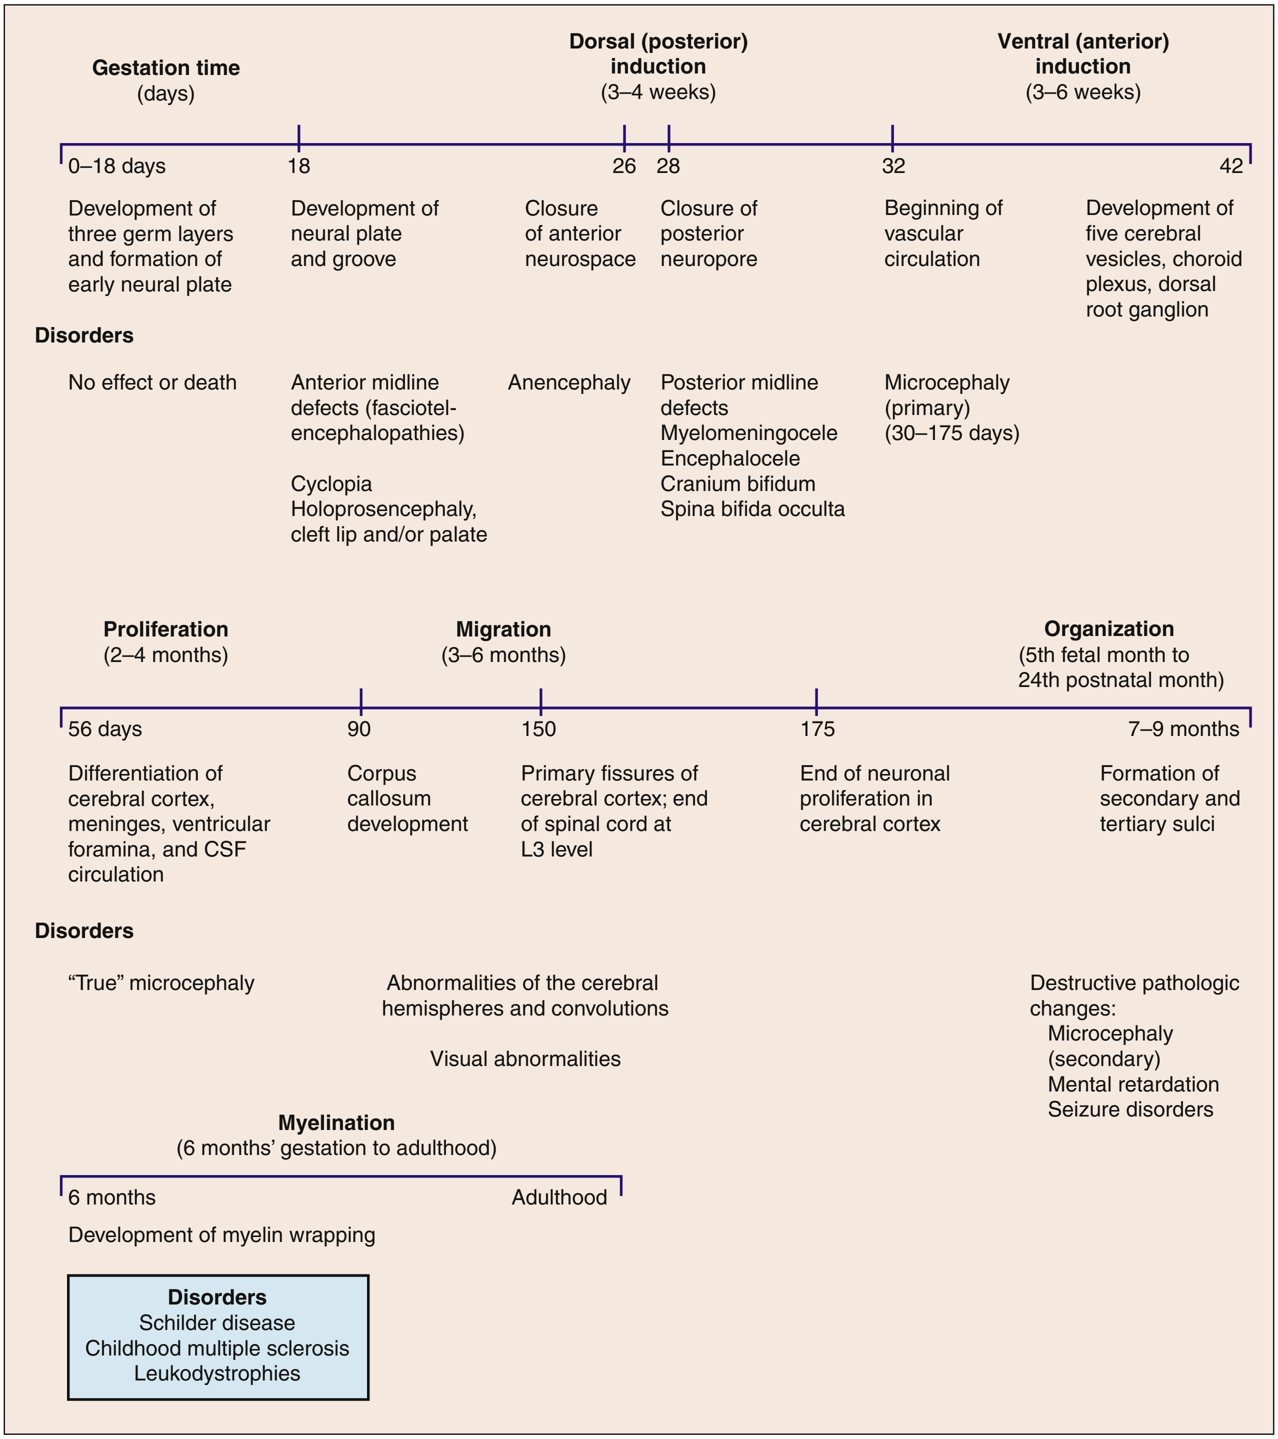

FIGURE 20-3 Disorders Associated with Specific Stages of Embryonic Development. *CSF,* Cerebrospinal fluid.

Healthcare providers carefully monitor head growth during the first 5 years of life by measuring head circumference and comparing the results with a standardized growth chart. In contrast, the adult cranium is a closed cavity with sutures firmly holding the cranial bones together. An adult’s head size will not expand regardless of intracranial events, e.g., tumor growth, bleeding, or increased production of cerebrospinal fluid (CSF).

Most neurons are formed during fetal life but the connections between brain circuits, myelination of those connections, and dendritic development are most significant after birth. Human neurologic functioning is primarily at a subcortical level at birth with many reflex patterns mediated by brainstem and spinal cord mechanisms that disappear at predictable times during infancy while brain axons are myelinated and connecting pathways develop. Myelination is a process by which lipid-protein material made by specialized connective tissue cells (Schwann cells in the peripheral nervous system and oligodendrocytes in the central nervous system) covers the axons of neurons, allowing electrical signals to travel more quickly (see Chapter 16). The development of myelin in the brain follows

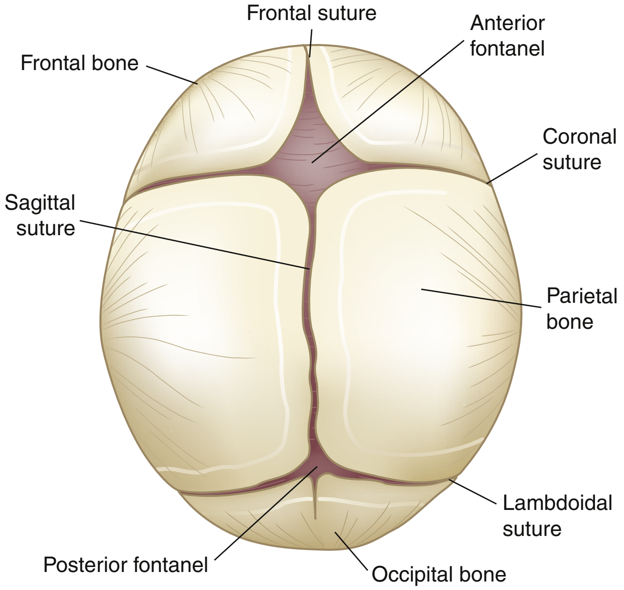

FIGURE 20-4 Cranial Sutures and Fontanels in Infancy. Fibrous union of suture lines and interlocking of serrated edges (occurs by 6 months; solid union requires approximately 12 years).

predictable patterns over time and is most extensive after birth and throughout childhood. The primitive reflex pathways require myelination and by 6 months of age they are integrated and inhibited for progression to voluntary movement. Table 20-1 summarizes the ages at which primitive reflexes appear and disappear. Testing for the presence or absence of these reflexes at various times enables the examiner to evaluate the function and development of the nervous system.

Absence of expected reflex responses at the appropriate age indicates general depression of central or peripheral motor function. Asymmetric responses may indicate lesions in the motor cortex on the opposite side or may occur with fractures of bones after traumatic delivery or postnatal injury. While the infant matures, the primitive reflexes disappear in a predictable order as voluntary motor functions supersede them. Abnormal persistence of these reflexes is seen in infants with developmental delays or with central nervous system lesions.

TABLE 20-1 REFLEXES OF INFANCY

REFLEX	AGE AT APPEARANCE OF REFLEX	AGE AT WHICH REFLEX SHOULD NO LONGER BE OBTAINABLE
Stepping	Birth	6 weeks
Moro	Birth	3 months
Sucking	Birth	4 months awake 7 months asleep
Rooting	Birth	4 months awake 7 months asleep
Palmar grasp	Birth	6 months
Plantar grasp	Birth	10 months
Tonic neck	2 months	5 months
Neck righting	4-6 months	24 months
Landau	3 months	24 months
Parachute reaction	9 months	Persists for life

WHAT'S NEW?

Reduction of Risks for Neural Tube Defects (NTDs)

Studies indicate that ingestion of multivitamins with folic acid before conception or early in pregnancy may offer protection against neural tube defects and reduction of stillbirths caused by NTDs. Folate is a coenzyme essential for DNA and RNA synthesis and cellular methylation. Recent repeated studies demonstrate a 60% to 86% reduction of risks for neural tube defects with periconceptional ingestion of vitamins containing the U.S. recommended daily allowance of 400 mcg of folic acid. There may also be an increased risk associated with maternal obesity.

Data from Branum AM, Bailey R, Singer BJ: *J Nutr* 143(4):486–492, 2013; Centers for Disease Control and Prevention: *MMWR Morb Mortal Wkly Rep* 53(36):847–850, 2004; Imdad A, Yakoob MY, Bhutta ZA: *BMC Public Health* 11(Suppl 3):S4, 2011; Mastroiacovo P, Leoncini E: *Biofactors* 37(4):272–279, 2011; Wolff T et al: *Ann Intern Med* 150(9): 632–639, 2009.

STRUCTURAL MALFORMATIONS

Defects of Neural Tube Closure

Neural tube defects (NTDs) are caused by an arrest of the normal development of the brain and spinal cord during the first month of embryonic development and occur in about 3000 pregnancies in the United States each year.[1] There is a strong association of fetal death with NTDs, reducing the actual prevalence of neural defects at birth. Maternal folate deficiency is associated with NTDs. The specific mechanism that relates to how folate supplements prevent these anomalies is unknown but genes involving folate metabolism and environmental factors are involved.[2] In 1996 the United States mandated folate fortification in many foods and since that time neural tube defects have decreased by 20% to 30%[3] (see What's New? Reduction of Risks for Neural Tube Defects [NTDs]).

Defects of neural tube closure are divided into two categories: posterior defects and anterior midline defects. Posterior defects are more common and will be discussed further below. These include anencephaly (*an,* "without"; *enkephalos,* "brain"), encephalocele, and a group of disorders collectively referred to as the *myelodysplasias* (*dys,* "bad"; *plassein,* "to form"). Although **myelodysplasia** is defined as a defect in formation of the spinal cord, the term is used to refer to anomalies of both the vertebral column and the spinal cord. Birth defects in which there is failure of closure of the vertebrae are known as spina bifida (split spine). Myelomeningocele is a form of spina bifida with incomplete development of the spine and protrusion of both the spinal cord and meninges through the skin. Meningocele is a form of spina bifida in which there is protrusion of the meninges but the spinal cord remains in the spinal canal. There is a broad spectrum of abnormalities within each of these categories depending on the location of the defect, the tissue involved, and other factors.

Anencephaly

Anencephaly is an anomaly in which the soft, bony component of the skull and much of the brain are missing. This is a

FIGURE 20-5 Meningoencephalocele of the Occipital Region. (From Gilbert-Barness: *Potter's pathology of the fetus, infant and child,* ed 2, Philadelphia, 2007, Mosby.)

relatively common disorder, with an incidence rate of approximately 1 per 4859 live births in the United States each year.[4] These infants are stillborn or die within a few days after birth. The pathologic mechanism is unknown. Diagnosis is often made prenatally using ultrasound or evaluating maternal serum alpha fetoprotein (AFP).[5]

Encephalocele

Encephalocele refers to a herniation or protrusion of various amounts of brain and meninges through a defect in the skull, resulting in a saclike structure. The incidence rate is approximately 1 in 10,000 live births in the United States each year.[6]

PATHOPHYSIOLOGY. Encephalocele occurs during the first weeks of pregnancy. When the defect contains only meninges, it is referred to as a **cranial meningocele.** Most encephaloceles, which contain neural tissue as well as meninges, occur in the occipital area, with the remainder found in the frontal, parietal, or nasopharyngeal regions.

CLINICAL MANIFESTATIONS. Encephalocele usually is seen at birth as a midline skull defect through which a large mass protrudes (Figure 20-5). If the defect is located in the nasopharynx, no external anomaly is visible, but the child may experience nasal airway obstruction. On examination with a nasal speculum, a smooth, round mass will be visible in the nasal passages. A frontal encephalocele may extend into the orbit of the eye and produce proptosis on the affected side.

EVALUATION AND TREATMENT. Diagnosis is based on clinical manifestations and examination of the meningeal sac. With cranial meningocele, surgical repair of the cranial defect affords a good prognosis for most affected infants whose intellectual and motor functioning is normal. An occipital encephalocele may be associated with other findings, such as blindness and cognitive impairment. The size, location, and involvement of the encephalocele help determine a child's development and intellectual outcome.

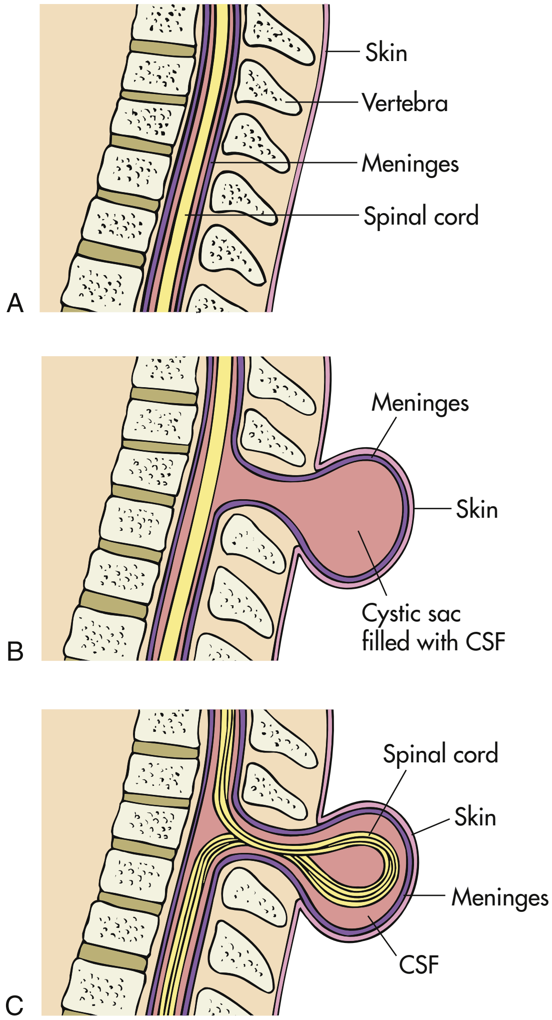

FIGURE 20-6 Comparison of Normal Spine and Spine with Meningocele and Myelomeningocele Neural Tube Defects. Diagram depicts section through normal spine **(A)**, spine with meningocele **(B)**, and spine with myelomeningocele **(C)**.

Meningocele and Myelomeningocele

Meningocele and myelomeningocele are different types of spina bifida that occur because of an incompletely formed or absent posterior vertebral arch in the spinal column, allowing protrusion of either a saclike cyst of meninges filled with spinal fluid (a meningocele) or a similar saclike cyst that also has neural tissue, spinal cord, or nerves in it, in which case it is a myelomeningocele. Both develop during the first 4 weeks of pregnancy when the neural tube fails to close completely (Figure 20-6). Meningoceles occur with equal frequency in the cervical, thoracic, and lumbar spine areas, whereas 80% of myelomeningoceles are located in the lumbar and lumbosacral regions, the last regions of the neural tube to close. Myelomeningocele is much more common than meningocele and has an incidence rate ranging from 0.5 to 1 per 1000 pregnancies in the United States.[7] It is thus is one of the most common developmental anomalies of the nervous system.

PATHOPHYSIOLOGY. Meningocele is a cystlike dilation of meninges protruding through a defect in the posterior arch of the vertebra. The dura mater may be missing and the arachnoid layer

of the meninges bulges beneath the skin. This defect does not involve the spinal cord. A **myelomeningocele** results in a cystic dilation of meninges and protuberance of various amounts of the spinal cord through the vertebral defect and is associated with more severe complications than those associated with a meningocele. Both defects occur during the first 4 weeks of the gestational period; at the end of this time the neural tube is normally closed anteriorly and posteriorly.

Because of changes in cerebrospinal fluid (CSF) flow, myelomeningoceles also are likely to be associated with a Chiari II malformation, which is a downward displacement of the cerebellum, brainstem, and fourth ventricle (Figure 20-7). The Chiari II malformation compresses and essentially stretches the posterior region of the cerebellum and brainstem downward through the foramen magnum. The brainstem houses cranial nerve nuclei and pressure on this region may result in altered function of these nerves or actual palsies. The Chiari II malformation is associated with hydrocephalus, an increase in intracranial pressure attributable to obstruction of the flow of CSF; syringomyelia, an abnormality causing cysts at multiple levels within the spinal cord; and cognitive and motor deficits.[8]

Other forms of Chiari malformation include type I, which is usually asymptomatic; type III, in which the brainstem or cerebellum extends into a high cervical myelomeningocele; and type IV, which is characterized by lack of cerebellar development.[9]

Seizures are present in about 30% of children with myelomeningocele,[10] and visual problems (perceptual and astigmatism) and intellectual deficits (ranging from learning problems to intellectual disability) also are common.[11]

CLINICAL MANIFESTATIONS. Myeloceles and myelomeningoceles are evident at birth as a pronounced skin defect on the infant's back (see Figure 20-6). The severity of the clinical presentation will depend on the amount of tissue involved (generally the more neural tissue that is included in the sac, the worse the clinical presentation; some children with meningocele will not have any functional problems) and the level of the defect (thoracic vs. sacral; a sacral defect will cause fewer problems than a defect higher in the neural axis). The bony prominences of the unfused neural arches can be palpated at the lateral border of the defect. The defect is usually covered by a transparent membrane that may have neural tissue attached to its inner surface. This membrane may be intact at birth or may leak CSF, thereby increasing the risks of infection and neuronal damage. Until the defect is closed surgically, CSF may accumulate and cause increased dilation and enlargement of the sac, which may further endanger the nervous system.

Motor and sensory functions below the level of the lesions are altered. Dysfunction may include degrees of weakness, paralysis, spasticity, and bowel and bladder dysfunction. These problems often worsen as the child grows. As the cord ascends within the vertebral canal, primary scar tissue can tether the cord. Several musculoskeletal deformities are related to myelomeningocele, including clubfoot, dislocation of hip or hips, and poor spinal alignment. Spinal deformities, such as scoliosis and kyphosis, are common.

Tethered cord syndrome may develop in children with myelomeningocele.[12] The cord becomes abnormally attached

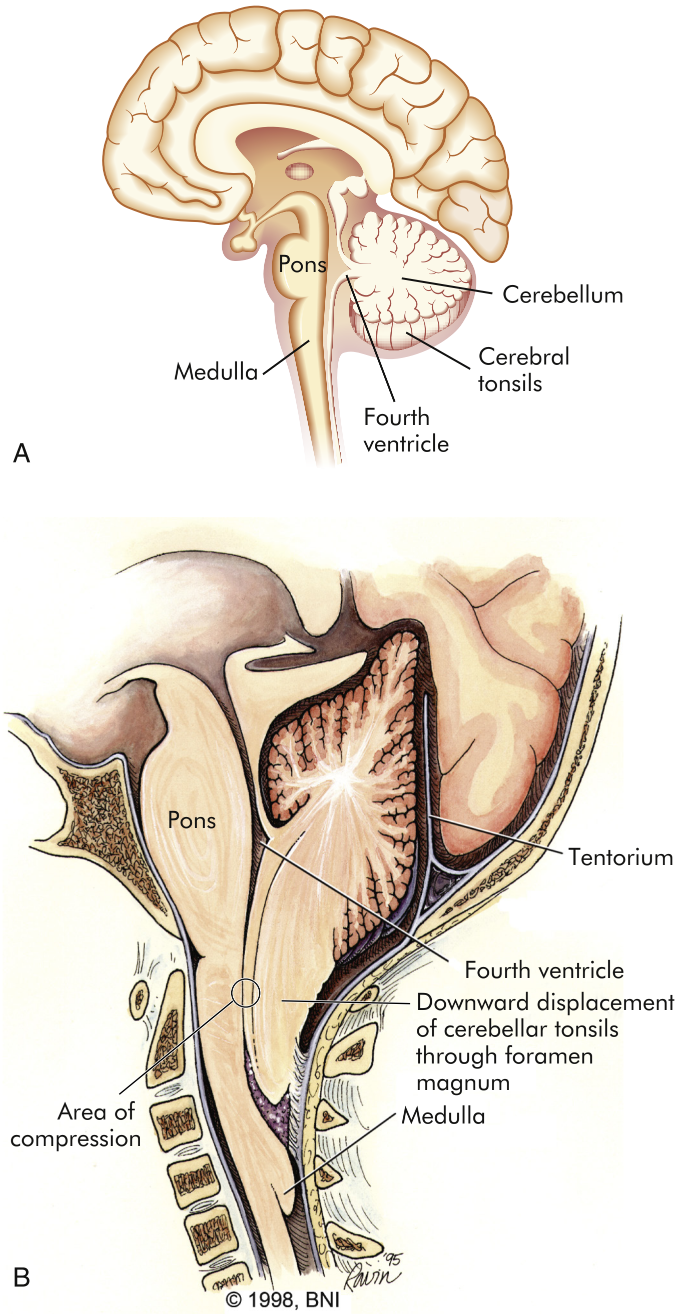

FIGURE 20-7 Normal Brain and Chiari Type II Malformation. **A,** Diagram of normal brain. **B,** Diagram of Chiari II malformation with downward displacement of cerebellar tonsils and medulla through foramen magnum causing compression and obstruction to flow of CSF. (**B** modified from Barrow Neurological Institute of St. Joseph's Hospital and Medical Center, Phoenix, Arizona. Reprinted with permission.)

or tethered as a result of scar tissue that develops as the cord transcends the vertebral canal with growth. Traction decreases blood flow and impairs oxidative metabolism. Symptoms are related to excessive tension on the lumbosacral cord and can include scoliosis, altered gait pattern, changes in muscle strength at or below the lesion, disturbance in urinary and bowel patterns, and back pain. The cord can be untethered surgically.[12]

It is possible for a defect to occur without any visible exposure of meninges or neural tissue. There is a cleft in the spine

TABLE 20-2 FUNCTIONAL ALTERATIONS IN MYELODYSPLASIA RELATED TO LEVEL OF LESION

LEVEL OF LESION	FUNCTIONAL IMPLICATIONS
Thoracic	Flaccid paralysis of lower extremities; variable weakness in abdominal trunk musculature; high thoracic level may mean respiratory compromise; absence of bowel and bladder control
High lumbar	Voluntary hip flexion and adduction; flaccid paralysis of knees, ankles, and feet; may walk with extensive braces and crutches; absence of bowel and bladder control
Midlumbar	Strong hip flexion and adduction; fair knee extension; flaccid paralysis of ankles and feet; absence of bowel and bladder control
Low lumbar	Strong hip flexion, extension, and adduction and knee extension; weak ankle and toe mobility; may have limited bowel and bladder function
Sacral	Normal function of lower extremities; normal bowel and bladder function

Data from Farley JA, Dunleavy MJ: Myelodysplasia. In Allen PJ, Vessey JA, editors: *Primary care of the child with a chronic condition,* ed 4, St Louis, 2004, Mosby.

because the posterior vertebral laminae have failed to fuse and the overlying skin is intact. Because the defect is not apparent to the unaided eye (i.e., it is "occult" or hidden), the term **spina bifida occulta** is used.[13] This extremely common defect occurs to some degree in 10% to 25% of infants. Approximately 80% of these vertebral defects are located in the lumbosacral regions, most commonly in the fifth lumbar vertebra and the first sacral vertebra. Spina bifida occulta usually causes no serious neurologic dysfunctions because the spinal cord and spinal nerves are generally anatomically and functionally normal, but the spinal defect can cause hydrocephalus.[14]

EVALUATION AND TREATMENT. Diagnosis is based on clinical manifestations and examination of the meningeal sac. Prenatal diagnosis of myelomeningocele is possible through ultrasonography. In the United States, most pregnant women receive triple or quad screening between 15 and 20 weeks of a pregnancy. The presence of a neural tube defect may result in an elevated amniotic fluid AFP level and subsequent maternal serum AFP levels. Additional testing is then performed if screening tests are positive, including a detailed ultrasound, which may allow for prenatal diagnosis of spina bifida. Prenatal diagnosis offers the parents the option to terminate the pregnancy or become a candidate for fetal intrauterine repair.[15] Cesarean delivery may be recommended to minimize trauma to the open myelomeningocele.[16]

In an effort to preserve neuronal function and minimize damage that may occur from infection and manipulation of the fragile sac, surgical closure is optimal prenatally or during the first 72 hours of life, as recommended by the management of Myelomeningocele Study (MOMS).[17] Functional implications depend on the level and severity of the defect (Table 20-2) and the presence of associated conditions, such as abnormal renal structure or function, or both, and the presence of a Chiari II malformation (see p. 665). These conditions are screened at birth in any child born with myelomeningocele or meningocele.

Because myelodysplasia affects several other body systems (e.g., renal, gastrointestinal, musculoskeletal), these infants require a comprehensive, multidisciplinary approach to treatment. The prognosis depends on the extent of the involvement at birth and the success of prophylactic and acute treatment for potential and actual complications that affect the many body systems. Symptomatic Chiari II malformations require surgical decompression and/or placement of cerebrospinal fluid shunts.

Craniosynostosis

Craniosynostosis (craniostenosis) is the premature closure of one or more of the cranial sutures during the first 18 to 20 months of an infant's life. The incidence of craniosynostosis is 1 in 1800 to 2200 live births.[18] Males are affected twice as often as females. Craniosynostosis can occur as part of a syndrome or, more commonly, as an isolated defect.[19] **Nonsyndromic craniosynostosis** is classified as *simple craniosynostosis* when only one suture is involved and *compound* or *complex craniosynostosis* when two or more sutures are involved. Craniosynostosis prevents normal skull expansion and causes asymmetric skull growth. Premature closure of a suture causes failure of the growth of the bone located at a right angle to the involved suture. Compensatory growth occurs in regions where the sutures are patent, and this causes the various cosmetic deformities of head shape. Where sutures are fused, cerebral growth may exceed the space present. Brain growth may be restricted, and compression may cause neurologic symptoms (Figure 20-8). Clinically, however, most children who present with small heads and developmental delay have microcephaly (see below) caused by defects in brain growth, not compression by prematurely closed sutures.

PATHOPHYSIOLOGY. The exact causes of craniosynostosis are unknown, but are associated with defects in multiple genes that control the fibroblast growth factor receptor family.[20]

Syndromic craniosynostosis refers to synostosis that occurs as part of a genetic syndrome. It is associated with various dysmorphisms involving the face, skeleton, and nervous system and is usually accompanied by developmental delay.

CLINICAL MANIFESTATIONS. Craniosynostosis is classified according to head contour or suture involvement. Final skull contour is determined by the sutures that close, the duration and order of closure, and the ability of other sutures to compensate by expansion (see Figures 20-8 and 20-9).

Premature closure of the sagittal suture, the most common form of craniosynostosis, causes elongation of the skull in the anteroposterior direction. Other anomalies are seen in 25% of these children. When the coronal suture fuses prematurely, the brain expands in a lateral direction. This type of craniosynostosis is associated with a 33% to 66% incidence of associated anomalies.

EVALUATION AND TREATMENT. Craniosynostosis must be differentiated from the more benign skull deformity known as positional plagiocephaly (flattening of one side of the head), which is quite common and may be related to the amount of time an infant spends on his or her back. When the American Academy

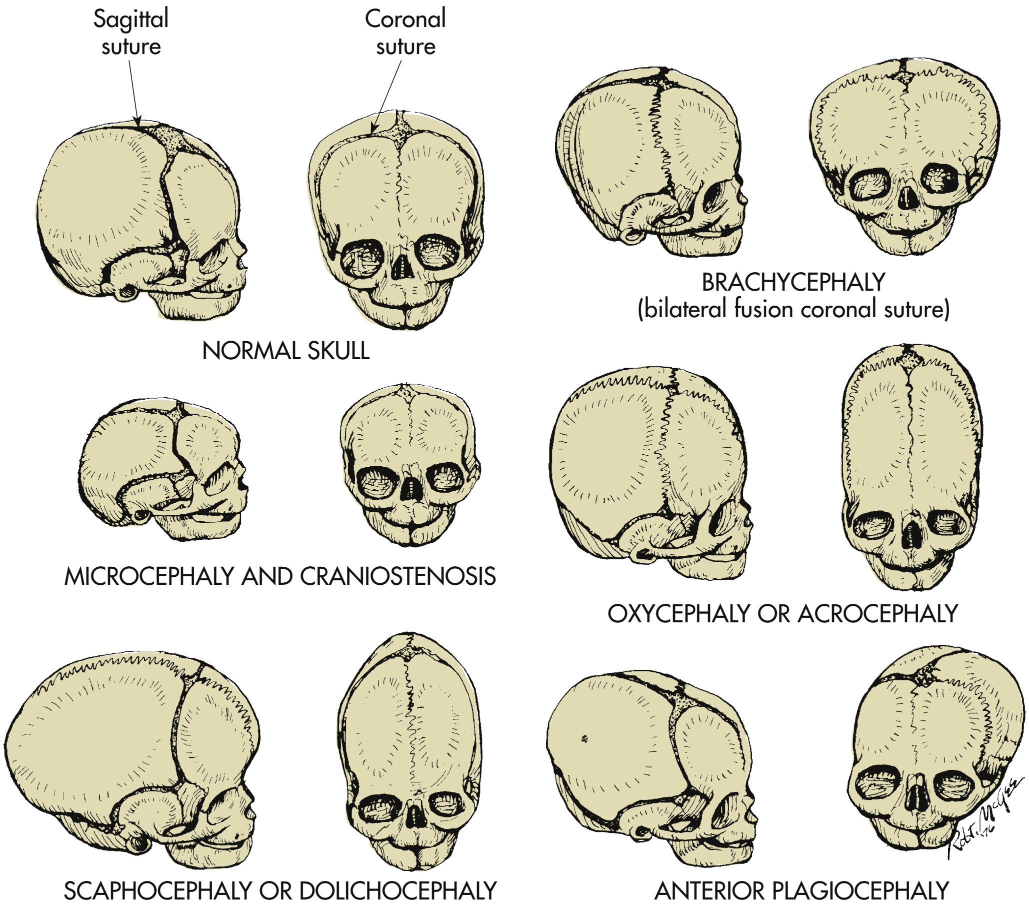

FIGURE 20-8 **Types and Frequency of Craniosynostosis.** Abnormal head configuration resulting from premature closing of cranial sutures. *Normal skull:* Bones separated by membranous seams until sutures gradually close. *Microcephaly and craniostenosis:* Microcephaly is head circumference more than 2 standard deviations below the mean for age, gender, race, and gestation and reflects a small brain; craniosynostosis is premature closure of sutures. *Scaphocephaly or dolichocephaly* (frequency 56%): Premature closure of sagittal suture, resulting in restricted lateral growth. *Brachycephaly:* Premature closure of coronal suture, resulting in excessive lateral growth. *Oxycephaly or acrocephaly* (frequency 5.8% to 12%): Premature closure of all coronal and sagittal sutures, resulting in accelerated upward growth and small head circumference. *Anterior plagiocephaly* (frequency 13%): Unilateral premature closure of coronal suture, resulting in asymmetric growth. (From Hockenberry JH et al: *Wong's nursing care of infants and children,* ed 9, St Louis, 2011, Mosby.)

of Pediatrics recommended that babies should sleep on their backs instead of their stomachs, the incidence of positional plagiocephaly increased (whereas the incidence of sudden infant death syndrome decreased). A custom-molded helmet or headband applied at about 4 months of age can correct plagiocephaly before closure of fontanels and sutures.

Diagnosis of craniosynostosis is made on the basis of physical examination, head circumference measurements, and radiologic examination. Surgical treatment is often indicated for craniosynostosis and is performed when closure of multiple sutures causes chronic increased intracranial pressure. Surgery then limits the extent of brain damage. In children with craniosynostosis of one suture, surgery often is performed for cosmetic purposes.[21]

Malformations of Cortical Development

Structural malformations of cortical development are a diverse, heterogeneous group of disorders caused by abnormal neuronal cell migration, abnormal neuronal and glial proliferation, and malformations secondary to abnormal postmigrational neuronal development. The processes of malformation can occur at any time during fetal development and after birth. There is a specific genetic defect for some of these disorders; others are multifactorial or acquired (i.e., intrauterine trauma or infection). Most increase the risk for seizures that are difficult to control, developmental delay, and motor dysfunction. Diagnosis is made by magnetic resonance imaging (MRI), family history, and clinical information. Genetic testing is done to assess risk in other family members and to guide prospective therapy.[22-25]

Microcephaly

Reduced proliferation or accelerated apoptosis causes congenital microcephaly (microencephaly—small brain), whereas increased proliferation causes megalencephaly (abnormally large brain). **Microcephaly** is a rare defect in brain growth as a whole (see Figure 20-8). The word *microcephaly* is derived

FIGURE 20-9 Lateral View of a Child with Scaphocephaly Resulting from Sagittal Synostosis. Note the frontal bossing, elongation along the anteroposterior (AP) axis, and prominent occiput, all of which are characteristic of this condition. (From Coran A et al: *Pediatric surgery,* ed 7, St Louis, 2012, Mosby.)

BOX 20-1 CAUSES OF MICROENCEPHALY

Defects in Brain Development
Hereditary (recessive) microcephaly
Down syndrome and other trisomy syndromes
Fetal ionizing radiation exposure
Maternal phenylketonuria
Seckel syndrome
Cornelia de Lange syndrome
Rubinstein-Taybi syndrome
Smith-Lemli-Opitz syndrome
Fetal alcohol syndrome

Intrauterine Infections
Congenital rubella
Cytomegalovirus infection
Congenital toxoplasmosis
Congenital syphilis

Perinatal and Postnatal Disorders
Intrauterine or neonatal anoxia
Severe malnutrition in early infancy
Neonatal herpesvirus infection

from the Greek (*mikro,* "small"; *kephale,* "head"). Cranial size is significantly below average for the infant's age, sex, race, and gestation. The small size of the skull reflects a small brain (microencephaly) that is caused by reduced proliferation or accelerated apoptosis. The condition is not treatable.

True (primary) microcephaly is present at birth and can be caused by genetic alterations, including autosomal dominant, autosomal recessive, or X-linked genetic abnormalities, or various chromosomal abnormalities. Environmental causes include toxin or radiation exposure or intrauterine infection during the period of induction and neural cell migration (Box 20-1). *Secondary microcephaly* develops postnatally (the baby's head size is normal at birth but then fails to grow as expected) and is associated with a variety of causes including infection, trauma, metabolic disorders, maternal anorexia experienced during the third trimester of pregnancy, and the presence of some genetic syndromes (e.g., Rett syndrome).[26]

Microcephalic brain weight may be as low as 25% of normal, and the number and size of the cortical gyri may be diminished. Growth of the frontal lobes is severely stunted, and the cerebellum often is disproportionately large. In microcephaly caused by perinatal or postnatal disorders, neuronal loss and gliosis may be present in the cerebral cortex. Children with microcephaly are usually developmentally delayed.

Cortical Dysplasias

Cortical dysplasias are a heterogeneous group of disorders caused by defects in neuronal cell migration and subsequent abnormalities in connections between cells. These disorders may range from a small area of abnormal tissue (e.g., heterotopia, which are pieces of gray matter that did not migrate to their normal position in the cortex of the brain; or focal cortical dysplasias, where brain organization in one small area is abnormal) to an entire brain that is smooth without the normal configuration of gyri and sulci of a developed brain (lissencephaly) (Figure 20-10).

FIGURE 20-10 Lissencephaly. The absence of cortical gyri defines this abnormality, seen here in the brain from a full-term infant. (From Kumar V et al: *Robbins & Cotran pathologic basis of disease,* ed 8, Saunders, 2010, Philadelphia.)

Congenital Hydrocephalus

Congenital hydrocephalus is present at birth and characterized by increased intracranial pressure (ICP). This increase may be caused by a blockage within the ventricular system in which the CSF flows, an imbalance in the production of CSF, or a reduced reabsorption of CSF that results in ventricular enlargement and increased ICP. The pressure within the ventricular system dilates the ventricles and pushes and compresses the brain tissue against the skull. When hydrocephalus develops before fusion

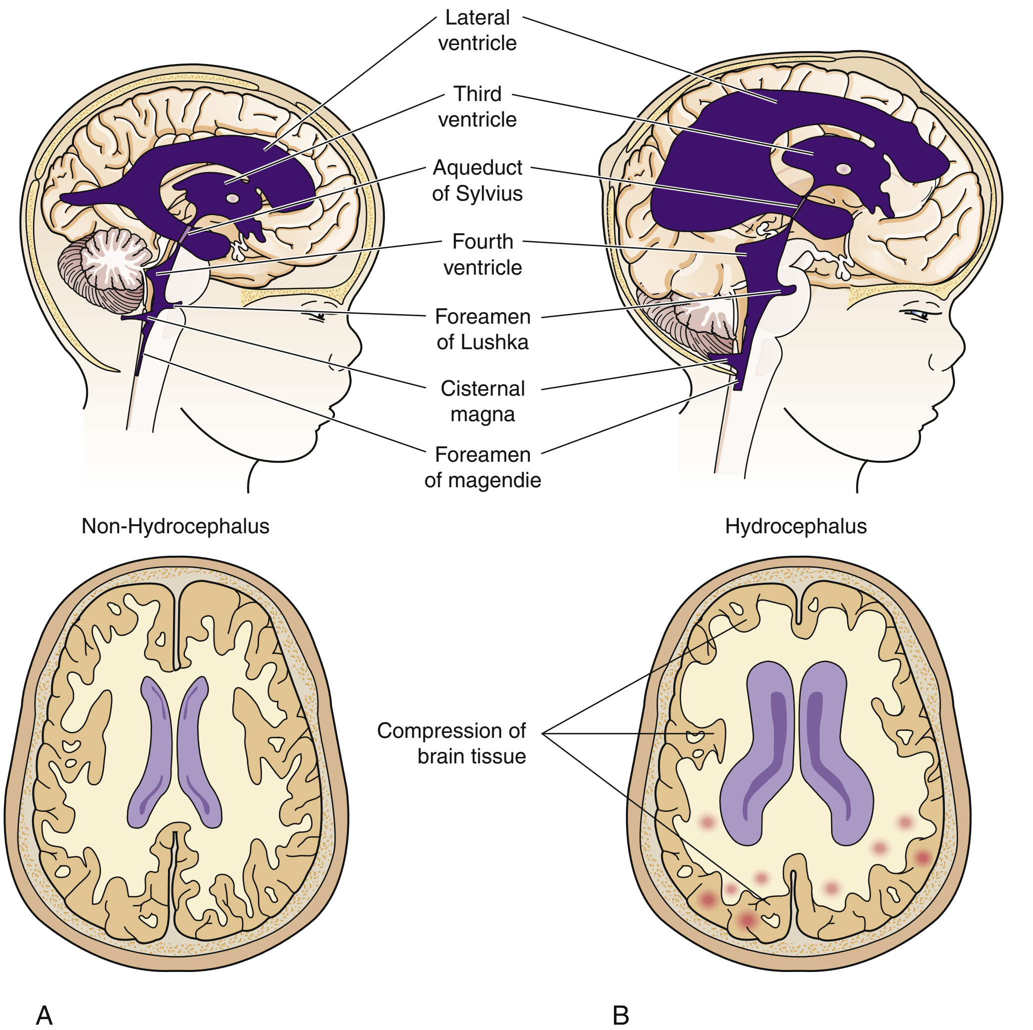

FIGURE 20-11 **Hydrocephalus.** A block in the flow of cerebrospinal fluid (CSF). **A,** Patent cerebrospinal fluid circulation. **B,** Enlarged lateral and third ventricles caused by obstruction of circulation—stenosis of aqueduct of Sylvius.

of the cranial sutures, the skull has the capacity to increase its size to accommodate this additional space-occupying volume and to preserve neuronal function. The overall incidence of hydrocephalus is approximately 1 to 3 per 1000 live births.[27] The incidence of hydrocephalus, excluding the hydrocephalus associated with myelomeningocele, is approximately 0.5 to 1 per 1000 live births, with aqueductal stenosis as the cause for approximately one third of these cases.[28] (Types of hydrocephalus are discussed in Chapter 17.)

PATHOPHYSIOLOGY. *Obstructive hydrocephalus* is caused most commonly by congenital aqueductal stenosis. The cerebral aqueduct, which connects the third ventricle to the fourth ventricle, is narrowed or replaced by multiple channels that end blindly. In a small number of children the stenosis is transmitted as an X-linked recessive trait. The **Dandy-Walker malformation** is a congenital defect of midline cerebellar structures and the fourth ventricle in which hydrocephalus is caused by atresia of the foramina of Luschka or Magendie, which normally allow the fourth ventricle to empty into the areas surrounding the brain, leading the ventricular flow of CSF into a "blind pouch." Other causes of obstructions within the ventricular system that can result in hydrocephalus include brain tumors, cysts, trauma, arteriovenous malformations, blood clots, infection, and spina bifida.

CSF travels throughout the ventricular system, surrounds the brain, and is reabsorbed into the venous system by the arachnoid villi. Blockage of the arachnoid villi may occur in conditions such as bacterial or viral meningitis, intraventricular hemorrhage, and subarachnoid hemorrhage, or may result from congenital malformations within this area. In this instance CSF flows or communicates effectively but is unable to be reabsorbed, resulting in hydrocephalus.

CLINICAL MANIFESTATIONS. Congenital hydrocephalus is present at birth, whereas acquired hydrocephalus usually becomes apparent in the first weeks to months of life. Symptoms of this condition depend directly on the cause and rate of hydrocephalus development. Typically, the fontanels enlarge and become full and bulging (Figures 20-11 and 20-12). The eyes may assume a staring expression, with sclera visible above the iris, a finding called *sunsetting eyes*.

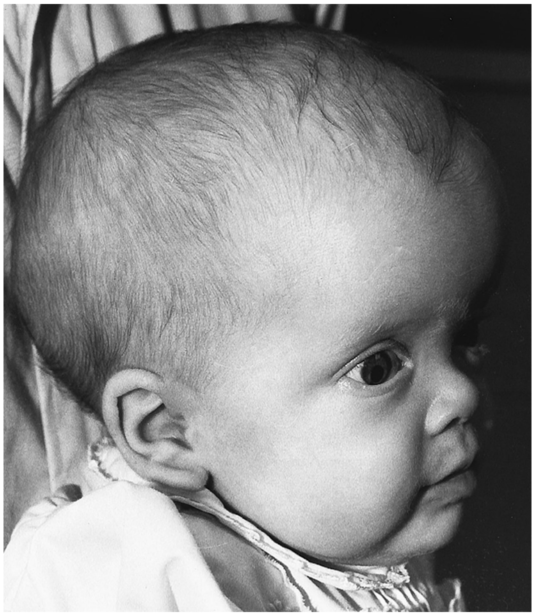

FIGURE 20-12 Child with Enlarged Head Caused by Hydrocephalus. (From McLaurin DC: *Pediatric neurosurgery,* ed 2, Philadelphia, 1989, Saunders.)

The infant may have difficulty holding the head upright. The scalp skin is thin and shiny, and scalp veins may become prominent. The large cranial vault and the face are disproportionate, and frontal bossing may be present. The infant's cry becomes high pitched as ICP rises; irritability, lethargy, vomiting, and other signs of increased ICP may develop. Dramatic head growth and enlargement, compression of the optic nerves, and optic chiasm occur in chronic, untreated hydrocephalus. However, because of early surgical intervention, these signs of hydrocephalus rarely are seen in developed countries. When hydrocephalus develops late in childhood, the head may not have the capacity to enlarge, and symptoms of increased ICP occur quickly (see Chapter 17).

The relationship between hydrocephalus and intellectual disability has been heavily debated. Correlation between the degree of hydrocephalus and impaired cognitive function often is a result of additional complications, such as severe congenital malformations, acute or chronic infections, or progressive brain tumors. Approximately two thirds of children with uncomplicated congenital hydrocephalus treated successfully with shunting may have normal to borderline intelligence.[29]

EVALUATION AND TREATMENT. Both cranial ultrasound and computed tomography (CT) are used to evaluate hydrocephalus. Magnetic resonance imaging (MRI) may add information about the specific cause of the hydrocephalus. In infancy, head circumference measurements are obtained and monitored, and if the head is enlarging too quickly the child is referred for imaging first and then, if needed, to neurosurgery for further evaluation. The treatment is surgical placement of a shunt to divert the excess CSF from the ventricular cavity to other areas of the body. Several types of shunts are available. The main objective of any shunt system is to decrease ICP and preserve neuronal function. With neurosurgical intervention and follow-up, the 5-year survival usually is greater than 80%. Most deaths that occur within this category result from severe congenital malformations and/or progressive disorders such as brain tumors. Children with hydrocephalus depend on the internal shunt system to maintain safe ICPs and therefore are at risk for sudden failure of this system, which leads to acute increased ICP and death. Endoscopic ventriculostomy with choroid plexus cauterization are two newer procedures performed together and offer hope to replace shunts, and avoiding shunt blocks, malfunction, and infection.[29a]

ALTERATIONS IN FUNCTION: ENCEPHALOPATHIES

Encephalopathy, a pathology involving the brain, is a general category of syndromes and diseases that include infections, ischemia, metabolic and toxic causes, and others. Encephalopathies in children are associated with a great variety of known and suspected causes. They can be divided into non-progressive and progressive subtypes. Progressive subtypes can be either acute or slowly progressive. Rare neurologic disorders with a genetic basis are summarized in Table 20-3.

Static Encephalopathies

Brain injury may occur during gestation or birth or at any time during childhood growth and development, causing a static disorder. Static encephalopathy may be a result of trauma near birth (cerebral palsy); a genetic syndrome (intellectual disability); or later trauma, such as a closed-head injury, which may cause a static encephalopathy with motor and cognitive deficits. The clinical manifestations of a static encephalopathy depend on the site and extent of the injury, as well as the age of the child and stage of development at the time of injury.

Cerebral Palsy

Cerebral palsy (CP) is a disorder of movement, muscle tone, or posture that is caused by injury or abnormal development in the immature brain, before, during, or after birth up to 1 year of age. CP is one of the most common crippling disorders of childhood, affecting nearly 500,000 children in the United States alone. Although the exact incidence is unknown, studies suggest that the prevalence is approximately 3.3 per 1000 live births in the United States.[30] Although the term cerebral palsy refers specifically to the motor deficits, associated intellectual disability, seizures, and other problems also are common in children with this disorder.

PATHOPHYSIOLOGY. Several factors, alone or in combination, can produce brain damage that leads to CP (Table 20-4). Prenatal factors that affect the developing nervous system may be endogenous or exogenous. The fetus may be affected by impaired embryo implantation, chromosomal abnormalities, infection, trauma, radiation exposure, and toxic substances. Maternal toxemia, diabetes mellitus, and maternal nutritional deficiencies can produce neurologic damage in the fetus. Anoxia, trauma, and infections are the most common factors that cause injury to the nervous system in the perinatal period. Low birth weight and birth asphyxia are commonly identified risk factors for cerebral palsy. Vascular abnormalities, arterial or venous stasis, and thrombosis can occur as a result of tissue

TABLE 20-3 SELECTED NEUROLOGIC DISORDERS WITH A GENETIC BASIS

SYNDROME/ DISORDERS	CURRENTLY KNOWN GENETIC COMPONENTS	PATHOPHYSIOLOGY	MAJOR NEUROLOGIC FEATURES
Angelman syndrome	Loss of function mutation of the *UBE3A* gene (ubiquitin protein ligase) can be acquired from mother (chromosome 15)	Protein, important in degradation of proteins in the brain	Little to no verbal language, mental retardation, seizure disorder, sleep disorder, movement/ balance disorder
Batten disease	Autosomal recessive; mutation of the *CLN3* gene (ceroid-lipofuscinosis, neuronal 3) (chromosome 16)	Lysosomal storage defect resulting in abnormal storage of cerebral lipofuscins	Develops normally until 6 months to 2 years of age when progressive brain disease becomes apparent; seizures, mental retardation, blindness, and death
Branched-chain ketoaciduria (maple syrup urine disease)	Autosomal recessive; most common type is classic caused by mutation of the *BCKDHA* gene (2-oxoisovalerate dehydrogenase subunit alpha, a mitochondrial enzyme) (chromosome 19)	All types result in inability to metabolize three amino acids; these acids accumulate and are toxic at high levels	Without early diagnosis and treatment, mental retardation, seizures, and death
Cri du chat syndrome	Autosomal dominant; deletion on the short arm of chromosome 5 (also called 5p minus syndrome)	Deletion of multiple genes responsible for phenotype; evidence that deletion of telomerase reverse transcriptase gene contributes to phenotype	High-pitched cry; mental retardation, microcephaly, low birth weight, failure to thrive; widely spaced eyes (ocular hypertelorism), unusually small jaw (micrognathia)
Lesch-Nyhan syndrome	X-linked recessive; mutation of the *HPRT* gene (hypoxanthine phosphoribosyltransferase 1)	Metabolism disturbance of purines; excessive production of uric acid	Mental retardation, progressive neurologic disorder, compulsively bitten lips and fingers; self-mutilating
Neurofibromatosis (NF)	Autosomal dominant	Variable expressivity	Multiple café-au-lait spots, neurofibromas, learning disability, seizure disorder
NF1 (von Recklinghausen disease)	Mutation of the *NF1* gene (neurofibromin) (chromosome 17)	A large, complex protein; this protein may act as a switch to regulate cell growth; mutation may lessen or inhibit the normal output of this protein and allow irregular cell growth that may lead to tumor development	Increased risk for nerve sheath tumors and brain tumors
NF2 (bilateral acoustic NF)	Autosomal dominant: mutation of either the *merlin* (moesin-ezrin-radixin-like protein or schwannomin) or the *NF2* gene (chromosome 22)	A tumor-suppressor protein (*merlin* or *schwannomin*)	Multiple tumors (schwannomas) on cranial and spinal nerves, acoustic neuromas, hearing loss
Progressive myoclonus epilepsy			
Unverricht-Lundborg disease	Autosomal recessive; mutation *CSTB* gene (cystatin B, a cysteine protease inhibitor) (chromosome 21)	This protein regulates enzymes that break down other proteins	Onset at age 6-15 years, severe incapacitating stimulus-sensitive progressive myoclonus, tonic-clonic epileptic seizures, and characteristic abnormalities on electroencephalogram; also may develop other neurologic symptoms. such as ataxia, incoordination, dysarthria
Lafora disease	Autosomal recessive; mutation of the *EMP2A* gene (epilepsy, progressive myoclonus type 2A or laforin) and *EMP2B* gene (malin) (chromosome 6)	Concentric amyloid (Lafora) bodies found in neurons, liver, skin, bone, and muscle; defects in protein degradation and clearance	Grand mal seizures and/or myoclonus at about age 15; rapid and severe motor and coordination impairments, rapid mental deterioration, often with psychotic features; survival is short, less than 10 years after onset
Rett syndrome	X-linked dominant; appears to occur only in girls; defective *MeCP2* gene (methyl CpG binding protein 2) (X-chromosome)	Protein involved in regulation of gene expression; defects in this gene allow other genes to be expressed at inappropriate times in development	Progressive neurologic disorder; develops normally in first year of life, then loss of mental capacity and motor skills begins; loss of purposeful hand move-ments; stereotypical hand wringing and flapping
Tay-Sachs disease	Autosomal recessive; mutation of the *HEXA* gene (chromosome 15)	Caused by a deficiency of hexosaminidase, an enzyme, which results in accumulation of a material that damages the brain	Failure to thrive, blindness, seizures, progressive paralysis; usually death by age 4
Tuberous sclerosis	Autosomal dominant; mutation of either the *TSC1* gene (hamartin) (chromosome 9) or the *TSC2* gene (tuberin) (chromosome 16)	These proteins act as tumor growth suppressors	Develops in early childhood; seizures, mental retardation, skin and eye lesions; multiple benign tumors in brain and other vital organs

TABLE 20-4 CEREBRAL PALSY: PREDISPOSING FACTORS AND KNOWN CAUSES

RISK FACTORS	ASSOCIATED CAUSES
Prenatal	
Maternal	Metabolic diseases Nutritional deficiencies (e.g., anemia) Twin or multiple births Bleeding Toxemia Blood incompatibilities Exposure to radiation Infection (e.g., rubella, toxoplasmosis, cytomegalic inclusion disease) Premature labor
Prematurity	Asphyxia leading to cerebral hemorrhage
Genetic factors	Absence of corpus callosum, aqueductal stenosis, cerebellar hypoplasia
Congenital anomalies of the brain	Unknown causes not evident on clinical examination
Perinatal	Anesthesia or analgesia during labor and delivery Mechanical trauma during delivery Immaturity at birth Metabolic disorders (e.g., hyperbilirubinemia, hypoglycemia, amino acid disorders, hyperosmolality) Electrolyte disturbances (e.g., hypernatremia, hypoglycemia)
Postnatal	Head trauma Infections (e.g., meningitis, encephalitis) Cerebrovascular accidents Toxicosis Environmental toxins (e.g., lead ingestion, methyl mercury ingestion from contaminated fish)

hypoxia or as unrelated structural alterations. These anomalies may result in direct brain trauma that leads to infarction, intraventricular hemorrhage, and subarachnoid hemorrhage. Physical trauma to the central nervous system can occur during the birthing process. Genetic, teratogenic, and early pregnancy influences on the development of cerebral palsy are multifactorial and not yet fully understood.[31,32] The severity of the damage depends on the gestational age at the time of the injury and the type and degree of injury sustained. Magnesium sulfate in preterm newborns and head cooling during or after resuscitation at birth may reduce brain damage and risk of CP.[33,34]

CLINICAL MANIFESTATIONS. Although CP is by definition nonprogressive, its clinical manifestations change with growth and maturation of the child. Associated problems are common and may involve vision and hearing impairment, intellectual disability, seizures, swallowing problems, and more.[35,36]

The syndromes associated with CP can be classified according to the areas of the brain that are damaged and the part of the body that is affected. Brain damage may affect the pyramidal system, causing spasticity, or the extrapyramidal system, leading to dyskinetic, ataxic, or hypotonic CP. **Pyramidal/spastic cerebral palsy** results from damage or defects in the brain's corticospinal pathways (upper motor neuron) in either one or both hemispheres and accounts for approximately 70% to 80% of cerebral palsy cases. It is associated with increased muscle tone, prolonged primitive reflexes, exaggerated deep tendon reflexes, clonus, rigidity of the extremities, scoliosis, and contractures. Cognitive impairment occurs in about 30% of children.[37] If spasticity occurs throughout the body, the child has *spastic quadriparesis;* if it occurs in primarily one half of the body, the child has *hemiparetic cerebral palsy*. The latter type can occur after a stroke in the middle cerebral artery territory before or at the time of birth.

Extrapyramidal/nonspastic cerebral palsy is caused by damage to cells in the basal ganglia, thalamus, or cerebellum and includes two subtypes: dyskinetic and ataxic. **Dyskinetic cerebral palsy** is associated with extreme difficulty in fine motor coordination and purposeful movements. Movements are jerky, uncontrolled, and abrupt, resulting from injury to the basal ganglia or thalamus. This form of CP accounts for approximately 20% to 25% of cases. **Ataxic cerebral palsy** is associated with damage to the cerebellum and manifests with gait disturbances and instability. The infant with this form of CP may have hypotonia at birth, but develops stiffness of the trunk muscles later in infancy. This lack of flexibility exaggerates the infant's inability to balance body position without support. This form of CP accounts for approximately 5% of cases. A child may have symptoms of each of these CP types, which leads to a mixed-variety disorder seen in approximately 13% of children with this disorder.

A few decades ago, a large percentage of children were identified as having CP for unknown reasons. Many had no history of trauma or other cause for their CP. As imaging techniques and other testing methods have improved, there is an increased chance that the underlying cause of a child's CP will be delineated. A small percentage of these children may actually have a treatable and slowly progressive condition; therefore, every attempt to find an underlying cause for a child's CP should be made. One example of such an underlying cause is glucose transporter deficiency, a condition where the concentration of glucose in the cerebral spinal fluid is very low. Children with this condition have ataxic movements that may be misidentified as CP and also have intractable seizures. If this defect is identified, the child is treated with the ketogenic diet (see Epilepsy section) with amelioration of some of the symptoms. Because of examples like this, the American Academy of Neurology has made specific recommendations regarding the evaluation of a child with CP of an unknown cause as it may actually be a slowly progressive encephalopathy.[38]

EVALUATION AND TREATMENT. Although the brain injury is static, the clinical picture of CP may change with growth and development. The use of intrathecal baclofen pumps, botulinum toxin, and selective dorsal rhizotomy for spasticity has led to improvement in selected children with CP.[39,40]

The management of children with CP varies with age, type and severity of involvement, and associated disorders. Thus the scope of care required by the child and family includes ongoing medical, social, and educational intervention, and a family-focused multidisciplinary team approach.[41]

TABLE 20-5 INHERITED METABOLIC DISORDERS OF THE CENTRAL NERVOUS SYSTEM PRESENTING AT DIFFERENT AGES

AGE OF ONSET	DISORDER
Neonatal period	Pyridoxine dependency, galactosemia, maple syrup urine disease and its variant, phenylketonuria (PKU)
Early infancy	Tay-Sachs disease and its variants, infantile Gaucher disease, infantile Niemann-Pick disease, Krabbe disease (leukodystrophy), Farber lipogranulomatosis, Pelizaeus-Merzbacher disease and other sudanophilic leukodystrophies, spongy degeneration, Alexander disease, Alpers disease, Leigh disease (subacute necrotizing encephalomyelopathy), congenital lactic acidosis, Zellweger encephalopathy, Lowe disease (oculocerebrorenal disease)
Late infancy and early childhood	Disorders of amino acid metabolism, metachromatic leukodystrophy, late infantile GM1 gangliosidosis, late infantile Gaucher and Niemann-Pick diseases, neuroaxonal dystrophy, mucopolysaccharidosis, mucolipidosis, fucosidosis, mannosidosis, aspartylglycosaminuria, amaurotic idiocy (Jansky-Bielschowsky disease, Batten disease, Vogt-Spielmeyer disease, neuronal ceroid lipofuscinosis), Cockayne syndrome
Later childhood and adolescence	Progressive cerebellar ataxias of childhood and adolescence, hepatolenticular degeneration (Wilson disease), Hallervorden-Spatz disease, Lesch-Nyhan syndrome and other uremic states, familial calcification of vessels in basal ganglia and cerebellum, familial polymyoclonus, chronic familial leukodystrophy, homocystinuria, Fabry disease

For more information regarding screening and parent education see Medical Home Portal at www.medicalhomeportal.org/.

Inherited Metabolic Disorders of the Central Nervous System

A large number of inherited metabolic disorders have been identified. The advent of newborn metabolic screening for 28 metabolic conditions (in some states as many as 50) has led to many of these children being identified before symptoms develop. In these disorders, there is either a deficiency of an essential product or an accumulation of a substrate with damage induced either by overaccumulation or toxicity or by a combination of both. Inborn errors of metabolism are present at birth, although they may not manifest until childhood or even adulthood, and most cause disturbances of the nervous system. Restrictive diets can prevent symptoms from developing for many children and those with these disorders can lead relatively normal lives. The following website contains a list of the newborn metabolic screening tests: www.marchofdimes.com/professionals/bringinghome_screening.html. Table 20-5 lists some of these inherited metabolic disorders. Defects in amino acid and lipid metabolism are more common than rarely occurring defects in carbohydrate metabolism.

Defects in Amino Acid Metabolism. Biochemical defects in amino acid metabolism are examples of defects in inherited metabolic disorders. They may be classified as (1) those in which the transport of an amino acid is impaired; (2) those involving an enzyme or cofactor deficiency; and (3) those grouped around certain chemical components, such as sulfur-containing amino acids.[42] Most of the disorders in the literature described to date suggest that the absence of enzymatic activity most often is caused by the genetically determined absence of the enzyme protein. Diseases caused by an enzymatic deficiency are associated with increased blood concentrations of the amino acid whose degradation pathway is impaired and with the appearance of the amino acid in the urine. With the exception of phenylketonuria, the estimated incidence of each of these defects is about 1 in 100,000 to 200,000 live births, although this number may increase with newborn screening.

Phenylketonuria. **Phenylketonuria (PKU)** is an example of an inborn error in the metabolism of amino acids. PKU is an autosomal recessive inborn error of metabolism characterized by mutations of the phenylalanine hydroxylase *(PAH)* gene. PKU has a prevalence rate of about 1 per 15,000 live births in the United States.[43] Because of its genetic component and distribution, this statistical prevalence varies widely on the basis of geographic and ethnic differences.[44] Most natural food proteins contain about 15% phenylalanine. The body uses tyrosine in the biosynthesis of protein, melanin, thyroxine, and the catecholamines in the brain and adrenal medulla. Loss of *PAH* activity results in phenylalanine hydroxylase deficiency and the inability of the body to convert the essential amino acid phenylalanine to tyrosine, leading to the accumulation of phenylalanine in the serum. It is the accumulation of phenylalanine and associated metabolites that causes damage to the central nervous system (Figure 20-13). One of these phenyl acids, phenylpyruvic acid, gives the urine a characteristic musty odor and is responsible for the name given to the disorder. High blood levels of phenylalanine prevent sufficient neutral amino acid entry into the brain, which contributes to the neuropathologic process of PKU. A baby with the genetic defect of PKU born to a mother without PKU or to a mother with PKU who is well controlled on a phenylalanine-restricted diet will not have any problems because he or she is receiving nutrients from the mother. When a baby is born with PKU and begins a regular diet high in phenylalanine without treatment, buildup of phenylalanine occurs, brain growth slows, and the child exhibits developmental delay or intellectual disability, concomitant with jerking movements, seizures, skin rashes, and attention problems. Because of the lack of tyrosine and its relationship to the biosynthesis of melanin, children with PKU have a characteristic phenotype that includes blond hair, blue eyes, and fair skin. Children with genetically darker complexions may be red haired or brunette.

Less severe variants of this disorder are caused by defects in the phenylalanine hydroxylase system rather than the phenylalanine hydroxylase enzyme itself. This related disorder, known as **hyperphenylalaninemia (HPA),** occurs when plasma phenylalanine levels rise above normal but do not rise as high as

in PKU.[45] Individuals with PKU also need to be screened for response to BH4 (6-*R*-L-erythro-5,6,7,8-tetrahydrobiopterin), which significantly decreases blood phenylalanine levels when given as an oral supplement (sapropterin dihydrochloride).[46]

When infants are treated appropriately, growth and development are normal. Treatment for PKU involves restriction of phenylalanine in the diet to maintain a nontoxic level and supplementation with other essential amino acids. Treatment must be continued for life and strict adherence to the diet is especially important for pregnant women with PKU so that damage does not occur prenatally to the fetus. The diet also must be supplemented with adequate sources of energy, protein, and nutrients to allow for optimal growth and brain development. Supplementation of tyrosine also may be required if plasma levels are low. Enzyme replacement and gene and cell therapies are under investigation.[47]

Storage Diseases. Some metabolic disorders are caused by abnormal accumulation of metabolites. These disorders are generally not included in newborn screening. Lysosomal storage diseases and Tay-Sachs disease will be discussed as examples of storage diseases.

Lysosomal Storage Disease. Lipids are fat-like substances that are important parts of the membranes found within and between each cell and in the myelin sheath that coats and protects the nerves. Lipids include oils, fatty acids, waxes, steroids (such as cholesterol and estrogen), and other related compounds. Although these compounds accumulate to some extent in cells, excess amounts are broken down in lysosomes (vesicles within the cell whose primary function is to degrade the breakdown products of cellular metabolism as discussed in Chapter 1). An estimated 25 to 30 enzymes within lysosomes participate in the breakdown of excess compounds. A genetic defect resulting in a missing or defective enzyme, such as lysosomal hydrolase, causes an excessive accumulation of the enzyme's substrate, which alters cell function. The enzyme defect may occur in the brain, liver, spleen, bone, or lung, thus involving several organ systems. Prenatal diagnosis is available. Enzyme replacement therapy and stem cell therapy have been successful in some cases.[48]

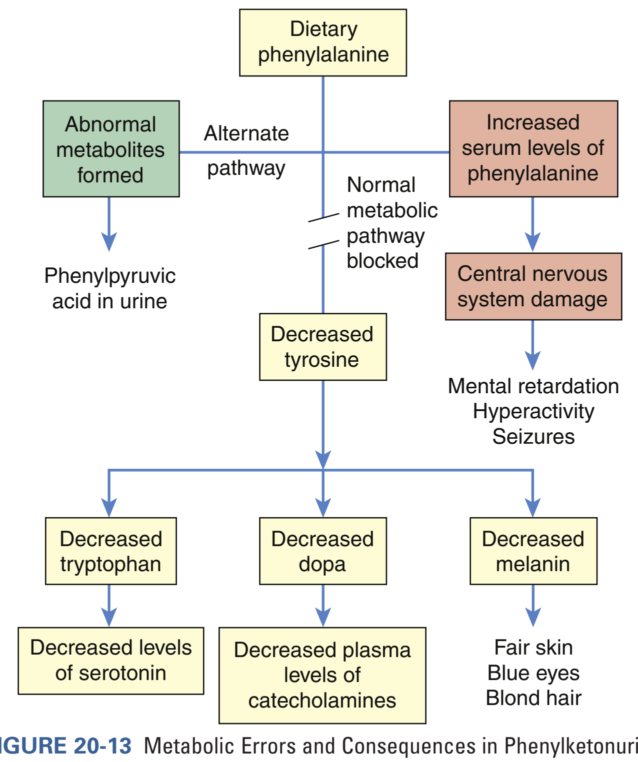

FIGURE 20-13 Metabolic Errors and Consequences in Phenylketonuria. (Redrawn from Hockenberry MJ et al: *Wong's nursing care of infants and children*, ed 9, St Louis, 2011, Mosby.)

Tay-Sachs Disease. Tay-Sachs disease (GM2 gangliosidosis) is an example of a lysosomal storage disease. It is a fatal autosomal recessive disorder (*HexA* gene on chromosome 15) caused by deficiency of the lysosomal enzyme hexosaminidase A (HexA), an enzyme that degrades GM2 gangliosides (fatty acids) within nerve cell lysosomes. Consequently, there is accumulation of gangliosides **(gangliosidosis),** which causes toxicity to nerve cells.[49] French Canadians, Louisiana Cajuns, and Ashkenazi Jews are all considered high-risk with a carrier rate of 1 per 27.[50] Prenatal screening is available.

In Tay-Sachs disease, GM2 ganglioside accumulates in neurons throughout the body, although the pathologic progressive changes prevail in the CNS. With time, neurons become distorted and balloon, and microglial cells, which also are swollen and filled with large granules, proliferate. Cystic degeneration of the cerebral white matter and atrophy of the cerebellar hemispheres often occur. The number of neurons is diminished. Changes in the spinal cord, particularly in the motor cells of the anterior horn of the cord, also are characteristic. Involvement of this region of the spinal cord results in hypotonia, hyporeflexia, and overall weakness.

Onset of symptoms usually occurs when the infant is 3 to 6 months old. A loss of milestones is associated with an excessive startle response. Seizures, muscular rigidity, and blindness become prominent after the first year of life, and head size may increase. Death usually occurs by 2 to 5 years of age. No beneficial therapy has been developed. Genetic counseling programs are available, and some states require screening techniques for couples and those at risk who may be carriers.[51]

Acute Encephalopathies

Intoxications of the Central Nervous System

Drug-induced encephalopathies always must be considered in the child with unexplained neurologic changes. Such encephalopathies may result from accidental ingestion, therapeutic overdose, intentional overdose, or ingestion of environmental toxins (the most commonly ingested poisons are listed in Box 20-2). Approximately 1.6 million children were exposed to poisons and approximately 263 children died in the United States in 2010 as a result of poisoning.[52]

Lead Poisoning. High blood levels of lead occur in lead poisoning. If lead poisoning is not treated, lead encephalopathy will result and cause serious and irreversible neurologic damage[53,54] (Figure 20-14). Those at greatest risk are children 2 to 3 years of age and those with pica or living in lead-contaminated environments. **Pica** is the habitual, purposeful, and compulsive ingestion of nonfood substances such as clay, dirt, or paint chips. Lead intoxication also may occur from

long-term exposure to smelters, sniffing of gasoline, exposure to lead-based paint, and ingestion of airborne lead.[55]

An estimated 203,000 U.S. children have excessive amounts of lead in their blood, which leads to varying amounts of intellectual disability depending on level and length of exposure time.[56] Young children are more likely to be exposed to lead-containing materials than older children and also absorb lead more easily than older children. Levels continue to be highest among non-Hispanic black children, Mexican American, and non-Hispanic white children, with the greatest risk being in the non-Hispanic black population.[57] The American Academy of Pediatrics has published recommendations for the treatment of lead poisoning depending on blood lead level.[58]

BOX 20-2 COMMON POISONS

PHARMACOLOGIC AGENTS	HEAVY METALS	MISCELLANEOUS AGENTS
Acetaminophen	Lead	Botulinum toxin
Amphetamines	Acute	Alcohols
Anticonvulsants	Chronic	Ethyl, isopropyl, methyl
Antidepressants	Mercury	Pesticides
Antihistamines	Thallium	Organophosphates
Atropine	Arsenic	Chlorinated hydrocarbons
Barbiturates		Mushrooms
Methadone		Venoms
Phencyclidine		Snake bite
Salicylates		Tick paralysis
Tranquilizers		Ethylene glycol

Data from Swaiman KF et al: *Swaiman's pediatric neurology: principles and practice,* vol 2, ed 5, St Louis, 2012, Mosby.

Infections of the Central Nervous System

Meningitis is inflammation of the meninges and subarachnoid space surrounding the brain and spinal cord, whereas the word **encephalitis** reflects inflammation within the brain. In many infections of the meninges, encephalitis also is present and the term *meningo-encephalitis* is used. The origin of such inflammation and acute encephalopathy can be caused by bacteria, viruses, or other microorganisms. **Aseptic meningitis** has no evidence of bacterial infection but may be associated with viral infection, systemic disease, or drugs.

Bacterial Meningitis. **Acute bacterial meningitis** is one of the most serious infections to which infants and children are susceptible. In the United States approximately 4100 cases of bacterial meningitis occurred each year between 2003 and 2007,

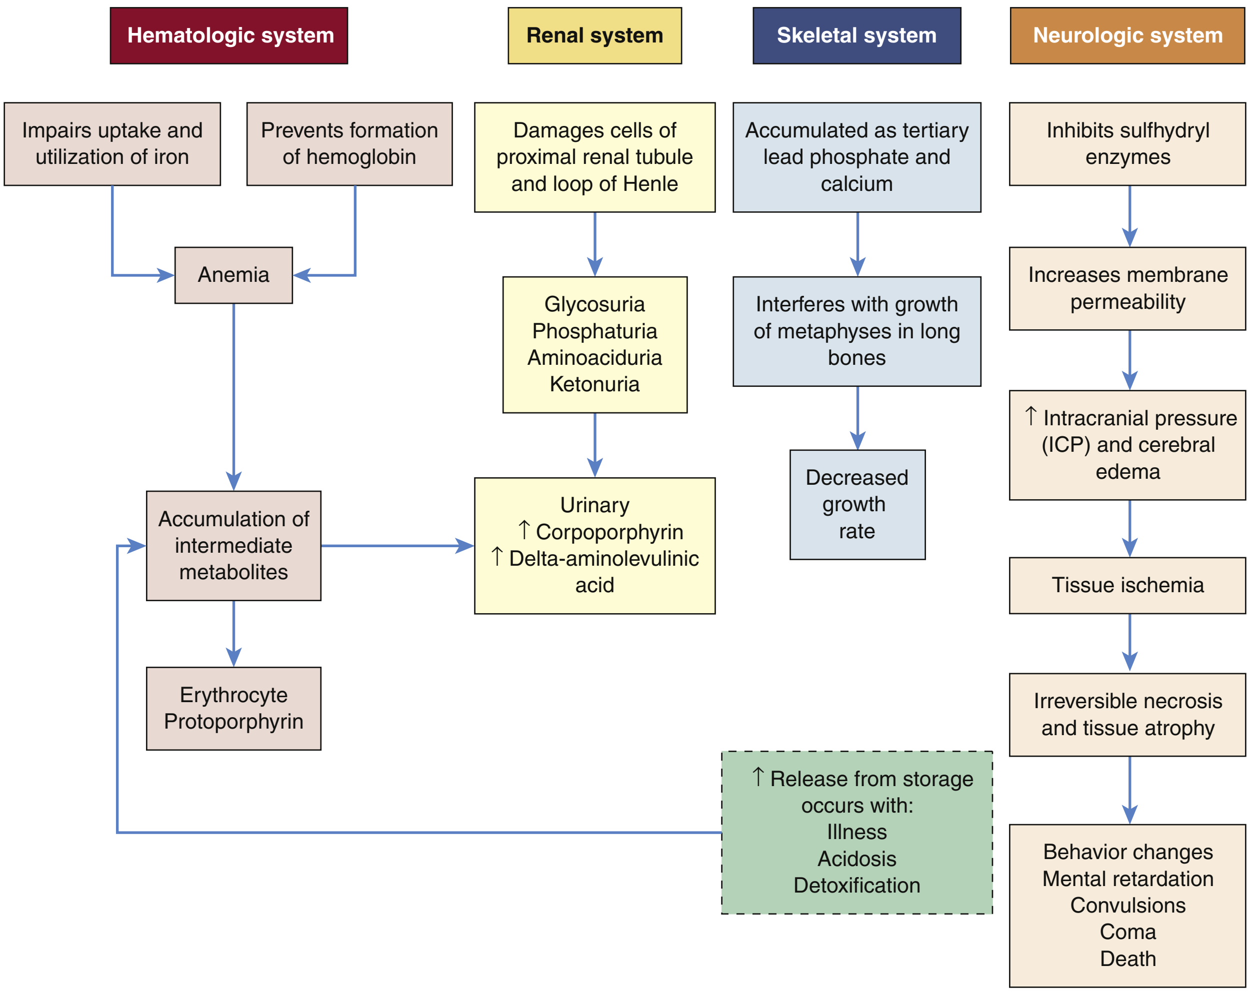

FIGURE 20-14 Systemic Effects of Increased Lead Absorption in Children.

TABLE 20-6 CAUSES OF BACTERIAL MENINGITIS

AGE GROUP	COMMON BACTERIAL PATHOGENS
Newborns	Group B *Streptococcus, Escherichia coli, Listeria monocytogenes*
Infants and children	*Streptococcus pneumoniae, Neisseria meningitidis, Haemophilus influenzae* type b
Adolescents and young adults	*Neisseria meningitidis, Streptococcus pneumoniae*

including 500 deaths.[59] About half of these cases occurred in children younger than 18 years of age. The microorganisms accountable for this illness are summarized in Table 20-6.

The introduction of conjugate vaccines against *Haemophilus influenzae* type B, *Streptococcus pneumoniae,* and *Neisseria meningitidis* (meningococcus) has decreased the incidence of bacterial meningitis.[60] Vaccines for serogroup B *N. meningitidis* are not yet available but clinical trials are in progress.[61] Meningitis is still prevalent in countries without access to the vaccine.[59] (Note that although many families are worried about giving their infants vaccines, the change in incidence of many illnesses has been drastically reduced with their introduction; bacterial meningitis is just one example.)

Group B *Streptococcus* causes lethal meningitis and sepsis in neonates and is transmitted to the child from the mother's birth canal. *S. pneumoniae* is the most common microorganism in children 1 to 23 months of age. Staphylococcal or streptococcal meningitis can occur in children of any age but shows a predilection for children who have had neurosurgery, skull fracture, or a complication of systemic bacterial infection. Infections that originate in the middle ear, sinuses, or mastoid cells also may lead to *S. pneumoniae* infection in children. Children who have sickle cell disease or have undergone a splenectomy are particularly at risk for infection.[62] *Escherichia coli* and group B streptococcus are the most common causes of meningitis in the newborn period. The second most common microorganism causing bacterial meningitis, particularly in children younger than 4 years, is *Neisseria meningitidis* (meningococcus) and it has the potential to occur in epidemics. Approximately 2% to 5% of healthy children are carriers of *N. meningitidis*. As the incidence of *N. meningitidis* infection increases in adolescence and with crowding, such as in dormitories and among military personnel, it is recommended that all individuals 11 to 18 years of age receive two immunizations against this pathogen.[63]

PATHOPHYSIOLOGY. The cause of bacterial meningitis is related to the age of the child and to a number of factors that predispose the child to bacterial infection or that alter the child's response to an invading microorganism. *Staphylococcus aureus* or *Pseudomonas aeruginosa* may develop in the child with cystic fibrosis or severe burns. (See Chapter 10 for further discussion of bacterial virulence and infection.) Any microorganism may be pathogenic under the appropriate circumstances in a given individual.

Pathogens enter the nervous system by direct extension (i.e., paranasal sinuses or mastoid cells) or, more commonly, by hematogenous spread (see Figure 18-32). Infection may travel through the blood to the meninges in children with infective endocarditis, pneumonia, or thrombophlebitis, or to those who have undergone recent procedures or been severely burned. Many bacteria are very successful at evading normal defenses (see Chapter 10). Pathogens cross the blood-brain barrier, enter the cerebrospinal fluid, and multiply. Bacterial toxins increase cerebrovascular permeability, causing alterations in blood flow and edema. Thrombosis and increased ICP can cause neurologic damage. As a result of meningitis, thickened meninges and fibrous exudate in the subarachnoid space at the base of the brain can obstruct CSF resorption, resulting in nonobstructing hydrocephalus. Untreated, this can cause brainstem herniation and death.

CLINICAL MANIFESTATIONS. Acute bacterial meningitis often is preceded by an upper respiratory tract or a gastrointestinal tract infection. Inflammation leads to the general symptoms of fever, headache, vomiting, and irritability and the CNS symptoms of photophobia, nuchal and spinal rigidity, decreased level of consciousness, and seizures. Irritation of the meninges and spinal roots causes pain and resistance to neck flexion (nuchal rigidity), a positive Kernig sign (resistance to knee extension in the supine position with the hips and knees flexed against the body), and a positive Brudzinski sign (flexion of the knees and hips when the neck is flexed forward rapidly). With severe meningeal irritation the child may demonstrate opisthotonic posturing (rigid arching of the back with the head extended). Infants may have bulging fontanels. Meningococcal meningitis can produce a characteristic petechial rash.

EVALUATION AND TREATMENT. A definitive diagnosis is made by examination of CSF obtained from a lumbar puncture. The principles of treatment are similar to those followed for adults (see Chapter 18) and are based on the culture results in which the causative microorganism is identified. Empirical antibiotic therapy should be initiated and continued until CSF cultures are negative[64] or changed if the empirical therapy is not correct for the bacteria cultured from the CSF. Bacterial lysis induced by antibiotics can cause subarachnoid inflammation; the severity can be reduced with corticosteroid treatment.[65] The factors that influence outcomes are the age of the child (mortality is highest in infants younger than 1 year), the infective microorganisms (the lowest mortality is in meningococcal meningitis and the highest in meningitis caused by gram-negative enteric microorganisms), and the duration and extent of inflammation before treatment. Approximately 8% of children with *H. influenzae* meningitis die; 35% of the survivors have serious and permanent sensory or motor dysfunction caused by pressure on the peripheral nerves during the early phases of the illness. Approximately 5% of the children who survive meningitis have hearing deficits; 10% to 15% have cerebral damage, hydrocephalus, motor deficits, or sensory impairments.[66,67]

Viral Meningitis. The hallmark of **viral meningitis** is a mononuclear response in the CSF and the presence of normal blood glucose level, although the findings with aseptic meningitis are similar to those seen in bacterial meningitis in some cases.

The clinical manifestations are similar to those in bacterial meningitis, although usually milder. Isolation of the specific virus is difficult. An exception is when the virus responsible is the herpes simplex virus, which can occur in infants after

exposure to the herpes virus type 2 in the birth canal, or sporadic cases caused by herpes virus type 1, which is the type that causes cold sores. It is possible to test for the herpes virus and, unlike most of the other viruses, there is a specific antiviral medication.[68] When a child has symptoms of bacterial or viral meningoencephalitis, antibiotic and antiviral treatments are administered until the cause is determined.

Human Immunodeficiency Virus Encephalopathy. Human immunodeficiency virus type 1 (HIV-1) causes a syndrome called HIV-1 encephalopathy (see Chapter 10 for details of HIV infection which results in developmental delays and impaired brain growth in children not directly related to opportunistic infections in the brain).

PATHOPHYSIOLOGY. The CNS is a distinct reservoir for HIV-1 but the pathogenesis of HIV encephalopathy in children is not clearly understood. HIV-1 invades the CNS early in infection, primarily through infected monocytes/macrophages and CD4+ T lymphocytes. The presence of viral products and inflammatory mediators and overstimulation of the *N*-methyl-D-aspartate–type receptor system lead to neuronal injury and death, particularly in the immature brain, and this is thought to cause the HIV-1 encephalopathy.[69]

CLINICAL MANIFESTATIONS. The 1994 classification from the Centers for Disease Control and Prevention (CDC) requires one of the following progressing findings to be present for at least 2 months,[70] in the absence of a concurrent illness other than HIV that could explain the findings:

1. Failure to attain or loss of developmental milestones, or loss of intellectual ability, verified by standard developmental scale or neuropsychologic tests
2. Impaired brain growth or acquired microcephaly demonstrated by head circumference measurements or brain atrophy established by CT or MRI, with serial imaging required in children younger than 2 years
3. Acquired symmetric motor deficits manifested by affecting a child 1 month of age or older

The onset of progressive encephalopathy may be a prognostic indicator of a poor outcome and it may be difficult to completely differentiate the effects of HIV infection on the CNS from the effects of prenatal and perinatal exposure. In addition, other insults may accompany HIV in a young child and affect growth and development, such as drug exposure, prematurity, and chronic illness.

EVALUATION AND TREATMENT. A definite diagnosis of HIV is made by patient history, viral culture, and clinical manifestations. Monitoring CD8+ T lymphocytes and monocytes, in addition to CD4+ T lymphocytes, has been suggested for predicting risk for progressive encephalopathy. Decreases in CD8+ T lymphocytes diminish defenses against viral infection and facilitate infected monocytes to cross the blood-brain barrier. In general, treatment is focused on preservation and maintenance of the immune system, aggressive response to opportunistic infections, and support and relief of symptomatic occurrences by administration of highly active antiretroviral therapy (HAART). (HIV treatment is discussed in Chapter 10.) Progressive HIV encephalopathy is an infrequent and reversible complication of HIV infection because the disease responds to HAART.[71,72]

BOX 20-3 STROKE IN CHILDREN

- Risk factors different than those for adult (i.e., hypertension, atherosclerosis, diabetes, smoking, obesity)
- Important risk factors (causes) include:
  Ischemic stroke—heart disease or cardiac disorders (most common), blood disorders, clotting or coagulation disorders, sickle cell anemia, infections (chickenpox, meningitis, encephalitis, moyamoya disease), and arterial dissection
  Hemorrhagic stroke—vascular malformations, including arteriovenous malformations (AVMs) and aneurysms; blood disorders, including thrombocytopenia and leukemia; and malignancy, including intracranial tumors
- Vascular occlusion occurs more often in intracranial vessels, including internal carotid, middle cerebral, and basilar arteries; infarcts more often limited to deep regions of the cerebral hemispheres, mostly basal ganglion and internal capsule areas
- Intracerebral hemorrhage and subarachnoid hemorrhage account for a much higher percentage of strokes in children

From *Causes and outcome in childhood stroke*. Available at www.pediatricstroke.org/child_stroke.htm. Accessed April 4, 2013.

CEREBROVASCULAR DISEASE IN CHILDREN

Perinatal Stroke

Perinatal arterial ischemic stroke is estimated to occur in 1 in 4000 live births and is a leading cause of perinatal brain injury, cerebral palsy, and lifelong disability.[73] Children with perinatal stroke may not be diagnosed until later in infancy or childhood when it becomes apparent that the child is not moving one side of the body as much as the other. Early signs may consist of the family noticing that one hand is preferred over the other at an early age—typical "handedness" does not usually occur until 16 to 18 months of age—or one foot is dragging. An MRI is often performed at this point and is most likely to show evidence of a previous middle cerebral artery stroke. The clinical pattern that usually results from this type of stroke is contralateral hemiplegia with the arm more affected than the leg. Children with hemiplegia caused by perinatal stroke (hemiplegic CP) are prone to seizures although generally do well cognitively. Testing for abnormalities in blood-clotting mechanisms, such as antithrombin enzyme activity, protein C and protein S deficiencies, or abnormal factor V Leiden, is often performed in children with prenatal stroke. Although often normal, abnormalities in these clotting mechanisms should be assessed because they may make the child prone to further vascular events.

Childhood Stroke

Childhood stroke occurs in about 1 to 13 per 100,000 live births (Box 20-3).[74]

Ischemic Stroke

PATHOPHYSIOLOGY. Ischemic stroke is rare in children and may result from embolism, arteriopathy, or, rarely, sinovenous thrombosis leading to a decreased flow of blood and oxygen to areas of the brain. Children with arterial ischemic stroke do not have the typical adult risk factors of atherosclerosis and hypertension. Approximately 40% of children with ischemic stroke

have no identifiable underlying risk factors. Sickle cell disease, cerebral arteriopathies, and cardiac anomalies are the most common disorders that lead to **arterial ischemic stroke.**[75,76] Treatment options for children with stroke are investigational.[77,78]

Hemorrhagic Stroke

PATHOPHYSIOLOGY. Congenital cerebral arteriovenous malformations are the most common cause of intracranial bleeding and hemorrhagic stroke in children.[79] Hemorrhagic stroke may result from vascular anomalies that lead to rupture, such as aneurysm, or from congenital arteriovenous malformation; the cause of hemorrhagic stroke is more likely to be found than the cause of ischemic stroke. The rupture of a cerebral aneurysm is rare in children younger than 19 years. Intraventricular hemorrhage associated with premature birth is related to immature blood vessels and unstable blood pressure. There is a high risk of developing posthemorrhagic hydrocephalus.[80,81]

Moyamoya disease is a rare, chronic, progressive stenosis of the anterior circulation, such as the internal carotid arteries and middle cerebral arteries. Obstruction of arterial flow to the brain occurs slowly, allowing time for new blood vessels to form and increase collateral blood flow to ischemic areas. *Moyamoya* is a Japanese term that means "puff of smoke," which describes the vascular appearance on cerebral angiogram. Moyamoya vasculopathy may be idiopathic or may be associated with certain genetic or metabolic syndromes, or it can develop as a result of cranial radiation therapy. Complications are developmental delay/intellectual disability, and cerebral hemorrhage.[82] Treatment is surgical bypass of the ischemic region.

CLINICAL MANIFESTATIONS. Symptoms of ischemic or hemorrhagic stroke may include degrees of hemiplegia (flaccid, spastic), weakness, seizures, headache, high fever, nuchal rigidity, hemianopia, sensory changes, facial palsy, and temporary aphasia.

EVALUATION AND TREATMENT. Diagnosis of cerebrovascular disease is made through a series of tests, including imaging studies.[83] History of evolving symptoms and medical history are of vital importance in attaining an accurate diagnosis of stroke etiology, although causative factors often cannot be determined. Prophylactic medications may be prescribed in those children who have suffered an ischemic stroke (e.g., from aspirin). Arteriovenous malformations that may leak and cause hemorrhagic stroke vary in size, location, and symptoms and these factors determine treatment. If a malformation is present, treatment options include surgery, radiation therapy, and embolic occlusion of the malformation[84] (see Chapter 18).

Excellent collateral circulation in the child's brain allows for more rapid recovery of motor function, as compared to adults. The developing brain, however, may suffer more global, long-term effects leading to intellectual disability, behavior disorders, and seizures.[85]

EPILEPSY

Epilepsy is the occurrence of seizures. The incidence of epilepsy varies greatly with age, geographic location, and study design. The incidence is estimated to be 40 to 95 cases per 100,000, with highest onset during the first 12 months of life. Incidence then decreases with age. Approximately 181,000 persons in the United States are newly diagnosed each year.[86,87]

PATHOPHYSIOLOGY. Seizures are caused by abnormal discharge of electrical activity within the brain. When a sufficient number of neurons become overexcited, they discharge abnormally, which sometimes results in clinical manifestations (seizures). Dysregulation of inhibitory $GABA_A$ neurotransmission with imbalance of excitatory and inhibitory mechanisms is speculated to be a cause of early childhood seizures. Dysregulation of other types of voltage- and ligand-gated ion channels (i.e., sodium, calcium, potassium, and chloride) is associated with genetically determined epileptic syndromes.[88,89] If seizures develop, the specific physical activity that occurs depends on the origin of the electrical activity and its extent within the brain. If a child has more than one unprovoked seizure, that child is said to have **epilepsy,** although there are a few exceptions—one example being febrile seizures. Either seizures can be symptoms of an underlying disorder (e.g., meningitis or a brain tumor) or seizures may, themselves, be diseases; the latter may have a genetic or a familial predisposition (for instance, childhood absence epilepsy and juvenile myoclonic epilepsy) (see Tables 17-16 and 17-17). Nearly half of childhood epilepsy is of unknown etiology.[90,91]

Seizures and seizure patterns may change as a child grows and develops. The differences between the immature and mature nervous systems may help explain the changing patterns of clinical seizures with age. For example, febrile seizures manifest in children 6 months to 3 years of age and juvenile myoclonic epilepsy is first noted in adolescence. The immature nervous system has a reduced capacity for sustaining well-organized seizures and, therefore, infants are prone to have seizures that occur only in small parts of the body compared to generalized tonic-clonic seizures in older children. This is because intracortical connections are poorly developed in children and the sending of impulses throughout the cortex is limited. At the cellular level, neurons are less capable of firing in repetitive high-frequency bursts. The excitatory output of a seizure focus is further diminished because the affected neurons do not act synchronously. In addition, changing neurotransmitters, immaturity of cells, and ongoing postnatal factors affect seizure expression in children.

During the newborn period, asphyxia, intracranial hemorrhage, CNS infections, injury, electrolyte imbalances, and inborn errors of metabolism may cause seizures, although often, despite an extensive search for a cause, the etiology remains unknown. Infants and children may have seizures based on earlier brain damage (e.g., cerebral palsy) or may manifest specific epilepsy syndromes (childhood absence epilepsy, Lennox-Gastaut syndrome). Adolescents may have seizures caused by juvenile myoclonic epilepsy or because of other underlying conditions. There is a peak new seizure occurrence in adolescents with autism for unknown reasons.

CLINICAL MANIFESTATIONS. The clinical manifestations at the time of the seizures vary depending on the primary cause and the extent and involvement of abnormal electrical discharges within the neuronal tissue. Because of the diversity and

complexity that seizure activity invariably displays, an international classification system was adopted. This classification system groups seizures with similar clinical manifestations (see Table 17-16). Its general purpose is to assist the clinician with the type of evaluation needed, the identification of the most appropriate treatment, and the evaluation of the individual's response to treatment.

The international classification system of epilepsy contains three major groupings: (1) partial seizures, (2) generalized seizures, and (3) unclassified epileptic seizures. Each major grouping is then divided into subsets on the basis of clinical manifestations and electroencephalogram (EEG) findings.

Partial seizures are characterized by seizure activity that begins in and usually is limited to one part of either the left or the right hemisphere. A *simple partial seizure* refers to seizure activity that occurs without loss of consciousness. A *complex partial seizure* refers to seizure activity that occurs with impairment of consciousness. The clinical activity displayed by the individual is contingent on the particular part of the cortex from which the seizure is generated. For example, partial seizures may result in abnormal motor activity, such as twitching or loss of tone, or sensory changes, such as tingling or numbness.

Both simple and complex partial seizures may evolve into a generalized tonic-clonic, tonic, or clonic convulsion. Partial seizures are more likely to be caused by an abnormality in a specific part of the brain, and thus brain imaging is usually performed in children whose seizures have started in a localized manner, even if they generalize later. Possibilities include brain tumors, small areas of localized brain damage, and other causes.

Generalized seizures are those in which the first clinical manifestations indicate that the seizure activity starts in or involves both cerebral hemispheres. Because both hemispheres are involved, the clinical manifestations are almost always bilateral. Consciousness may be impaired in this grouping of seizures. The clinical manifestations may include convulsive activity (tonic-tonic, tonic, or clonic activity) or nonconvulsive activity (absence seizures). Generalized seizures are more likely than partial seizures to have a genetic component; although the genetics of some of the epilepsy syndromes have been identified, many appear to have a multifactorial genetic etiology.[92-94]

Childhood absence epilepsy (also called petit mal seizures or nonconvulsive epilepsy) is a type of generalized epilepsy. The age of onset is 4 to 10 years. The genetic causes are unknown and probably multifactorial; it also can be sporadic. Mutations in inhibitory $GABA_A$ receptor subunit genes are associated with absence seizures. The seizures are initiated at a cortical site and spread to other cortical areas and to the thalamus. The EEG shows a characteristic 3- to 4-Hz spike-wave discharge.[95] The characteristic absence seizure is of sudden onset and sudden termination with impairment of consciousness and unresponsiveness usually lasting less than 10 seconds with no residual deficits. There is interruption of ongoing voluntary activity accompanied by staring, mild eyelid fluttering, or myoclonic jerks. There is no aura. Seizures may be provoked by about 3 minutes of hyperventilation. Hundreds of seizures can occur per day, disrupting school work and socialization. Antiepileptic drugs provide beneficial treatment.[96,97]

Unclassified epileptic seizures are seizure disorders that do not fit neatly into a classified grouping. These seizures characteristically have a wide variety of abnormal clinical activity. Examples of this activity include rhythmic eye movements, chewing, and swimming movements. These activities are commonly seen in neonatal seizures.[98]

Epilepsy Syndromes

In addition to the seizures classified by the international system, there are several types of epileptic syndromes. These are seizure disorders that display a group of signs and symptoms that occur collectively and that characterize or indicate a particular condition. Several syndromes associated with epilepsy occur in infants and children. The four syndromes that occur most often are febrile seizures, infantile spasms, Lennox-Gastaut syndrome, and juvenile myoclonic epilepsy.

Febrile seizures are defined as seizures associated with fever in the absence of central nervous system infection. They are divided into two types: simple febrile seizures and complex febrile seizures. **Simple febrile seizures** occur in 2% to 5% of children. They are benign and the most common childhood seizure.

The pathogenesis of simple febrile seizures is unknown. A familial incidence of simple febrile seizures indicates a genetic predisposition to the problem. Factors that contribute to susceptibility include age, degree and rate of temperature elevation, and nature of the particular fever-inducing illness. Any disorder producing a high fever may provoke benign febrile seizures in susceptible children.

The following characteristic features distinguish simple febrile seizures from complex seizures precipitated by fever:

1. Simple febrile seizures are rare before 9 months of age or after 5 years of age.
2. The convulsion occurs with a rise in temperature greater than 39° C (102.2° F).
3. An acute respiratory tract or ear infection usually is present, with no evidence of CNS infection or inflammation.
4. Most seizures occur during the first 24 hours of the illness.
5. The convulsion is short (15 minutes or less), generalized, and predominantly tonic.
6. Interictal (period between seizures) EEG is normal.
7. The seizure usually does not recur during the same infection.
8. No acute systemic metabolic disorder is present.

Complex febrile seizures have characteristic features similar to those of simple febrile seizure except that (1) they have a longer duration than do benign febrile seizures, usually longer than 15 minutes; (2) they have focal characteristics; and (3) they usually occur more than once in a 24-hour period. Complex febrile seizures are considered a risk factor for the development of epilepsy.[99]

Infantile spasms (also known as West syndrome) are a severe form of epilepsy characterized by a variety of clinical manifestations.[100] The infant may have episodes of sudden flexion or extension movements involving the neck, trunk, and extremities. Infantile spasms in some children are caused by underlying brain abnormalities such as intrauterine stroke

or tuberous sclerosis, whereas others may be caused by mutations in several genes.[101] Clinical manifestations of the resulting spasms may range from subtle head nods to violent body contractions, commonly referred to as *jackknife seizures*. Onset of infantile spasms usually is between 4 and 8 months of age and may be idiopathic or may occur in response to a CNS insult.[102] An EEG will display the classic hypsarrhythmic chaotic pattern of epileptic discharges on a slow, disorganized background. After infantile spasms begin, there is usually a typical clinical course. The "spasms" usually occur in clusters and transpire 5 to 150 times per day. They are usually worse when the infant is waking up or falling asleep. Once begun, the seizure activity increases in intensity and severity over time. Invariably, a loss of developmental milestones and disability is associated with this syndrome. A short-term course of high-dose oral corticosteroids (usually prednisolone) is effective in many cases of infantile spasms.[103]

Infantile spasms are present in about 30% of children with **tuberous sclerosis complex (TSC).**[104] TSC develops from mutations in hamartin *(TSC1)* or tuberin *(TSC2)* genes. *Tubers* are cortical developmental malformations in the brain; they also form in other organs. Epilepsy associated with TSC is often difficult to treat. Vigabatrin, which may cause vision defects, is the medication of choice for children with infantile spasms attributable to tuberous sclerosis because it seems to be particularly effective in these children.[105]

Lennox-Gastaut syndrome is an epileptic syndrome characterized by an onset of seizures early in childhood; it occurs in males more often than females and begins between 1 and 8 years of age. This syndrome includes a variety of generalized seizures—predominantly tonic-clonic, atonic (drop attacks), akinetic, absence, and myoclonic activity and a specific pattern on EEG (slow spike and wave). Seizures associated with this syndrome are usually very difficult to treat; children may be prescribed multiple medications and alternate therapies, such as a ketogenic diet or a vagal nerve stimulator. Epilepsy surgery may be necessary. Although children may be developmentally on track when manifestations of this syndrome begin, development is usually affected and the future manifestation of intellectual disability is common.[106]

Juvenile myoclonic epilepsy is a primary, generalized epilepsy that usually affects adolescents and young adults. Although not fully understood, the genetics are in the process of being elucidated. It is a relatively benign form of epilepsy involving myoclonic jerks of the neck, shoulders, and arms as well as generalized tonic-clonic seizures. The seizures may occur singularly or repetitively. This form of epilepsy is commonly associated with a normal neurologic examination, normal intelligence, and a family history of seizures. It is often underdiagnosed.[107] Children with this syndrome will usually need to take medications for life.

EVALUATION AND TREATMENT OF EPILEPSY. Diagnoses of epilepsy and seizure classification are based on history, clinical presentation, physical and developmental examination, and the record of milestone achievements. The first step in the evaluation is to rule out other entities that may appear to be seizures; examples include breath-holding spells and syncope. If the diagnosis of seizure is confirmed, evaluation and testing include an EEG to isolate the focus or origin and involvement of seizure activity and an MRI brain scan to investigate the presence of a lesion or abnormal tissue if the seizure semiology (the appearance of the seizure to the observer) or the EEG shows a focal onset of abnormal electrical activity. Depending on associated symptoms, a complete metabolic workup or genetic testing, or both, may be performed to explore the possibility of deficiency or malabsorption.[108]

Specific treatment for epilepsy is directed at the particular clinical manifestations or syndrome of seizure activity and its underlying causes. Treatment usually begins with the use of anticonvulsant medications. Although seizures in most children are controlled by one medication, the epileptic pattern and clinical course may require more than one drug to control the seizures.[109] A ketogenic diet may be effective as a supplement treatment for epilepsy that is difficult to control with drugs (see Nutrition & Disease: Ketogenic Diet in Children with Epilepsy).

Surgery provides treatment for some forms of epilepsy that cannot be controlled with drugs. As with medical interventions, surgical therapy focuses on the particular clinical manifestations of seizure activity. Surgical interventions include resection of the epileptogenic zone of brain tissue (i.e., the temporal lobe for partial seizures or partial or complete severing of the corpus callosum for intractable generalized epilepsy). Children with intractable epilepsy have shown some benefit from using a vagal nerve stimulator.[110]

NUTRITION & DISEASE

Ketogenic Diet in Children with Epilepsy

The goal of the ketogenic diet is to maintain a state of ketosis, which appears to facilitate reduced seizure frequency and severity for difficult-to-control seizures in children. The diet may be helpful to children who do not respond to conventional therapy or have intolerable side effects. Seizure reduction can occur within 5 to 14 days of initiating the diet and usually within 6 months. Two basic approaches to the ketogenic diet are: (1) a traditional approach with four parts fat to one part carbohydrate/protein in the diet, and (2) the medium-chain triglyceride (MCT) approach, in which MCTs make up about 50% to 70% of the diet. Either diet may be unpalatable and difficult to follow, particularly if the child has free access to food. Carbohydrates can be added by 5-g increments after 3 to 6 months if there has been no seizure activity, provided ketosis is maintained. Both dietary approaches include adequate protein for growth. A medium-chain triglyceride diet, modified Atkins diet, and low glycemic index treatment can also induce ketosis and does not restrict protein, fluid, or calories. The mechanisms are not clearly understood, but enhanced mitochondrial respiration, adenosine triphosphate (ATP) production, and reduced reactive oxygen species formation may influence the dynamics of excitatory and inhibitory neurotransmitter systems in the brain and may be neuroprotective. Side effects can include acidosis, kidney stones, hypoglycemia, gastrointestinal distress, dehydration, lethargy, and poor growth. Most side effects are treatable.

Data from Groomes LB et al: *J Child Neurol* 26(2):160–165, 2011; Jóźwiak S, Kossoff EH, Kotulska-Jóźwiak K: *Neurol Neurochir Pol* 45(4):370–378, 2011; Kessler SK et al: *Epilepsy Behav* 22(1):17–22, 2011; Lee PR, Kossoff EH: *Epilepsy Behav* 21(2):115–121, 2011; Wang HS, Lin KL: *Biomed J* 36(1):16–17, 2013.

For febrile seizures, the cause of the child's fever should be determined and meningitis should be considered in the differential diagnosis. Phenobarbital may be an effective medication for preventing recurrence of simple febrile seizures in selected children who have frequent, prolonged febrile seizures but it is rarely used because it needs to be given daily to be effective.[111]

Status epilepticus is defined as the state of continuing or recurring seizure activity in which the recovery from seizure activity is incomplete. Seizure activity is unrelenting and usually lasts for 30 minutes or more. Any one of the seizure activities discussed can evolve into status epilepticus. Status epilepticus is a medical emergency that requires immediate intervention. Most emergency departments have a structured algorithm of how to respond to a child in status epilepticus.[112]

The prognosis for epilepsy greatly depends on the type and severity of the disorder; the age of onset; coexisting factors; and the type and success of medical, surgical, and nutritional therapy. Many children will become seizure free or have sustained seizure remission after initiation of treatment.[113]

CHILDHOOD TUMORS

Brain Tumors

Brain tumors are the most common solid tumor and the second most common primary neoplasm in children, second only to leukemia. Approximately 45% of primary brain tumors in children are nonmalignant.[114] Overall, primary brain tumors account for nearly 20% of all childhood cancers, with an annual incidence of 3.82 per 100,000 for malignant tumors and 3.44 per 100,000 for nonmalignant tumors in the United States; approximately 4300 new cases will be diagnosed in 2013.[115] Brain tumors remain the leading cause of death from disease in children ages 1 to 15 years.[116]

Primary brain tumors arise from brain tissue and do not metastasize outside the brain. The cause of brain tumors is largely unknown.

PATHOPHYSIOLOGY. Most childhood brain tumors arise from glial tissue, the supportive tissue of the brain. Tumors also may originate in other tissue such as nerve cells, cranial nerves, the pineal and pituitary glands, blood vessels, or neuroepithelium. Brain tumors are classified by the tissue and location from which they arise. Because a uniform pathologic nomenclature has yet to be established, inconsistencies occur when statistical data are compared.

Two thirds of all pediatric brain tumors are found in the posterior fossa region of the brain. This area also may be referred to as infratentorial because it is located below the tentorium. The tentorium is the layer of dura mater that separates the cerebellum from the hemispheres or cerebrum. Thus the area above the tentorium is referred to as the *supratentorial region.* Approximately one third of childhood brain tumors are located in the supratentorial space, whereas in the adult population two thirds of brain tumors are located in the supratentorial region and only one third in the infratentorial region. The types and characteristics of childhood brain tumors are summarized in Table 20-7.

TABLE 20-7 BRAIN TUMORS IN CHILDREN

TYPE	CHARACTERISTICS	TREATMENT	PROGNOSIS
Astrocytoma	Arises from astrocytes, often in cerebellum or lateral cerebral hemisphere Slow growing, solid or cystic Often very large before diagnosed Varies in degree of malignancy	*Cerebellar astrocytoma* Surgery; possibly curative Radiation and chemotherapy not proved successful but may delay recurrence *Cerebral astrocytoma* Surgery used if resection is possible Radiation useful for all grades of astrocytoma Chemotherapy beneficial in higher grade tumors but further study required	*Cerebellar astrocytoma* 90-100% 5-year survival rate if pilocytic type (most common); if tumor recurs, it does so very slowly *Cerebral astrocytoma* 75% 5-year survival rate with lower grade tumors 20% 5-year survival rate if high-grade tumor
Optic pathway glioma	Arises from optic chiasm or optic nerve (association with neurofibromatosis type 1) Slow-growing, low-grade astrocytoma	In setting of visual impairment or progression (increase in size), chemotherapy is usual initial treatment Radiation therapy for tumors that progress or recur in spite of chemotherapy Surgery for large tumors, or hydrocephalus, or other complications; rarely for diagnosis	100% 5-year survival when confined to optic nerve 70% 5-year survival for tumor progression beyond optic chiasm
Medulloblastoma (infiltrating glioma)	Often located in cerebellum, extending into fourth ventricle and spinal fluid pathway Can extend outside CNS Rapidly growing malignant tumor	Type of treatment is age and tumor type dependent Surgery, primarily as partial resection to relieve increased intracranial pressure and "debulk" tumor Radiation as primary treatment; may include spinal radiation Chemotherapy showing some promise in conjunction with craniospinal radiation	65-85% 5-year survival rate depending on stage/type
Brainstem glioma	Arises from pons Numerous cell types Compresses cranial nerves V through X	Surgery, resection occasionally possible Radiation, primarily palliative treatment Chemotherapy not yet proven beneficial, but new protocols being studied	20-40% 5-year survival rate

Continued

TABLE 20-7 BRAIN TUMORS IN CHILDREN—cont'd

TYPE	CHARACTERISTICS	TREATMENT	PROGNOSIS
Ependymoma	Arises from ependymal cells lining ventricles Circumscribed, solid, nodular tumors	Tumor possibly indolent for many years Surgery rarely curative; risk of resecting an infratentorial tumor too great Radiation for palliation (current controversy over whether local or craniospinal radiation is best) Chemotherapy used for recurrent disease but with disappointing results	20-80% 5-year survival rate dependent on total resection
Craniopharyngioma	Arises near pituitary gland, optic chiasm, and hypothalamus Cystic and solid tumors that affect vision, pituitary, and hypothalamic functions	Surgery possibly successful when complete resection is performed (partial resection usually requires further treatment) Radiation after partial surgical resection Chemotherapy not commonly used	80-95% 5-year survival rate

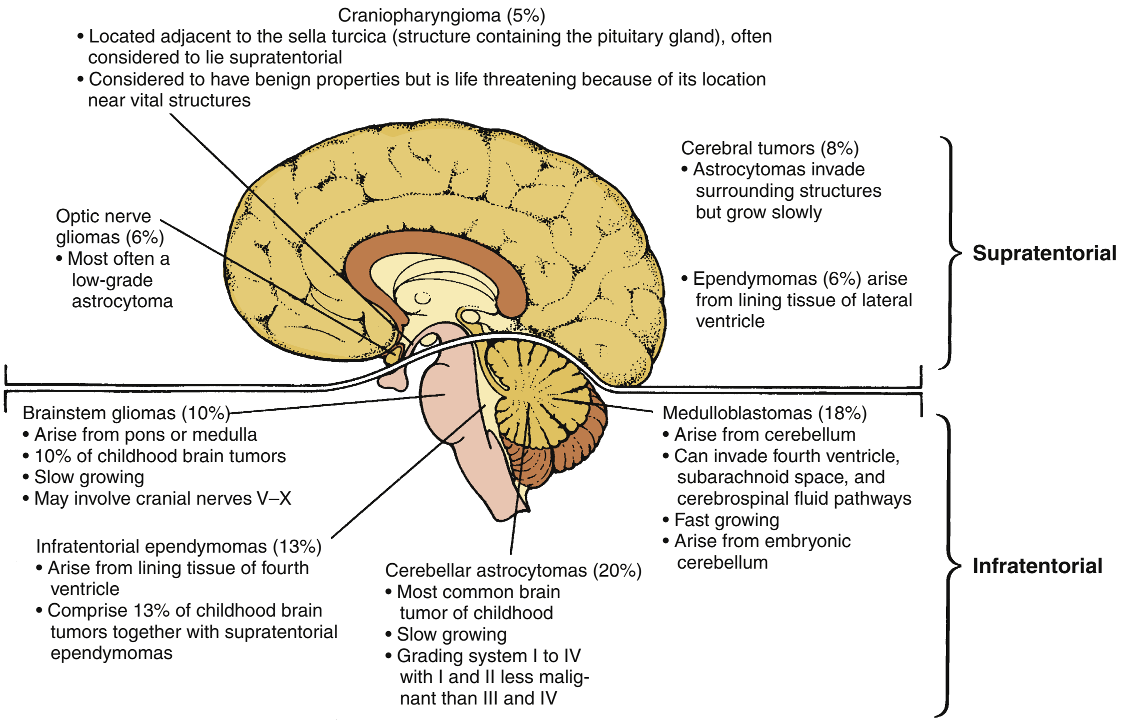

FIGURE 20-15 Location of Brain Tumors in Children.

Brain tumors, by virtue of their location, have unique characteristics that distinguish them from tumors found elsewhere in the body. A number of brain tumors in children may be considered histologically benign yet clinically malignant and life threatening because of their location. For example, a tumor located in the brainstem region may appear benign under the microscope, but the clinical presentation threatens and all too often overrides the vital functions of the brainstem.

Types

Medulloblastoma, ependymoma, gliomas (astrocytoma, brainstem glioma, and optic nerve glioma), and craniopharyngioma comprise approximately 75% to 80% of all pediatric brain tumors.[115] The location of brain tumors in children is illustrated in Figure 20-15; specific characteristics, treatment strategies, and prognoses are listed in Table 20-7.

CLINICAL MANIFESTATIONS. The location of the brain tumor, cell type, and rate of growth dictate the presenting signs and symptoms (discussed in greater detail with each particular brain tumor type). The ability of the brain and intracranial cavity to compensate for tumor growth is directly related to the rate of its growth. This compensatory mechanism allows the components of the intracranial space (blood, brain, and CSF) to adapt temporarily to slow changes in increased intracranial pressure. Therefore slow-growing tumors can grow to enormous size before signs and symptoms are apparent. Conversely, fast-growing tumors allow little time for compensation of the space-occupying lesion, and clinical symptoms occur quickly. Clinical symptoms may range from changes in personality to paralysis, depending on the location of the tumor.

Signs and symptoms of brain tumors in children vary from generalized and vague to those that are localized and related

specifically to the anatomic area. If the tumor is located in the posterior fossa region, the fourth ventricle may become blocked, which leads to hydrocephalus and signs of increased ICP. Increased ICP also may occur because of the additional mass volume within the fixed container of the skull vault. The symptoms of increased ICP include headache, vomiting, lethargy, and irritability. If a young child complains of a headache, a thorough investigation should take place because headache is an uncommon complaint in young children. Headache caused by increased ICP usually is worse in the morning and gradually improves during the day when the child is upright and venous drainage is enhanced. Frequency of headache and other symptoms worsens as the tumor grows. A headache related to increased ICP generally occurs because of expansion of the lateral ventricle and cerebral hemisphere, which causes a stretching of the pain-sensitive dura mater. Irritability or possible apathy and increased somnolence also may result from increased ICP. Like headache, vomiting occurs more commonly in the morning. It frequently is not preceded by nausea and may become projectile, differing from a gastrointestinal disturbance in that the child may be ready to eat immediately after vomiting. Other signs and symptoms that can accompany increased ICP include increased head circumference with bulging fontanel in children younger than 2 years, cranial nerve palsies, and papilledema.

Localized findings relate to the degree of disturbance in physiologic functioning in the area where the tumor is located (see Table 18-14). Infratentorial tumors exhibit localized signs of impaired coordination and balance, including ataxia, gait difficulties, truncal ataxia, and loss of balance. A **medulloblastoma** is an embryonal tumor and the most common childhood malignant tumor. It occurs as a fast-growing, invasive tumor that develops in the vermis of the cerebellum and may extend into the fourth ventricle.[117] Angiogenesis is the hallmark of progressive medulloblastomas. The **ependymoma** develops in the fourth ventricle and arises from the ependymal cells that line the ventricular system. The histologic appearance of the ependymoma varies, which makes the treatment course and prognosis difficult to establish. They may contain cysts and areas of calcification. Because both tumors are located in the posterior fossa region along the midline, presenting signs and symptoms are similar. In addition to those already described, they may obstruct the fourth ventricle, resulting in hydrocephalus and generalized increased ICP, headache, nausea and vomiting, and nystagmus (involuntary eye movement).

In contrast, **cerebellar astrocytomas** are located on the surface of the right or left cerebellar hemisphere. Most cerebellar astrocytomas are low-grade, localized cystic tumors. They cause unilateral symptoms (occurring on the same side of the tumor), such as head tilt, limb ataxia, and nystagmus when the eyes are turned toward the tumor.

Brainstem gliomas often cause a combination of cranial nerve involvement, cerebellar signs of ataxia, and corticospinal tract dysfunction. A common clinical pattern includes unilateral paralysis of cranial nerves with contralateral paralysis of the arm and leg, hyperreflexia, and extensor plantar responses. Increased ICP generally does not occur. Children with diffuse tumors usually die within 1 to 2 years.[118]

The area of the sella turcica, the structure containing the pituitary gland, is the site of several childhood brain tumors, including **craniopharyngioma** (the most common and is benign) and pituitary adenoma (see Chapter 22)**.** These tumors may originate from the pituitary gland or the hypothalamus. They are usually slow growing and may be quite large by the time of diagnosis. Obstruction of the interventricular foramen can increase ICP. Symptoms include headache, seizures, diabetes insipidus, early onset of puberty, and growth delay. Other tumors located in this region of the brain include **optic gliomas.** Tumors that involve the optic tract may cause complete unilateral blindness and hemianopia of the other eye. Optic atrophy is another common finding. Optic gliomas are common in children with neurofibromatosis, a relatively common genetic condition.

Supratentorial tumors of the cerebral hemispheres in children are not very common. **Pilocytic astrocytomas** are the most common supratentorial tumors. These are localized (grade I) slow-growing, cyst-filled tumors that are often completely removed surgically. Tumors located in the cortex may cause focal cerebral dysfunction, weakness, hemiparesis, seizures, and visual changes. Involvement of particular lobes may result in more specific localized symptoms. For example, a tumor located in the frontal lobe may cause changes in affect and behavior, and a tumor in the occipital lobe may cause cortical blindness or blindness in half of the visual field.

EVALUATION AND TREATMENT. A child with signs and symptoms of a brain tumor requires a complete workup, including a neurologic, developmental, and ophthalmic examination. CT with contrast enhancement allows direct visualization of the tumor mass. MRI provides advanced, dramatic examination of the brain and neoplasms. Small low-grade tumors not seen on CT may be detected by MRI. Although less commonly used, magnetic resonance angiography (MRA) is very helpful in assessing the vascularity of the tumor and its relationship to major blood vessels. Spine MRI examination may be used to evaluate tumor dissemination along the spinal column. Lumbar puncture to examine CSF for tumor cells also may be performed. Tumors more likely to spread throughout the neuraxis include medulloblastomas and ependymomas.

The most useful treatment for brain tumors is surgical resection. Surgery to establish the diagnosis by biopsy or to excise the tumor is part of the initial treatment for most brain tumors. Some brain tumors may be cured with complete resection alone, such as low-grade cerebellar astrocytomas. Contraindications to such interventions are tumors in which surgical resection and biopsy carry a high risk of mortality or serious morbidity (brainstem gliomas). In these instances, diagnosis is made on the basis of radiologic evidence and clinical manifestations.

Most brain tumors require additional radiation and chemotherapy. Although these treatments are essential for potential eradication of the brain tumor, radiation to the child's brain is associated with significant morbidity, including acute- and long-term sequelae. Prognosis varies according to the type and location of the brain tumor (see Table 20-7). Historically, survival rates have been low; however, advances have been made with the combination of surgery, radiation therapy, and chemotherapy. Comprehensive care and management of these

children and their families are vital. Multidisciplinary teams composed of neurosurgeons, neurologists, radiation therapists, oncologists, nurses, social workers, physical therapists, and other providers are necessary to provide the continuity and consistency needed to care for these children.

Embryonal Tumors

Neuroblastoma

Neuroblastoma is an embryonal aggressive tumor that originates outside the CNS in the developing sympathetic nervous system (sympathetic ganglia and the adrenal medulla). The primitive neural crest cells (also called *sympathogonia*) are pluripotential (i.e., they develop into several cell types) and mature into sympathetic ganglion cells, pheochromocytes (which are found in the sympathetic nervous system), or neurofibrous tissue. Thus tumors that develop from neural crest cells reflect the varying degrees of differentiation of the cells. **Ganglioneuroblastomas** are tumors of an intermediate level of cellular differentiation. The most differentiated tumor is a **ganglioneuroma,** which is considered benign and does not metastasize.

Because neuroblastoma involves a defect of embryonal tissue, it is most commonly diagnosed in infants and young children. Although it accounts for 8% to 10% of pediatric malignancies, neuroblastoma causes approximately 50% of all solid tumors in children in the first year, and about 15% of cancer deaths in children of all ages.[119] Although familial tendency has been noted in individual cases, a nonfamilial or sporadic pattern is found in most children with neuroblastoma. Familial cases of neuroblastoma are considered to have an autosomal dominant pattern of inheritance (mechanisms of inheritance are discussed in Chapter 4).

PATHOPHYSIOLOGY. Neuroblastoma is the most primitive, or immature, form of the sympathetic nervous system tumors. Areas of necrosis and calcification often are present in the tumor. Neuroblastomas also are known to regress or mature into benign lesions.[120]

The cause of neuroblastoma is elusive. The tumor has been associated with a number of conditions, including neurofibromatosis and Hirschsprung disease, but most children with neuroblastoma have neither of these conditions.

CLINICAL MANIFESTATIONS. The most common location of neuroblastoma is in the retroperitoneal region (65% of cases), most often the adrenal medulla. The tumor is evident as an abdominal mass and may cause anorexia, bowel and bladder alteration, and sometimes spinal cord compression. The second most common location of neuroblastoma is the mediastinum (15% of cases), where the tumor may cause dyspnea or infection related to airway obstruction. Less commonly, neuroblastoma may arise from the cervical sympathetic ganglion (3% to 4% of cases). Cervical neuroblastoma often causes Horner syndrome, which consists of miosis (pupil contraction), ptosis (drooping eyelid), enophthalmos (backward displacement of the eyeball), and anhidrosis (sweat deficiency). Neuroblastoma can present with a neurologic syndrome called opsoclonus-myoclonus syndrome (jerky movements of the limbs, ataxia, and chaotic eye movements in all directions).[121]

A number of systemic signs and symptoms are characteristic of neuroblastoma, including weight loss, irritability, fatigue, and fever. Intractable diarrhea occurs in 7% to 9% of children and is caused by tumor secretion of a hormone called *vasoactive intestinal polypeptide (VIP).*

More than 90% of children with neuroblastoma have increased amounts of catecholamines and associated metabolites in their urine. High levels of urinary catecholamines and serum ferritin are associated with a poor prognosis.

EVALUATION AND TREATMENT. Initial diagnostic studies are dictated by the location of the primary tumor. Diagnosis begins with a complete physical and neurologic examination. Imaging studies provide further information. Laboratory analyses include measurement of levels of urinary catecholamines; plasma ferritin; serum neuron-specific enolase (NSE), an enzyme produced by neuronal tissues; and gangliosides, lipid molecules that may be shed from the surface of tumor cells.[122] The diagnosis of neuroblastoma is confirmed by surgical biopsy and histopathologic results. Antenatal ultrasound may detect the tumor in the antenatal period.

Treatment is based on the extent of the disease and prognostic markers, such as age, *MYCN* copy numbers (a proto-oncogene), chromosome 11q status and DNA ploidy, and high serum ferritin or NSE levels.[123] Low-risk disease is treated surgically. Chemotherapy is used if there is recurrence. Intermediate-risk tumors are treated with surgery and chemotherapy. High-risk neuroblastomas are being treated with high-dose chemotherapy and radiotherapy followed by transplantation of purged autologous bone marrow. Monoclonal antibody–based immunotherapy has been shown to be effective for high-risk tumors.[124] Approximately 60% of children with high-risk disease will die despite intensive therapy, although this percentage is improving over time.

SUMMARY REVIEW

Structure and Function of the Nervous System in Children

1. The central nervous system develops from the neural tube, which is ectodermal in origin. The cranial end of the tube forms the brain, and the spinal cord is formed from the remainder of the tube.
2. The cranial and spinal ganglia (peripheral nervous system) develop from the neural crest.
3. The nervous system develops in six stages, and disruption of any of the stages can lead to malfunction of the nervous system.
4. The bones of the skull are joined by sutures; the wide, membranous junctions of the sutures, known as *fontanels,* close by 20 months of age.
5. Myelin is a sheath that develops around axons to facilitate speed of nerve impulse conduction. Progressive development of reflexes corresponds to normal maturation of nerve tissue and development of voluntary movement.
6. Neurologic functioning at birth is at the subcortical level with reflex patterns mediated by the brainstem and spinal

SUMMARY REVIEW—cont'd

cord. With maturation, neonatal reflexes disappear and voluntary motor functions develop.

7. The fontanels allow for cranial expansion because the head is the fastest growing body part during infancy. Sutures close by 5 to 8 years after birth.

Structural Malformations

1. Defects of neural tube closure include anencephaly (absence of part of the brain and soft, bony part of skull), encephalocele (protrusion of brain and meninges through a skull defect), and myelodysplasias: meningocele (cystlike defect with protrusion of spinal fluid–filled meninges through a vertebral defect), myelomeningocele (a defect like meningocele only also containing the spinal cord), and spina bifida (failure of the vertebrae to close with protrusion of neural tube contents with intact skin).
2. Craniosynostosis (craniostenosis) is premature closure of one or more of the cranial sutures and prevents normal skull expansion, causing compression of growing brain tissue.
3. Microcephaly is lack of brain growth and retarded mental and motor development.
4. Cortical dysplasias are a heterogeneous group of disorders caused by defects in neuronal cell migration and subsequent abnormalities in connections between cells.
5. Congenital hydrocephalus results from an imbalance between the production and reabsorption of cerebrospinal fluid.

Encephalopathies

1. Static encephalopathies (i.e., cerebral palsy and epilepsy) are nonprogressive disorders of the brain that can occur during gestation, birth, or childhood and can be caused by trauma or genetic factors.
2. Cerebral palsy (CP) is a group of nonprogressive syndromes that can be caused by prenatal cerebral hypoxia or perinatal or postnatal trauma with symptoms of mental retardation, seizure disorders, or developmental disabilities. CP can be **extrapyramidal/nonspastic or pyramidal/spastic.**
3. Inherited disorders that damage the nervous system include metabolic defects in amino acid metabolism (phenylketonuria) and storage diseases.
4. Storage diseases include lysosomal storage disease, such as Tay-Sachs disease (GM2 gangliosidosis). Both inherited disorders and storage diseases result in abnormal behavior, seizures, and deficient psychomotor development.
5. Accidental poisonings from a variety of toxins can cause serious neurologic damage.
6. Bacterial meningitis is commonly caused by *H. influenzae* type B, *S. pneumoniae,* or *N. meningitidis* and may result from respiratory tract or gastrointestinal tract infections with symptoms of fever, headache, photophobia, seizure, rigidity, and stupor.
7. Viral meningitis presents similar to bacterial meningitis, and the specific virus is often unknown.
8. HIV-1 encephalopathy is a CNS infection that can occur in infants and children.

Cerebrovascular Disease in Children

1. Ischemic stroke is rare in children and may result from embolism, arteriopathy, or, rarely, sinovenous thrombosis.
2. Hemorrhagic stroke results from congenital arteriovenous malformations that rupture and cause intracranial bleeding.

Seizure Disorders in Children

1. Epilepsy is the occurrence of seizures. Seizures are the abnormal discharge of electrical activity within the brain. Seizure disorders are associated with numerous nervous system disorders and more often are a generalized rather than a partial type of seizure.
2. Generalized forms of seizures involve both brain hemispheres and include tonic-clonic, myoclonic, atonic, akinetic, and infantile spasms.
3. Partial seizures suggest more localized brain dysfunction.
4. Childhood absence epilepsy (petit mal seizures or nonconvulsive epilepsy) is a type of generalized epilepsy.
5. Epilepsy syndromes include febrile seizures, infantile spasms, Lennox-Gastaut syndrome, and juvenile myoclonic epilepsy.

Childhood Tumors

1. Brain tumors are the most common primary neoplasm in children and the second most common type of childhood cancer. The most common tumors include medulloblastoma, ependymoma, gliomas (astrocytoma, brainstem glioma, and optic nerve glioma), and craniopharyngioma.
2. Tumors in children are most often located below the tentorial membrane in the posterior fossa.
3. Fast-growing tumors produce symptoms early in the disease, whereas slow-growing tumors may become very large before symptoms appear.
4. Symptoms of brain tumors may be generalized or localized. The most common general symptom is increased ICP (headache, irritability, vomiting, somnolence, and bulging of fontanels).
5. Localized signs of infratentorial tumors in the cerebellum include impaired coordination and balance. Cranial nerve signs occur with tumors near the brainstem.
6. Supratentorial tumors may be located near the cortex or deep in the brain. Symptoms depend on the specific location of the tumor.
7. Neuroblastoma is an embryonal tumor of the sympathetic nervous system and can be located anywhere there is sympathetic nervous tissue. It is the most common type of solid tumor occurring in the first year.
8. Symptoms are related to tumor location and size of metastasis.

- Review Questions and Answers

CHAPTER OUTLINE

The endocrine system is composed of various glands located throughout the body (Figure 21-1). These glands are capable of synthesizing and releasing special chemical messengers called **hormones.** The endocrine system has five general functions:

1. Differentiation of the reproductive and central nervous systems in the developing fetus
2. Stimulation of sequential growth and development during childhood and adolescence
3. Coordination of the male and female reproductive systems, which makes sexual reproduction possible
4. Maintenance of an optimal internal environment throughout the life span
5. Initiation of corrective and adaptive responses when emergency demands occur

Hormones convey specific regulatory information among cells and organs and are integrated with the nervous system to maintain communication and control. The mechanisms of communication include autocrine (within cell), paracrine (between local cells), and endocrine (between remote cells).

MECHANISMS OF HORMONAL REGULATION

The endocrine glands respond to specific signals by synthesizing and releasing hormones into the circulation. Although a wide variety of hormones function within the body, they share certain general characteristics:

1. Hormones have specific rates and rhythms of secretion. Three basic secretion patterns are: (1) circadian or diurnal patterns, (2) pulsatile and cyclic patterns, and (3) patterns that depend on levels of circulating substrates (e.g., calcium, sodium, potassium, or the hormones themselves).
2. Hormones operate within feedback systems, either positive or negative, to maintain an optimal internal environment.
3. Hormones affect only cells with appropriate receptors and then act on those cells to initiate specific cell functions or activities.
4. Steroid hormones are either excreted directly by the kidneys or metabolized (conjugated) by the liver, which

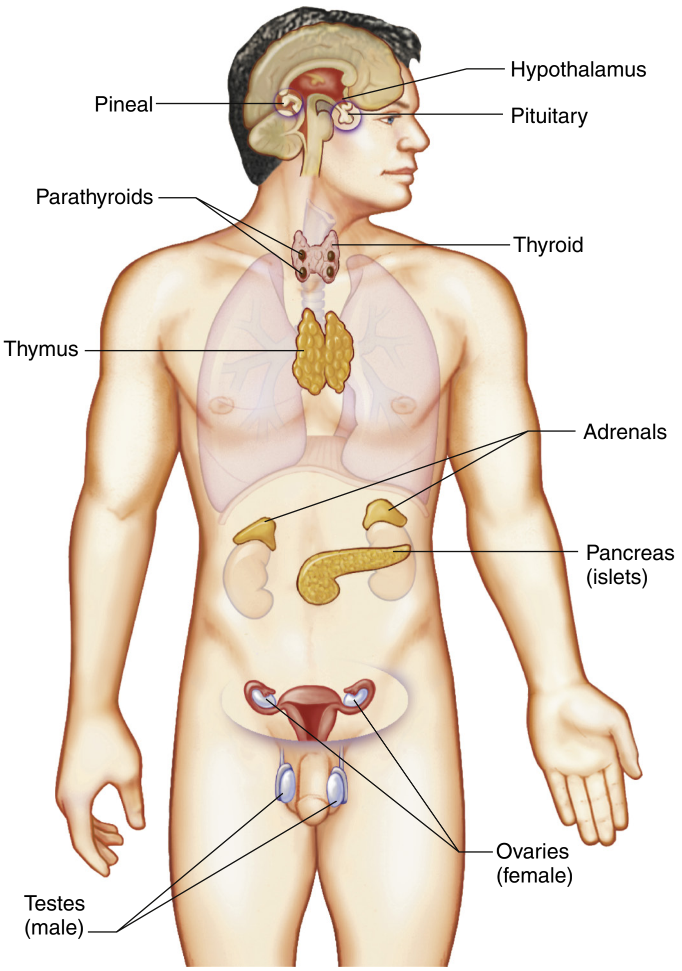

FIGURE 21-1 Principal Endocrine Glands. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

inactivates them and renders the hormone more water soluble for renal excretion. Peptide hormones are catabolized by circulating enzymes and eliminated in the feces or urine.

Hormones may be classified according to their structure, gland of origin, effects, or chemical composition. (Table 21-1 categorizes hormones based on structure.) The secretion and mechanisms of action of hormones represent an extremely complex system of integrated responses. Although much has been learned about these complex systems, many of the specific mechanisms of action are not yet understood. The endocrine and nervous systems work together to regulate responses to the internal and external environments.

Regulation of Hormone Release

The release of hormones occurs either in response to an alteration in the cellular environment or in the process of maintaining a regulated level of certain hormones or certain substances. Hormone release is regulated by one or more of the following mechanisms: (1) chemical factors (such as blood glucose or calcium levels); (2) endocrine factors (a hormone from one endocrine gland controlling another endocrine gland); and (3) neural control (such as stress-induced release of catecholamines from the adrenal medulla).

TABLE 21-1 STRUCTURAL CATEGORIES OF HORMONES

STRUCTURAL CATEGORY	EXAMPLES
Water Soluble	
Peptides	Growth hormone
	Insulin
	Leptin
	Parathyroid hormone
	Prolactin
Glycoproteins	Follicle-stimulating hormone
	Luteinizing hormone
	Thyroid-stimulating hormone
Polypeptides	Adrenocorticotropic hormone
	Antidiuretic hormone
	Calcitonin
	Endorphins
	Glucagon
	Hypothalamic hormones
	Lipotropins
	Melanocyte-stimulating hormone
	Oxytocin
	Somatostatin
	Thymosin
	Thyrotropin-releasing hormone
Amines	Epinephrine
	Norepinephrine
Lipid Soluble	
Thyroxine (an amine but lipid soluble)	Thyroxine (both thyroxine [T_4] and triiodothyronine [T_3])
Steroids (cholesterol is a precursor for all steroids)	Estrogens
	Glucocorticoids (cortisol)
	Mineralocorticoids (aldosterone)
	Progestins (progesterone)
	Testosterone
Derivatives of arachidonic acid (autocrine or paracrine action)	Leukotrienes
	Prostacyclins
	Prostaglandins
	Thromboxanes

Feedback systems provide precise monitoring and control of the cellular environment. The most common feedback system, **negative feedback,** occurs because the changing chemical, neural, or endocrine response to a stimulus negates the initiating change that triggered the release of the hormone. An example of hormone negative feedback is shown in Figure 21-2, *A*. Thyroid-stimulating hormone (TSH) secretion from the anterior pituitary is stimulated by **thyrotropin-releasing hormone (TRH)** from the hypothalamus. Secretion of TSH stimulates the synthesis and secretion of thyroid hormones. Increasing levels of T_4 (thyroxine) and T_3 (triiodothyronine) then generate negative feedback on the pituitary and hypothalamus to inhibit TRH and TSH synthesis.

Negative-feedback systems are important in maintaining hormone concentrations within physiologic ranges. The lack of negative-feedback inhibition on hormonal release often results in pathologic conditions. As discussed in Chapter 22, various

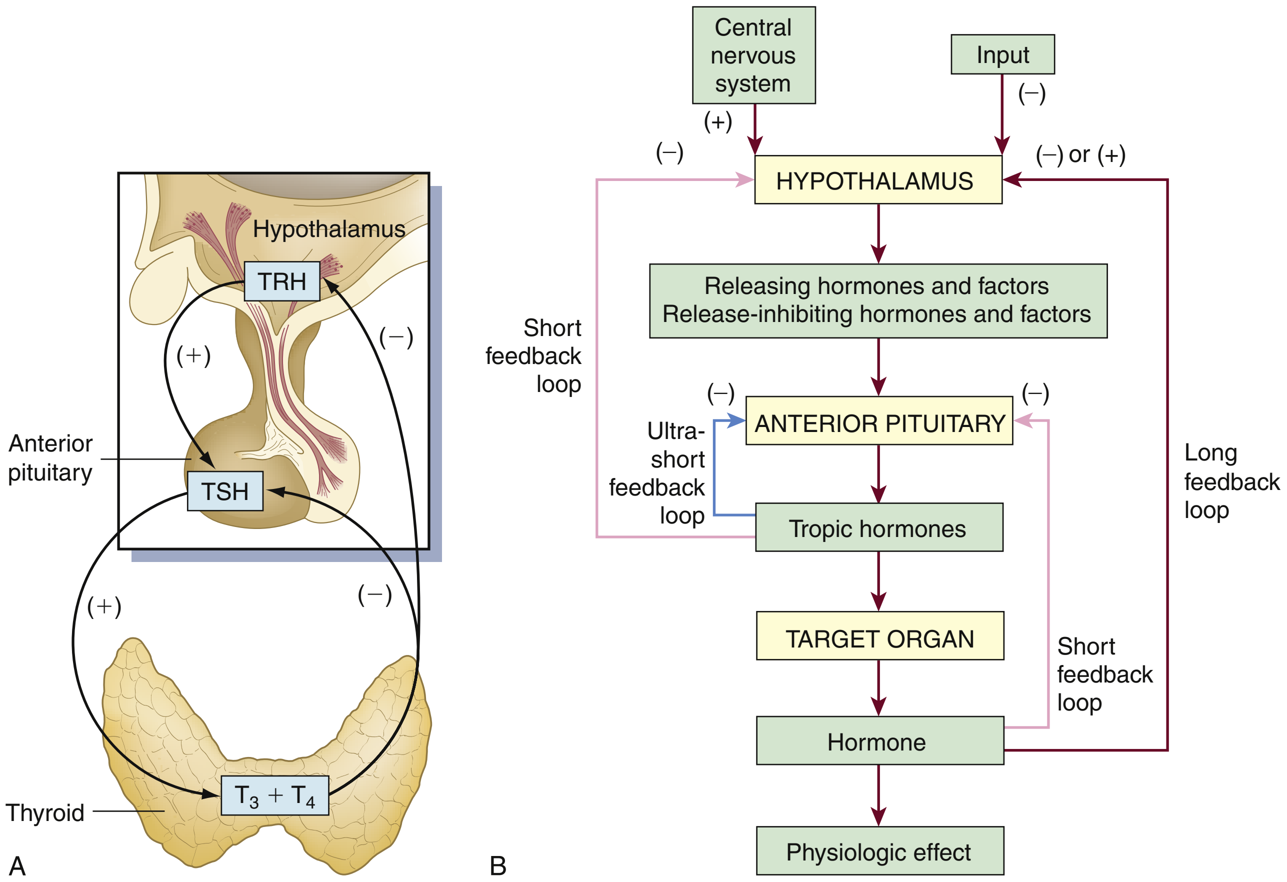

FIGURE 21-2 Feedback Loops. **A,** Endocrine feedback loops involving the hypothalamus-pituitary gland and end organs; in this example, the feedback loops for the thyroid gland (endocrine regulation). **B,** General model for control and negative feedback to hypothalamic-pituitary target organ systems. Negative-feedback regulation is possible at three levels: target organ (ultrashort feedback), anterior pituitary (short feedback), and hypothalamus (long feedback). *TRH,* Thyrotropin-releasing hormone; *TSH,* thyroid-stimulating hormone; T_3, triiodothyronine; T_4, tetraiodothyronine (thyroxine).

hormonal imbalances and related conditions are caused by excessive hormone production, which is the result of failure to "turn off" the system. These negative-feedback regulatory systems are diagrammed in Figure 21-2, *B*.

Hormone Transport

Once hormones are released into the circulatory system, they are distributed throughout the body. Peptide or protein hormones (pituitary, hypothalamic, and parathyroid hormones; and insulin) are water soluble and circulate in free (unbound) forms. Water-soluble hormones generally have a short half-life because they are catabolized by circulating enzymes. For example, insulin has a half-life of 3 to 5 minutes and is catabolized by insulinases. Lipid-soluble hormones, such as cortisol and adrenal androgens, are transported bound to a carrier or transport protein (Table 21-2) and can remain in the blood for hours to days. Only free hormones (those not bound to the carrier protein) can signal a target cell. Because an equilibrium exists between the concentrations of free hormones and hormones bound to plasma proteins, a significant change in the concentration of binding proteins can affect the concentration of free hormones in the plasma (see Table 21-2). (Mechanisms of hormone binding are discussed in Chapter 1.)

Hormone Receptors

When a hormone is released into the circulatory system, it is distributed throughout the body, but only those cells with appropriate **hormone receptors** for that hormone are affected. The target cell hormone receptors have two main functions: (1) to recognize and bind with high affinity to their particular hormones and (2) to initiate a signal to appropriate intracellular effectors. See Chapter 1 for cell signaling pathways, particularly Figures 1-19 and 1-20 on pp. 21-22.

The sensitivity of the target cell to a particular hormone is related to the total number of receptors per cell: the more receptors, the more sensitive the cell. Low concentrations of hormone increase the number of receptors per cell, called **up-regulation** (Figure 21-3, *A*). High concentrations of hormone decrease the number of receptors, called **down-regulation** (Figure 21-3, *B*). Thus the cell can adjust its sensitivity to the concentration of the signaling hormone. The receptors on the plasma membrane are continuously synthesized and degraded, so that changes in receptor concentration may occur within hours. Various physiochemical conditions also can affect both the receptor number and the affinity of the hormone for its receptor. Some of these physiochemical conditions are the fluidity and structure of the plasma membrane, pH, temperature, ion concentration, diet, and the presence of other

TABLE 21-2 BINDING PROTEINS, THEIR HORMONES, AND VARIABLES THAT AFFECT THEIR CIRCULATING LEVELS

BINDING PROTEIN	HORMONE	FACTORS THAT INCREASE BINDING PROTEIN LEVELS	FACTORS THAT DECREASE BINDING PROTEIN LEVELS
Corticosteroid-binding globulin	Cortisol Progesterone	Estrogen	Liver disease
Sex hormone–binding globulin	Dihydrotestosterone Testosterone Estradiol	—	Androgens Hypothyroidism Liver disease
Thyroid-binding globulin	Thyroxine (T_4) Triiodothyronine (T_3)	Estrogen Hyperthyroidism	Testosterone Glucocorticoids Liver disease
Albumin	All lipid-soluble hormones	Estrogen	Liver disease Malnutrition Renal disease

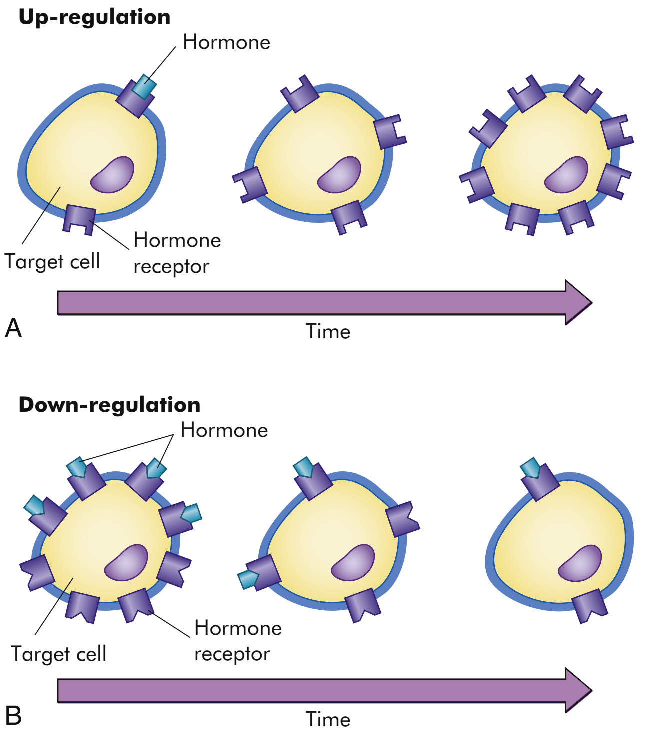

FIGURE 21-3 Regulation of Target Cell Sensitivity. **A,** Low hormone level and up-regulation, or an increase in the number of receptors. **B,** High hormone level and down-regulation, or a decrease in the number of receptors. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

chemicals (e.g., drugs). Finally, mutations in receptor structure can affect target cell activation such that normal cellular responses are increased or decreased. For example, mutations in thyroid hormone receptors can lead to resistance to thyroid hormone and can contribute to the development of tumors.[1,2]

Hormone receptors may be located in or on the plasma membrane or in the intracellular compartment of the target cell (Figure 21-4). Water-soluble hormones (see Table 21-1) have a high molecular weight and cannot diffuse across the cell membrane. They interact or bind with receptors in or on the cell membrane and mediate short-acting responses.[3] Lipid-soluble steroids, vitamin D, retinoic acid, and thyroid hormones diffuse freely across the plasma and nuclear membranes and bind with cytosolic or nuclear receptors (see Figure 21-4). The hormone-receptor complex binds to a specific region in the deoxyribonucleic acid (DNA) and stimulates the expression of a specific gene. Some lipid-soluble hormones (e.g., estrogen) also may bind with plasma membrane receptors. By these mechanisms, lipid-soluble hormones can mediate both long-acting and rapid-acting responses.[4]

Plasma Membrane Receptors and Signal Transduction

First Messenger

A hormone is the **first messenger,** is secreted into the bloodstream, and carries a message to a target cell. **Signal transduction** is the process by which this message is communicated into a cell. In general, signal transduction involves a series of steps that includes receptor activation or binding of a hormone to its receptor, activation of a G protein (transducer) and membrane-associated enzyme (effector enzyme), and production of a second messenger (see Figure 1-22, p. 24, and Figure 21-5). The final event is activation of an intracellular enzyme, such as protein kinase A or C, which causes alterations in gene transcription and the resulting target cell response to the hormone.

Cell surface receptors are usually classified according to how they initiate signal transduction: (1) G-protein–linked receptors, (2) ion-channel receptors, and (3) enzyme-linked receptors (including tyrosine kinase, serine kinase, and the cytokine-receptor superfamily with intrinsic enzyme activity—such as the Janus family of tyrosine kinases [JAK] and signal transducers and activators of transcription [STAT] molecules). With the exception of insulin, growth hormone, and prolactin, most water-soluble hormones—such as adrenocorticotropic hormone (ACTH), glucagon, norepinephrine, and epinephrine—activate G-protein–linked receptors. Other hormones, such as angiotensin II, activate G-protein–linked and ion-channel receptors. Insulin activates a tyrosine kinase receptor. Growth hormones, prolactin, and cytokines—such as interleukins—activate the JAK/STAT receptors.

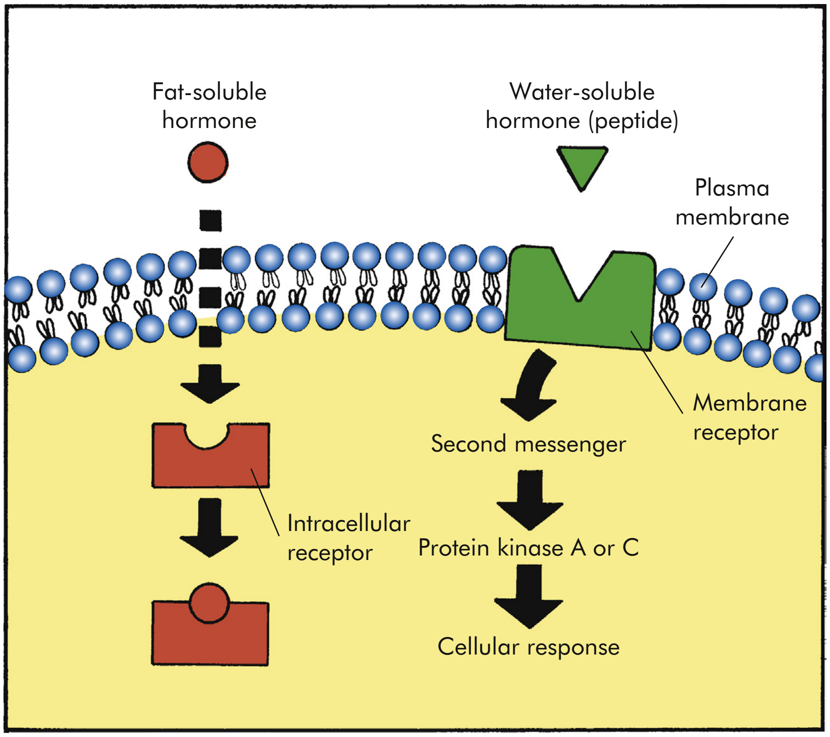

FIGURE 21-4 Hormone Binding at Target Cell.

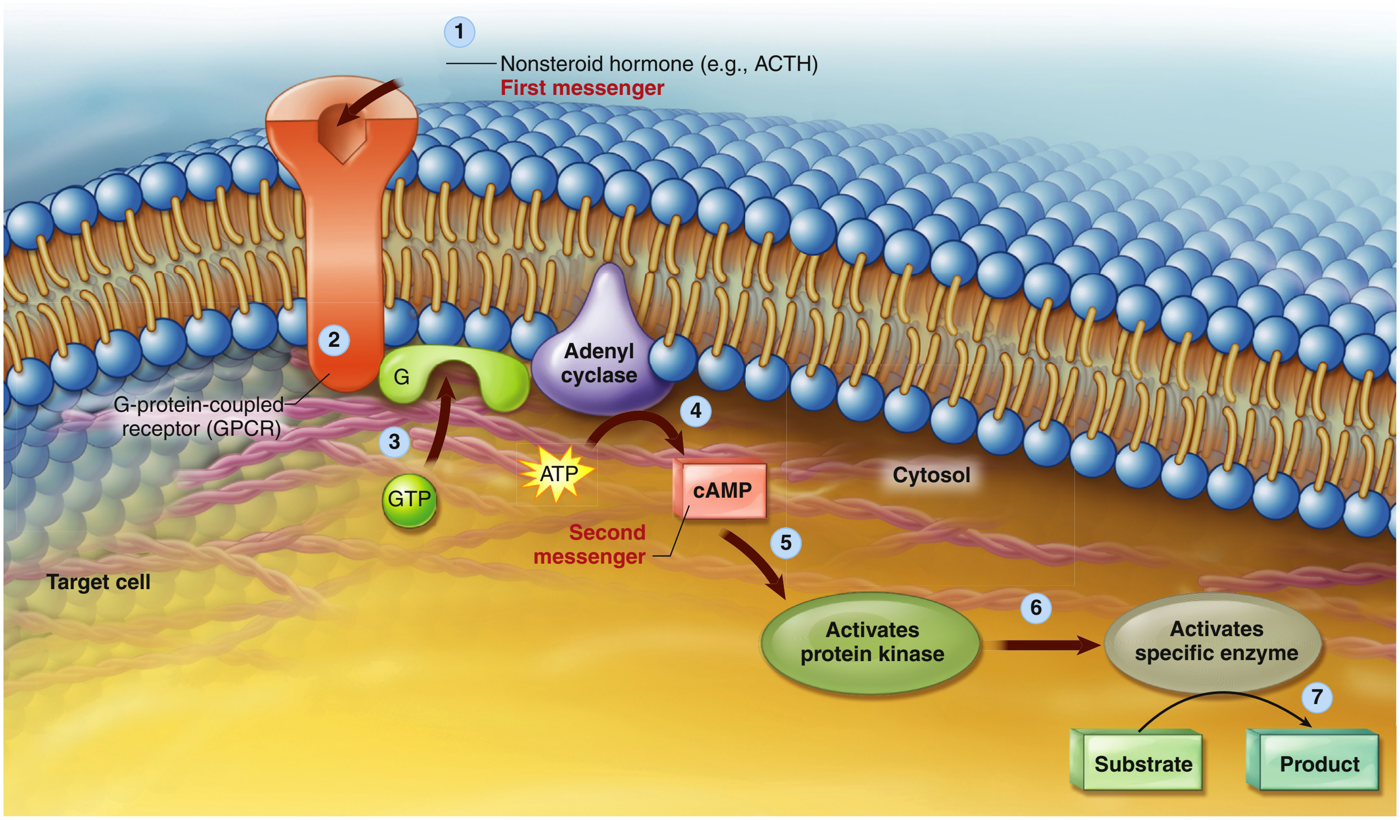

FIGURE 21-5 **Examples of First- and Second-Messenger Signaling.** A nonsteroid hormone (first messenger) binds to a fixed receptor of the target cell **(1).** The hormone-receptor complex activates the G protein **(2).** The activated G protein *(G)* reacts with guanosine triphosphate *(GTP),* which in turn activates the membrane-bound enzyme adenylyl cyclase **(3).** Adenylyl cyclase catalyzes the conversion of adenosine triphosphate *(ATP)* to cyclic adenosine monophosphate (*cAMP;* second messenger) **(4).** cAMP activates protein kinase **(5).** Protein kinases activate specific intracellular enzymes **(6).** These activated enzymes then influence specific cellular reactions and metabolic pathways, thus producing the target cell's response to the hormone **(7).** (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby). *ACTH,* Adrenocorticotropic hormone.

TABLE 21-3 SECOND MESSENGERS IDENTIFIED FOR SPECIFIC HORMONES

SECOND MESSENGER	ASSOCIATED HORMONES
Cyclic AMP	Adrenocorticotropic hormone (ACTH) Luteinizing hormone (LH) Human chorionic gonadotropin (hCG) Follicle-stimulating hormone (FSH) Thyroid-stimulating hormone (TSH) Antidiuretic hormone (ADH) Thyrotropin-releasing hormone (TRH) Parathyroid hormone (PTH) Glucagon
Cyclic GMP	Atrial natriuretic peptide
Calcium	Angiotensin II Gonadotropin-releasing hormone (GnRH) Antidiuretic hormone (ADH)
IP_3 and DAG	Angiotensin II Antidiuretic hormone (ADH) Luteinizing hormone–releasing hormone (LHRH)
Tyrosine phosphorylation	
Tyrosine kinase	Insulin
JAK-STAT	Growth hormone Leptin Prolactin

AMP, Adenosine monophosphate; *DAG,* diacylglycerol; *GMP,* guanosine monophosphate; *IP_3,* inositol triphosphate; *JAK,* Janus family of tyrosine kinases; *STAT,* signal transducers and activators of transcription.

Second-Messenger Molecules: cAMP, cGMP, and Ca^{++}

Cyclic Adenosine Monophosphate (cAMP). **Second-messenger** molecules are the initial link between the first signal (hormone) and the inside of the cell (Table 21-3). For example, binding of epinephrine to a β-adrenergic receptor subtype activates (through a stimulatory G protein [G_s]) the enzyme adenylyl cyclase. Adenylyl cyclase catalyzes the conversion of adenosine triphosphate (ATP) to the second messenger 3′,5′-cAMP. Elevation of cAMP activates the enzyme cAMP-dependent *protein kinase A (PKA)*. PKA phosphorylates and activates nuclear transcription factors (cAMP response element–binding [CREB] proteins) that influence numerous cellular functions.[5] For example, CREB proteins associated with the L-type channel in cardiac muscle increase the influx of calcium into the cell, which increases myocardial contractility. Alterations in CREB activity have been implicated in many disease states including diabetes and cancer.[6,7] The actions of cAMP are terminated by the enzyme phosphodiesterase (PDE) III, which hydrolyzes cAMP into inactive adenosine monophosphate (AMP).

Cyclic Guanosine Monophosphate (cGMP). Guanylyl cyclase is an enzyme that converts guanosine triphosphate (GTP) to the second-messenger 3′,5′-cGMP. cGMP activates cGMP-dependent kinase (protein kinase G), which in turn activates a number of physiologic processes. The effects of various ligands, such as atrial natriuretic hormone (vascular smooth muscle relaxation) and nitric oxide (e.g., vascular smooth muscle relaxation and platelet inhibition), are mediated by the second-messenger cGMP. Drugs that target the actions of cGMP are being explored for the treatment of vascular and pulmonary disorders.[8]

Calcium (Ca^{++}). In addition to being an important ion that participates in a multitude of cellular actions, Ca^{++} is considered an important second messenger. The binding of a hormone (such as norepinephrine or angiotensin II) to a surface receptor activates the enzyme *phospholipase C* through a G protein inside the plasma membrane. This enzyme breaks down membrane phospholipid phosphatidylinositol biphosphate (PIP_2) into second-messengers **inositol triphosphate (IP_3)** and **diacylglycerol (DAG)** (see Figure 1-22, p. 24) IP_3 mobilizes Ca^{++} from intracellular stores (endoplasmic reticulum). Increased intracellular calcium levels can lead to the formation of the calcium-calmodulin complex, which mediates the effects of calcium on intracellular activities that are crucial for cell metabolism and growth. For example, calmodulin-dependent protein kinases control intracellular contractile components (myosin and actin, which cause contraction), alter plasma membrane permeability to calcium, and regulate the intracellular enzyme activity that promotes hormone secretion.

DAG, together with Ca^{++}, activates *protein kinase C (PKC)*. Similar to other kinase enzymes, PKC activates (by phosphorylation) other proteins or enzymes. PKC initiates a variety of cellular responses that are linked to cell metabolism and growth. For example, PKC activates glycogen synthase in liver cells to convert glucose to glycogen. Calcium signaling systems are crucial to healthy functioning of virtually every tissue system in the body including heart, brain, bone, smooth muscle, and many others.[9]

Some hormones, such as insulin, growth hormone, and prolactin, bind to surface receptors that directly activate tyrosine kinases. These tyrosine kinases include the Janus family of tyrosine kinases (JAK) and signal transducers and activators of transcription (STAT). They regulate a wide range of intracellular processes that contribute to cellular metabolism and growth, and are being targeted in emerging treatments for diabetes.[10] An example of first- and second-messenger systems is presented in Figure 21-5.

Steroid (Lipid-Soluble) Hormone Receptors

The lipid-soluble hormones are steroid hormones and are synthesized from cholesterol. They include androgens, estrogens, progestins, glucocorticoids, mineralocorticoids, vitamin D, and retinoid. Thyroid hormones are lipid soluble but are not synthesized from cholesterol (see p. 701). Because these hormones are relatively small, lipophilic, hydrophobic molecules, they can cross the lipid plasma membrane by simple diffusion (see Chapter 1). Some steroid hormones bind to receptor molecules in the cytoplasm and then diffuse into the nucleus, whereas others bind to receptors in the nucleus. The resulting hormone-receptor complex binds to a specific site on the promoter region of DNA. This binding activates ribonucleic acid (RNA) polymerase, which stimulates DNA transcription and increased synthesis of specific proteins (increased gene expression) (Figure 21-6). Modulation of gene expression can take hours to days.

Steroid hormone receptors also may be found in the plasma membrane and are associated with rapid responses (seconds or minutes) that have nongenomic and genomic effects. Crosstalk

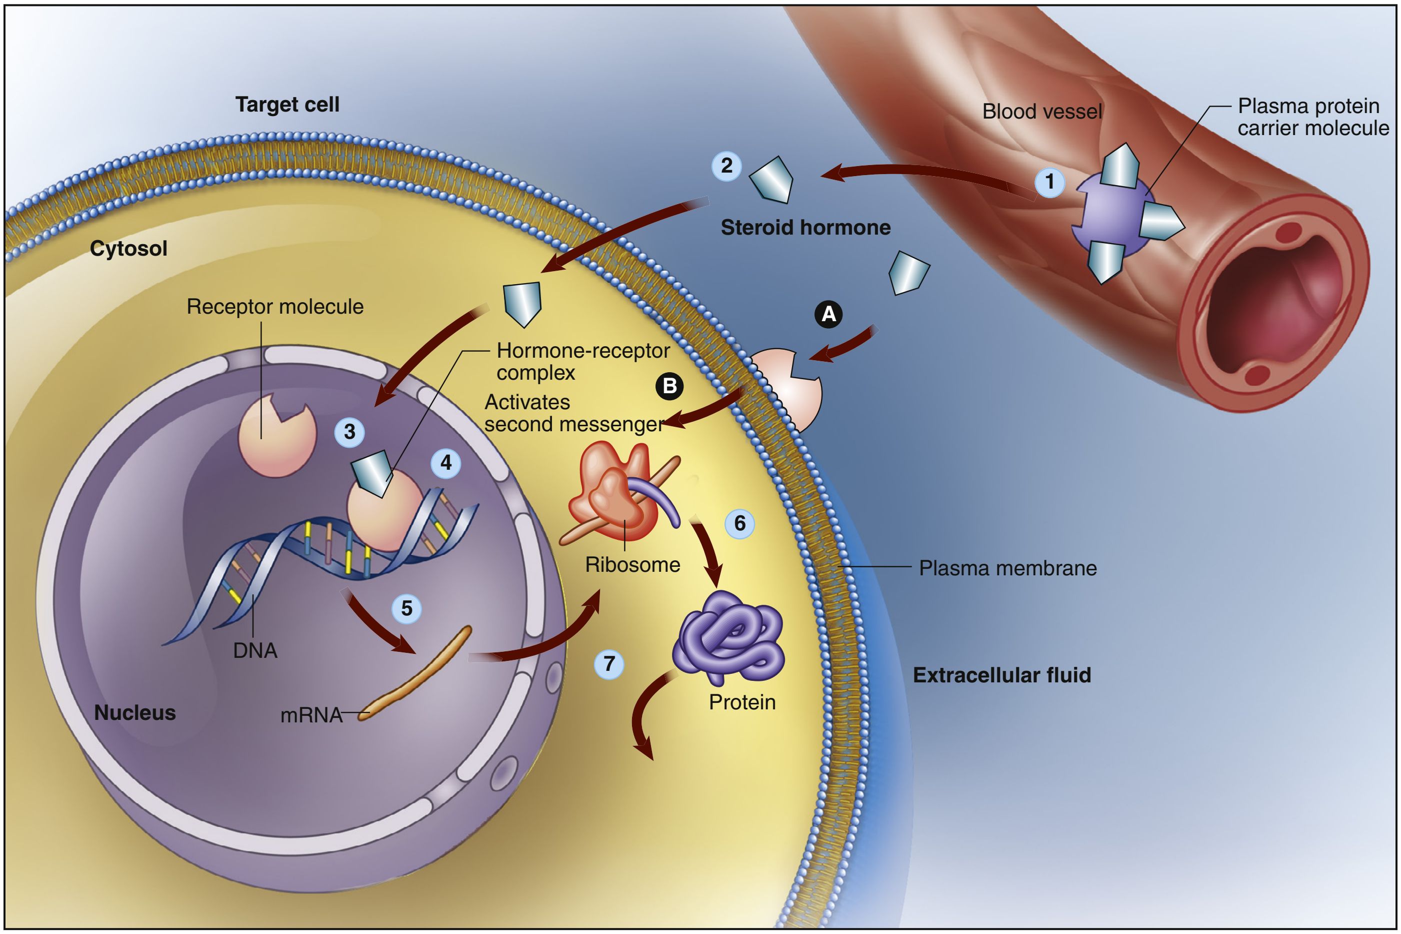

FIGURE 21-6 Steroid Hormone Mechanism. Lipid-soluble steroid hormone molecules detach from the carrier protein **(1)** and pass through the plasma membrane **(2).** Hormone molecules then diffuse into the nucleus, where they bind to a receptor to form a hormone-receptor complex **(3).** This complex then binds to a specific site on a DNA molecule **(4),** triggering transcription of the genetic information encoded there **(5).** The resulting messenger ribonucleic acid *(mRNA)* molecule moves to the cytosol, where it associates with a ribosome, initiating synthesis of a new protein **(6).** This new protein—usually an enzyme or channel protein—produces specific effects on the target cell **(7).** The classic genomic action is typically slow *(red arrows).* Steroids also may exact rapid effects by binding to receptors on the plasma membrane **(A)** and activating an intercellular second messenger **(B).** (Modified from Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

between gene transcription and nongenomic responses modulate each other, allowing cells to adapt rapidly to environmental changes. Thyroid hormone, a nonsteroid lipid-soluble hormone, also has been found to use a cell surface receptor for its nongenomic actions. It first binds to an integrin receptor on the plasma membrane, and then uses a specific transport mechanism to gain access to its nuclear receptors where it can influence cell division and metabolic function.[11]

Hormone Effects

The binding of hormones with their receptors stimulates three general types of effects by:

1. Acting on pre-existing channel-forming proteins to alter membrane channel permeability
2. Activating pre-existing proteins through a second-messenger system
3. Activating genes to cause protein synthesis

Hormones have two general types of effects on target cells: direct and permissive. **Direct effects** are the obvious changes in cell function that specifically result from stimulation by a particular hormone. **Permissive effects** are less obvious hormone-induced changes that facilitate the maximal response or functioning of a cell. For example, insulin has a direct effect on skeletal muscle cells with insulin receptors, causing increased glucose transport into these cells. Insulin also has a permissive effect on mammary cells, facilitating the response of these cells to the direct effects of prolactin.

Some hormones have biphasic pharmacologic effects that are dependent on the concentration of the hormone. For example, low or physiologic levels of antidiuretic hormone (ADH, or arginine-vasopressin) stimulate renal tubular reabsorption of sodium and water. However, at supraphysiologic levels (i.e., those that can be achieved by exogenous administration), ADH acts as a vasoconstrictor.

STRUCTURE AND FUNCTION OF THE ENDOCRINE GLANDS

Hypothalamic-Pituitary Axis

The hypothalamic-pituitary axis (HPA) forms the structural and functional basis for central integration of the neurologic and endocrine systems, creating what is called the **neuroendocrine system.** The HPA produces a number of releasing/inhibitory hormones and tropic hormones that affect a number of diverse body functions (Figure 21-7). For example, the functions of the thyroid gland, adrenal gland, and male and female reproductive glands, as well as somatic growth and lactation, are regulated by hormones originating from the HPA.

Hypothalamus

The hypothalamus is divided into several nuclei and nuclear areas and is located at the base of the brain. The pituitary gland is located at the sella turcica, a saddle-shaped depression on the superior surface of the sphenoid bone (Figure 21-8). The communication or anatomic connection (blood vessels and neural tract) between the hypothalamus and anterior and posterior pituitary is quite elaborate and well described. However, simply described, the hypothalamus is connected to the anterior pituitary by way of portal blood vessels (Figure 21-9), whereas the hypothalamus is connected to the posterior pituitary by way of a nerve tract referred to as the *supraopticohypophysial tract* (Figure 21-10). These connections are vital to the functioning of the hypothalamus-pituitary system.[12]

The special cells of the hypothalamus are like other neurons in that they have similar electrical properties, organelles, membranes, and synapses. Hypothalamic neurosecretory cells, however, can synthesize and secrete the hypothalamic-releasing hormones and synthesize the hormones of the posterior portion of the pituitary gland. For example, **antidiuretic hormone (ADH)** and **oxytocin** are synthesized in hypothalamic neurons but are stored and secreted by the posterior pituitary. ADH and oxytocin travel to the posterior pituitary by way of the hypothalamohypophysial nerve tract. Releasing/inhibitory hormones also are synthesized in the hypothalamus and are secreted into the portal blood vessels, through which they travel to the anterior pituitary and control the release of tropic hormones. These releasing/inhibitory hormones from the hypothalamus include **prolactin-inhibiting factor (PIF), thyrotropin-releasing hormone (TRH), gonadotropin-releasing hormone (GnRH),**

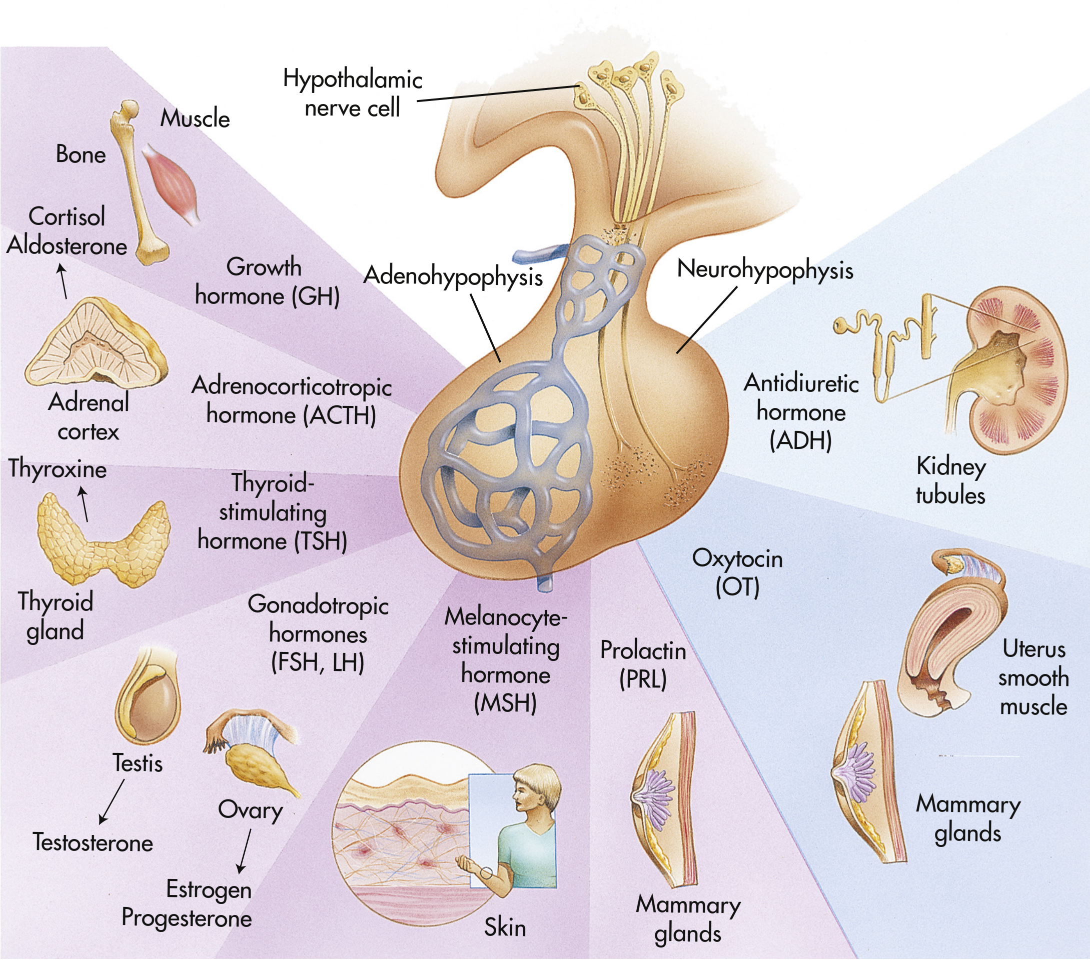

FIGURE 21-7 Pituitary Hormones and Their Target Organs. *FSH,* Follicle-stimulating hormone; *LH,* luteinizing hormone. (Modified from Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

somatostatin, growth hormone–releasing factor (GRF), **corticotropin-releasing hormone** (CRH), and **substance P.** These hormones are summarized in Table 21-4.

Pituitary Gland

The **anterior pituitary** (adenohypophysis) accounts for 75% of the total weight of the pituitary gland. It is composed of three regions: (1) the pars distalis, (2) the pars tuberalis, and (3) the pars intermedia. The **pars distalis** is the major component of the anterior pituitary and the source of the anterior pituitary hormones. The **pars tuberalis** is a thin layer of cells on the anterior and lateral portions of the pituitary stalk. The **pars intermedia** lies between the two. In the adult the distinct intermediate lobe disappears, and the individual cells are distributed diffusely throughout the pars distalis and **pars nervosa (neural lobe),** which are part of the posterior pituitary.

The **posterior pituitary** (neurohypophysis) arises embryologically from an outpouching of the floor of the third ventricle within the brain. The posterior pituitary consists of three parts: (1) the median eminence located at the base of the hypothalamus, (2) the pituitary stalk, and (3) the infundibular process, also known as the *pars nervosa* or *neural lobe*. The **median eminence** is composed largely of the nerve endings of axons that arise primarily in the ventral hypothalamus. The median eminence often is designated as part of the posterior pituitary but contains at least 10 biologically active hypothalamic-releasing hormones, as well as the neurotransmitters dopamine, norepinephrine, serotonin, acetylcholine, and histamine. The median eminence therefore might be more appropriately considered part of the hypothalamus. The **pituitary stalk** contains the axons of neurons that originate in the supraoptic and paraventricular nuclei of the hypothalamus. Axons originating in the hypothalamus terminate in the pars nervosa, which secretes the hormones of the posterior pituitary.

Because of the anatomic location and connection of the pituitary gland to the brain, several neurotransmitters as well as physical and emotional stressors influence the release of specific hypothalamic releasing–inhibitory hormones and their respective tropic hormones. This allows for the integrated and coordinated function of the hypothalamic-pituitary axis. Interestingly, hypothalamic hormones also are synthesized outside the HPA. For example, CRH is synthesized in cells of the immune system, female and male reproductive organs, and the placenta. These peripherally synthesized neuropeptides are thought to play a role in the reproductive and immune responses to stress.[13,14]

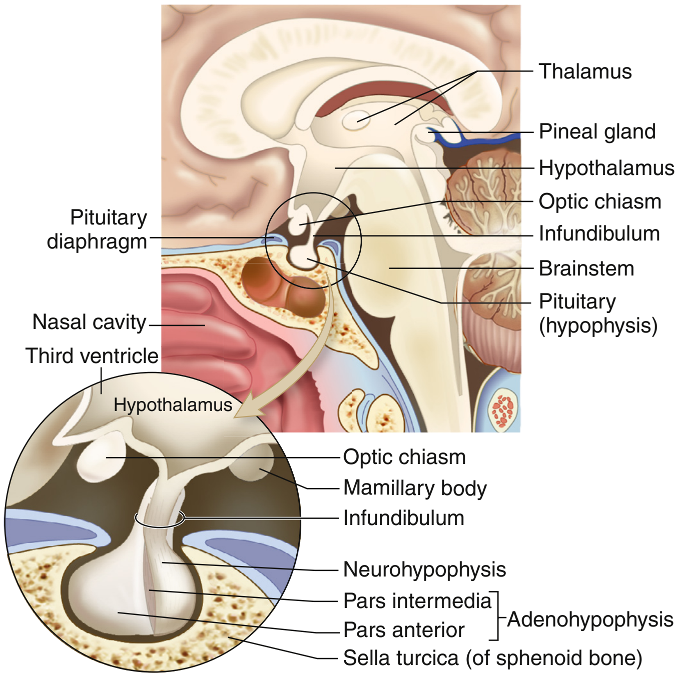

FIGURE 21-8 Location and Structure of the Pituitary Gland (Hypophysis). The pituitary gland is located within the sella turcica of the skull's sphenoid bone and is connected to the hypothalamus by a stalklike infundibulum. The infundibulum passes through a gap in the portion of the dura mater that covers the pituitary (the pituitary diaphragm). The inset shows that the pituitary is divided into an anterior portion, the adenohypophysis, and a posterior portion, the neurohypophysis. The adenohypophysis is further subdivided into the pars anterior and pars intermedia. The pars intermedia is almost absent in the adult pituitary. (Modified from Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

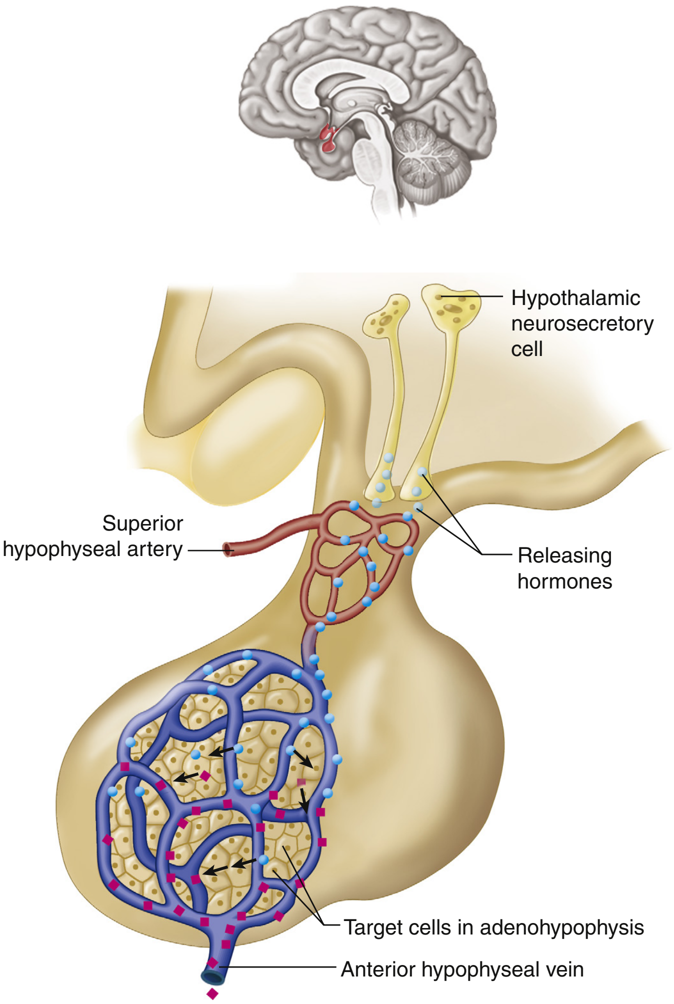

FIGURE 21-9 Hypophyseal Portal System. Neurons in the hypothalamus secrete releasing hormones into veins that carry the releasing hormones directly to the vessels of the adenohypophysis, thus bypassing the normal circulatory route. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

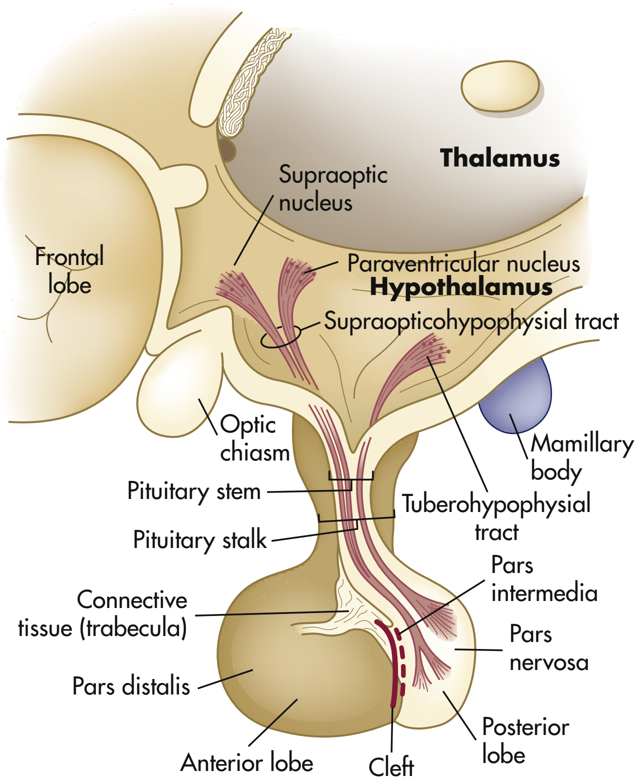

FIGURE 21-10 Nerve Tracts from Hypothalamus to Posterior Lobe of Pituitary Gland.

TABLE 21-4 HYPOTHALAMIC HORMONES (HYPOPHYSIOTROPIC HORMONES)

HORMONE	TARGET TISSUE	ACTION
Thyrotropin-releasing hormone (TRH)	Anterior pituitary	Stimulates release of thyroid-stimulating hormone (TSH) Modulates prolactin secretion
Gonadotropin-releasing hormone (GnRH)	Anterior pituitary	Stimulates release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH)
Somatostatin	Anterior pituitary	Inhibits release of growth hormone (GH) and TSH
Growth hormone–releasing hormone (GHRH)	Anterior pituitary	Stimulates release of GH
Corticotropin-releasing hormone (CRH)	Anterior pituitary	Stimulates release of adrenocorticotropic hormone (ACTH) and β-endorphin
Substance P	Anterior pituitary	Inhibits synthesis and release of ACTH Stimulates secretion of GH, FSH, LH, and prolactin
Dopamine	Anterior pituitary	Inhibits synthesis and secretion of prolactin
Prolactin-releasing factor (PRF)	Anterior pituitary	Stimulates secretion of prolactin

Hormones of the Posterior Pituitary

The posterior pituitary secretes two polypeptide hormones: (1) ADH, also called *arginine-vasopressin;* and (2) oxytocin. These peptide hormones are similar in structure, differing by only two amino acids. They are synthesized, along with their carrier proteins (the neurophysins), in the supraoptic and paraventricular nuclei of the hypothalamus (see Figure 21-10). Once synthesized, these hormones and their neurophysins are packaged in secretory vesicles and are moved down the axons of the pituitary stalk to the pars nervosa for storage. The posterior pituitary thus can be seen as a storage and releasing site for hormones synthesized in the hypothalamus.

The release of ADH and oxytocin is mediated by cholinergic and adrenergic neurotransmitters. The major stimulus to both ADH and oxytocin release is glutamate, whereas the major inhibitory input is through gamma-aminobutyric acid (GABA). Before release into the circulatory system, ADH and oxytocin are split from the neurophysins and are secreted in unbound form.[15]

Antidiuretic Hormone. The major homeostatic function of the posterior pituitary is the control of plasma osmolality, as regulated by ADH (see Chapter 3). At physiologic levels, ADH acts on the vasopressin 2 (V2) receptors of the renal tubular cells to increase their permeability (see Chapter 37). This increased permeability leads to an increase in water reabsorption into the blood and the production of more concentrated urine. These effects may be inhibited by hypercalcemia, prostaglandin E, and hypokalemia. At pathophysiologically high serum levels, ADH acts on vasopressin 1 (V1) receptors and causes vasoconstriction.

The secretion of ADH is regulated primarily by the osmoreceptors of the hypothalamus, located near or in the supraoptic nuclei. As plasma osmolality increases, these osmoreceptors are stimulated, the rate of ADH secretion increases, more water is reabsorbed from the kidney, and the plasma is diluted to its set-point osmolality (approximately 280 mOsm/kg).[15] ADH has no direct effect on electrolyte levels, but by increasing water reabsorption, serum electrolyte concentrations may decrease because of a dilutional effect.

ADH secretion also is increased by changes in intravascular volume, which are monitored by mechanoreceptors in the left atrium and in the carotid and aortic arches. A volume loss of 7% to 25% acts through these receptors to stimulate ADH secretion. Stress, trauma, pain, exercise, nausea, nicotine, exposure to heat, and drugs such as morphine also increase ADH secretion. ADH secretion decreases with a decrease in plasma osmolality; an increase in intravascular volume; hypertension; an increase in estrogen, progesterone, and angiotensin II levels; and alcohol ingestion.

As mentioned previously, ADH at high serum levels acts on the V1 receptors and causes vasoconstriction and a resulting

TABLE 21-5 TROPIC HORMONES OF THE ANTERIOR PITUITARY AND THEIR FUNCTIONS

HORMONE	SECRETORY CELL TYPE	TARGET ORGANS	FUNCTIONS
Adrenocorticotropic hormone (ACTH)	Corticotropic	Adrenal gland (cortex)	Increased steroidogenesis (cortisol and androgenic hormones) Synthesis of adrenal proteins contributing to maintenance of the adrenal gland
Melanocyte-stimulating hormone (MSH)	Melanotropic	Anterior pituitary	Promotes secretion of melanin and lipotropin by anterior pituitary; makes skin darker
Somatotropic hormones			
Growth hormone (GH)	Somatotropic	Muscle, bone, liver	Regulates metabolic processes related to growth and adaptation to physical and emotional stressors, muscle growth, increased protein synthesis, increased liver glycogenolysis, increased fat mobilization
		Liver	Induces formation of somatomedins, or insulin-like growth factors (IGFs) that have actions similar to insulin
Prolactin	Lactotropic	Breast	Milk production
Glycoprotein hormones			
Thyroid-stimulating hormone (TSH)	Thyrotropic	Thyroid gland	Increased production and secretion of thyroid hormone Increased iodide uptake Promotes hypertrophy and hyperplasia of thymocytes
Luteinizing hormone (LH)	Gonadotropic	In women: granulosa cells In men: Leydig cells	Ovulation, progesterone production Testicular growth, testosterone production
Follicle-stimulating hormone (FSH)	Gonadotropic	In women: granulosa cells In men: Sertoli cells	Follicle maturation, estrogen production Spermatogenesis
β-Lipotropin	Corticotropic	Adipose cells	Fat breakdown and release of fatty acids
β-Endorphins	Corticotropic	Adipose cells Brain opioid receptors	Analgesia; may regulate body temperature, food and water intake

increase in arterial blood pressure. This baroreceptor-mediated response is much less sensitive than the ADH response to changes in osmolarity. Therefore, physiologic levels of ADH do not significantly affect vessel tone. However, significant vasoconstriction may be achieved pharmacologically. For example, high doses of ADH (given as the drug vasopressin) may be administered to achieve hemostasis during hemorrhage and to raise blood pressure in shock states.[16]

Oxytocin. Oxytocin is responsible for contraction of the uterus and milk ejection in lactating women and may affect sperm motility in men. In a woman, oxytocin is secreted in response to suckling and mechanical distention of the female reproductive tract. Stimulated by sucking, oxytocin binds to its receptors on myoepithelial cells in the mammary tissues and causes contraction of those cells. This results in increased intramammary pressure and milk expression ("let down" reflex). In response to distention of the uterus, oxytocin stimulates contractions. Oxytocin functions near the end of labor to enhance the effectiveness of contractions, promote delivery of the placenta, and stimulate postpartum uterine contractions, thereby preventing excessive bleeding. The function of this hormone is discussed in more detail in Chapter 23.

Oxytocin has been implicated in behavior responses, especially in women. It has been suggested that oxytocin and its receptor play a role in the brain's responsiveness to stressful stimuli, especially in the pregnant and postpartum states. Its potential role in the treatment of maternal child neglect and a variety of anxiety disorders is being explored.[17,18]

Hormones of the Anterior Pituitary

The anterior pituitary is composed of two main cell types: (1) the **chromophobes,** which appear to be nonsecretory; and (2) the **chromophils,** which are considered the secretory cells of the adenohypophysis. The chromophils are subdivided into seven secretory cell types, each type secreting one or more specific hormones (Table 21-5). In general, the regulation of the anterior pituitary hormones is achieved by (1) feedback of hypothalamic releasing–inhibitory hormones and factors, (2) feedback from target gland hormones (i.e., cortisol, estrogen), and (3) direct effects of neurotransmitters.

The major tropic hormones secreted by the anterior pituitary include ACTH, melanocyte-stimulating hormone (MSH), luteinizing hormone (LH), growth hormone (GH), prolactin, follicle-stimulating hormone (FSH), and TSH. The actions of these anterior pituitary tropic hormones are summarized in Table 21-5. These major hormones can be grouped into three categories: corticotropin-related hormones (ACTH and MSH), glycoproteins (LH, FSH, and TSH), and somatomammotropins (GH and prolactin). The corticotropin-related hormones are all derived from the precursor pro-opiomelanocortin (POMC). The role of ACTH is discussed later in this chapter. MSH promotes the secretion of melanin, which makes the skin darker. β-Lipotropin and β-endorphins are minor corticotropic hormones also released from the anterior pituitary. β-Lipotropin plays a role in fat catabolism and β-endorphins impact pain perception, body temperature, and food and water intake. The glycoprotein gonadotropins FSH and LH control reproductive

processes in men and women and are discussed in Chapter 23. TSH and its effects on the thyroid gland are discussed later in this chapter. Growth hormone and prolactin have diverse and important effects on body tissues and are discussed next.

Growth Hormone (GH). GH secretion is controlled by two hormones from the hypothalamus: growth hormone–releasing hormone (GHRH), which increases GH secretion; and somatostatin, which inhibits it. GH is released from the pituitary in a pulsatile fashion, and overall secretion peaks during adolescence. This hormone is essential to normal tissue growth and maturation, and affects aging, sleep, nutritional status, stress, and reproductive hormones. In the bone, GH stimulates epiphyseal growth and increases osteoclast and osteoblast activity, resulting in increased bone mass. GH also increases amino acid transport in muscles. Other functions of GH include lipolysis and enhancement of hepatic protein synthesis.

Many of the anabolic functions of GH are mediated, at least in part, by the insulin-like growth factors (IGFs), also known as the somatomedins. There are two primary forms of IGF: IGF-1 and IGF-2, of which IGF-1 is the most biologically active. They both circulate bound to a group of binding proteins (IGFBP). IGF-1 binds to both insulin receptors, providing an insulin-like effect on skeletal muscle, and with the IGF-1 receptor, which mediates the anabolic effects of GH. IGF-2 causes a negative effect on tissue growth, thus balancing the activity of the IGF-1. Because of the anabolic effects of GH and IGF, they can be used to treat growth disorders and increase muscle mass but their use also has been linked to increased rates of cancer.[19] Interestingly, deficiencies in the growth hormone receptor have been linked to decreased risk of cancer and diabetes.[20]

Prolactin. Prolactin functions to induce milk production during pregnancy and lactation. It also has effects on reproduction and immune function. Its synthesis is stimulated by vasoactive intestinal polypeptide, serotonin, and growth factors. Its release is inhibited by dopamine. Hyperprolactinemia is a complication of tumors of the pituitary gland and some medications and is discussed in Chapter 22.

Pineal Gland

The pineal gland is located within the brain itself (see Figure 21-1) and is composed of photoreceptive cells that secrete melatonin. It is innervated by noradrenergic sympathetic nerve terminals controlled by pathways within the hypothalamus. **Melatonin** release is stimulated by exposure to dark and inhibited by light exposure. It is synthesized from tryptophan, which is first converted to serotonin and then to melatonin. Melatonin regulates circadian rhythms and reproductive systems, including the secretion of GnRH and the onset of puberty. It also plays an important role in immune regulation and is postulated to affect the aging process. Further effects of melatonin include increasing nitric oxide release from blood vessels, removing toxic oxygen free radicals, and decreasing insulin secretion. Melatonin has been used therapeutically in humans to help with sleep disturbances, jet lag, and psychologic disorders. Its utility for numerous other disorders is being explored.[21,22]

Thyroid and Parathyroid Glands

The thyroid gland, located in the neck just below the larynx, produces hormones that control the rates of metabolic processes throughout the body. The four parathyroid glands are located near the posterior side of the thyroid and function to control serum calcium levels.

Thyroid Gland

The **thyroid gland** is composed of two lobes that lie on either side of the trachea, inferior to the thyroid cartilage (Figure 21-11). The lobes are joined by a small band of tissue, the **isthmus,** which crosses the anterior surface of the trachea and larynx at the cricoid cartilage. The normal thyroid gland is not visible on inspection, but it may be palpated on swallowing, which causes upward displacement of the gland.

The thyroid gland is composed of **follicles** (Figure 21-12). The follicles are composed of follicular cells that surround a viscous substance called *colloid.* The follicular cells synthesize and secrete some of the thyroid hormones. Neurons of the autonomic nervous system terminate on blood vessels within the thyroid gland and on the follicular cells themselves. Acetylcholine, catecholamines, and other peptides directly affect secretory activity of the follicular cells and thyroid blood flow.

Regulation of Thyroid Hormone Secretion. **Thyroid hormone (TH)** is regulated through a negative-feedback loop involving the hypothalamus, the anterior pituitary, and the thyroid gland (see Figure 21-2). Thyrotropin-releasing hormone (TRH), which is synthesized and stored within the hypothalamus, initiates this loop. TRH is released into the hypothalamic-pituitary portal system and circulates to the anterior pituitary, where it stimulates the release of TSH. TRH levels increase with exposure to cold or stress and from decreased levels of T_4.

Thyroid-stimulating hormone (TSH) is a glycoprotein hormone synthesized and stored within the anterior pituitary. Once TSH is secreted by the anterior pituitary, it circulates to

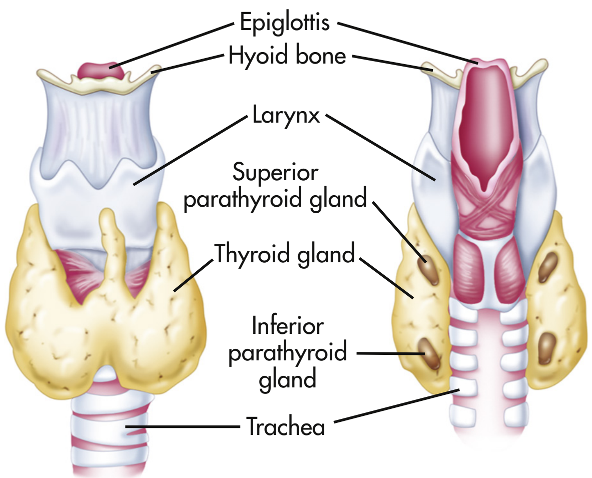

FIGURE 21-11 Thyroid and Parathyroid Glands. Note the relationship of the thyroid and parathyroid glands to each other, to the larynx (voice box), and to the trachea. (From Thibodeau GA, Patton KT: *Structure & function of the body,* ed 14, St Louis, 2012, Mosby.)

bind with TSH receptor sites located on the plasma membrane of the thyroid follicular cells. The effects of TSH on the thyroid include: (1) an immediate increase in the release of stored thyroid hormones, (2) an increase in iodide uptake and oxidation, (3) an increase in thyroid hormone synthesis, and (4) an increase in the synthesis and secretion of prostaglandins by the thyroid. TSH is also important in stimulating the growth and maintenance of the thyroid gland by stimulating thyrocyte hypertrophy and hyperplasia and decreasing apoptosis.[23] Thyroid gland hormones and their regulation and function are summarized in Table 21-6.

Thyroid hormones have a negative-feedback effect and inhibit TRH and TSH, which decreases TH synthesis and secretion. Thyroid hormone synthesis is also controlled by circulating enzymes called deiodinases that inactivate the precursor molecule thyroxine.

Synthesis of Thyroid Hormone. Thyroid hormone synthesis is summarized in the following steps:

1. Uniodinated thyroglobulin (a large glycoprotein) is produced by the endoplasmic reticulum of the follicular cells.
2. Tyrosine is incorporated into the thyroglobulin as it is synthesized.

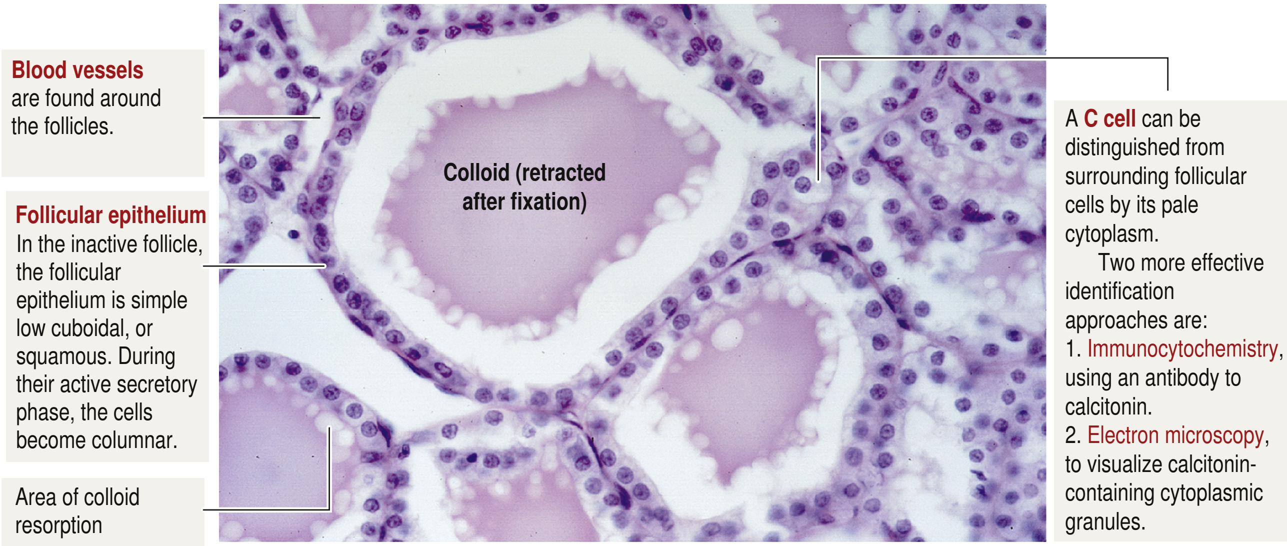

FIGURE 21-12 Thyroid Follicle Cells. (From Kierszenbaum AL, Tres L: *Histology and cell biology: an introduction to pathology,* ed 3, Philadelphia, 2012, Mosby.)

TABLE 21-6 THYROID GLAND HORMONES AND THEIR REGULATION AND FUNCTIONS

HORMONE	REGULATION	FUNCTIONS
Thyroxine (T_4) and triiodothyronine (T_3)	T_4 and T_3 levels are controlled by TSH	Regulates protein, fat, and carbohydrate catabolism in all cells
	Released in response to metabolic demand	Regulates metabolic rate of all cells
	Influences on amount secreted:	Regulates body heat production
	Gender	Insulin antagonist
	Pregnancy	Maintains growth hormone secretion, skeletal maturation
	Gonadal and adrenocortical-increased steroids = ↑ levels	Affects CNS development
	Exposure to extreme cold = ↑ levels	Necessary for muscle tone and vigor
	Nutritional state	Maintains cardiac rate, force, and output
	Chemicals	Maintains secretion of GI tract
	GHIH = ↓ levels	Affects respiratory rate and oxygen utilization
	Dopamine = ↓ levels	Maintains calcium mobilization
	Catecholamines = ↑ levels	Affects RBC production
		Stimulates lipid turnover, free fatty acid release, and cholesterol synthesis
Calcitonin	Elevated serum calcium—major stimulant for calcitonin	Lowers serum calcium by opposing bone-resorbing effects of PTH, prostaglandins, and calciferols by inhibiting osteoclastic activity
	Other stimulants	
	Gastrin	
	Calcium-rich foods (regardless of serum Ca^{++} levels)	Lowers serum phosphate levels
	Pregnancy	May also decrease calcium and phosphorus absorption in GI tract
	Lowered serum calcium—suppresses calcitonin release

3. Iodide (the inorganic form of iodine) is actively transferred (pumped) from the blood into the colloid by carrier proteins located in the outer membrane of the follicular cells. This active transport system is called the *iodide trap* and is very efficient at accumulating the trace amounts of iodide from the blood.
4. Iodide is oxidized and quickly attaches to tyrosine within the thyroglobulin molecule.
5. Coupling of iodinated tyrosine forms thyroid hormones. Triiodothyronine (T_3) is formed from coupling of monoiodotyrosine (one iodine atom and tyrosine) and diiodotyrosine (two iodine atoms and tyrosine). Tetraiodothyronine (T_4), commonly known as thyroxine, is formed from coupling of two diiodotyrosines.
6. Thyroid hormones are stored attached to thyroglobulin within the colloid until it is released into the circulation.

The thyroid gland normally produces 90% T_4 and 10% T_3. Once released into the circulation, T_3 and T_4 are primarily transported bound to one of three carrier proteins: thyroxine-binding globulin, thyroxine-binding prealbumin (transthyretin), or albumin. A small amount of thyroid hormone is also carried by lipoproteins. In the body tissues, T_4 is converted to T_3. T_3 binds with three different receptors (TRα1, TRβ1, and TRβ2).

Thyroid hormones affect many body tissues. Similar to some steroid hormones, thyroid hormones bind to intracellular receptor complexes and then influence the genetic expression of specific proteins. Thyroid hormones affect cell metabolism by altering protein, fat, and glucose metabolism and, as a result, heat production and oxygen consumption are increased. Thus these hormones are essential for maintaining healthy metabolic processes and normal growth and maturation. Their use is being explored for the therapy of many metabolic disorders.[24,25]

It is important to note that thyroid hormones exert a number of permissive effects on many organs, which are rather modest at physiologic thyroid hormone levels. However, these effects can become very pronounced when there are either high or low levels of circulating thyroid hormones. For example, in the heart, T_3 stimulates the synthesis of specific contractile proteins (e.g., α-myosin heavy chain), sarcolemmal ion pumps (Na^+-K^+-ATPase pump, Ca^{++}-ATPase pump), and membrane receptors (β-adrenergic receptors). Therefore, in hyperthyroidism, which is associated with elevated levels of thyroid hormones, cardiac effects include increased heart rate and cardiac output, as well as the development of cardiomyopathy. Thyroid hormones also affect the respiratory center, contributing to the normal hypoxic and hypercapnic drives. In severe hypothyroidism, ventilation can become very depressed. Thyroid hormone also stimulates bone resorption, and hyperthyroidism is associated with osteopenia, hypercalcemia, and hypercalciuria. Thyroid hormone is essential for normal neurologic development in the fetus and infant and affects neurologic functioning in adults. Other manifestations of thyroid hormone alteration are explained in Chapter 22. A newly described group of hormones called thyronamines have effects that oppose those of thyroid hormone (see What's New? Thyronamines).[26]

WHAT'S NEW?

Thyronamines

Thyronamines (TAMs) are a newly identified class of endogenous signaling compounds. Their structure is nearly identical to that of thyroid hormone but they have very different effects on tissues. Two TAMs, 3-iodothyronamine (T1AM) and thyronamine (TAM), have been identified in humans. Among the physiologic effects of TAMs found in experimental models are hypothermia, decreased metabolic rate, decreased cardiac contractility, hyperglycemia, and changes in adipose tissue metabolism. T1AM has been implicated in heart failure and insulin resistance. TAMs may have future therapeutic uses because they can induce hypothermia as a potential neuroprotective treatment for stroke, and affect metabolism in many kinds of cells including cancer cells.

Data from Galli E et al: *J Clin Endocrinol Metab* 97:E69–E74, 2012; Piehl S et al: *Endocr Rev* 32(1):64–80, 2011; Roy G, Placzek E, Scanlan T: *J Biol Chem* 287:1790–1800, 2012; Saba A et al: *Endocrinology* 151:5063–5073, 2010.

Also found in the tissue of the thyroid are parafollicular cells, or **C cells** (see Figure 21-12). The C cells secrete various polypeptides, including calcitonin. **Calcitonin,** also called *thyrocalcitonin,* acts to lower serum calcium levels by inhibition of bone-resorbing osteoclasts. High levels of calcitonin are required for these effects, and deficiencies of calcitonin do not lead to hypocalcemia. (Bone resorption is described in Chapter 43.) Consequently, the metabolic consequences of calcitonin deficiency or excess do not appear to be significant in humans (see Table 21-6). However, calcitonin is used for treatment of osteoporosis, osteoarthritis, Paget bone disease, hypercalcemia, osteogenesis imperfecta, and metastatic cancer of the bone. The precursor molecule to calcitonin, called procalcitonin, is a stress hormone that is elevated in infectious and inflammatory disorders and its measurement can aid in the diagnosis of these serious diseases.[27,28]

Parathyroid Glands

Two pairs of parathyroid glands normally are present, but the number may range from two to six. They are small and located behind the upper pole and lower pole of the thyroid gland (see Figure 21-11). The parathyroid glands produce **parathyroid hormone (PTH),** which works in concert with vitamin D to increase serum calcium concentration (Figure 21-13).[29] The overall effect of PTH secretion is to increase serum calcium concentration and decrease serum phosphate level. Magnesium and phosphate levels also affect PTH secretion. Hypomagnesemia in persons with normal calcium levels acts as a mild stimulant to PTH secretion, whereas in hypocalcemic individuals, hypomagnesemia decreases PTH secretion. Hyperphosphatemia leads to hypocalcemia because of calcium phosphate precipitation in soft tissue and bone. Alterations in serum phosphate levels therefore may indirectly influence PTH secretion by affecting serum calcium levels.

Once the parathyroid gland is stimulated, PTH is secreted. On release, PTH enters the circulation in unbound form. The hormone attaches to plasma membrane receptors in target tissues, where the biologic effects of PTH are mediated primarily by activation of the adenylyl cyclase system (see Chapter 1).

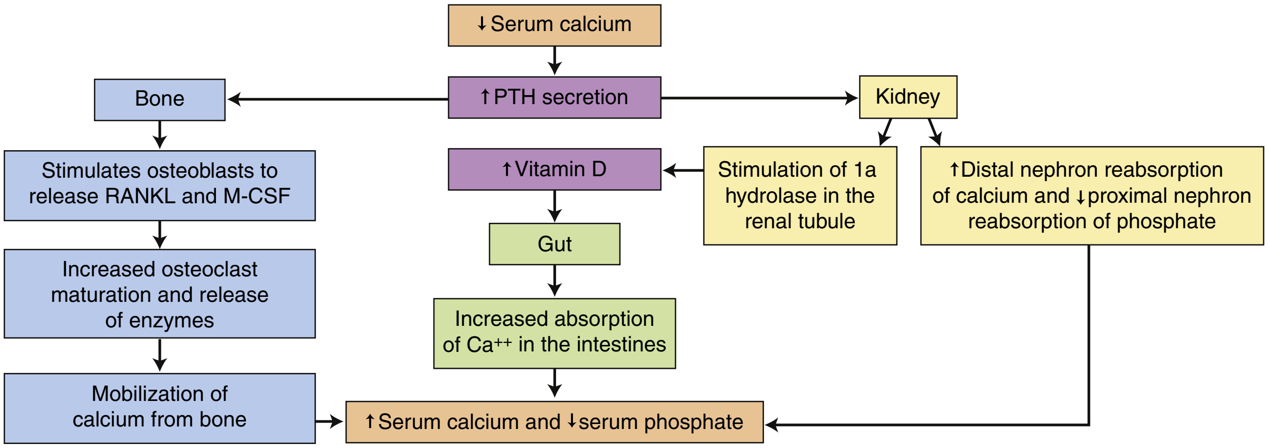

FIGURE 21-13 Normal Calcium Metabolism Regulated by PTH and Vitamin D. *M-CSF,* Macrophage-colony stimulating factor; *PTH,* parathyroid hormone; *RANKL,* receptor activator of NF-κβ ligand.

To achieve regulation of serum calcium concentration, PTH acts directly on bone and the kidneys. In bone, PTH has at least two effects. In acute hypocalcemia, PTH secretion stimulates osteoblasts to release receptor activator for nuclear factor–kappa beta (NF-κβ) ligand (RANKL) and macrophage-colony stimulating factor (M-CSF), which results in osteoclast proliferation, maturation, and release of acidic enzymes, such as cathepsin.[30] These enzymes mobilize calcium release from bone, which increases the serum calcium level. Chronic stimulation by PTH results in bone remodeling, a process in which bone is broken down and re-formed. Chronic stimulation can occur because of parathyroid tumors (primary hyperparathyroidism) or because of chronic hypocalcemia, such as that seen in end-stage renal disease (secondary hyperparathyroidism).[29] This process can weaken the bone, leading to an increased risk for fracture (e.g., renal osteodystrophy).[31] Paradoxically, intermittent therapeutic bursts of PTH can actually strengthen bone and this treatment modality is used in individuals with osteoporotic fractures.[32,33]

In the kidneys, PTH acts on its plasma membrane receptor in the distal tubules of the nephron to increase reabsorption of calcium. It acts on the proximal tubules to decrease reabsorption of phosphorus and bicarbonate. In renal cells, PTH stimulates the activity of 1α-hydroxylase, which mediates a step in the formation of the biologically active form of vitamin D (1,25-dihydroxy-vitamin D_3). The primary role of vitamin D_3 is to serve as a cofactor with PTH to increase gastrointestinal absorption of calcium. Vitamin D also increases PTH-mediated osteoclast stimulation. Vitamin D deficiency is associated with poor bone health and has been implicated in many other disorders (see What's New? Vitamin D).

Another hormone that plays an important role in calcium and bone physiology is parathyroid hormone–related peptide (PTHrP). This hormone is synthesized in many adult and fetal tissues and affects tissues around it in a paracrine fashion. It has similar biologic properties to PTH and utilizes the same receptors; however, it also plays a role in placental calcium transport, lactation, and tooth development in the fetus. It was discovered as the primary hormone involved in malignancy-related hypercalcemia (paraneoplastic disorders).[30]

WHAT'S NEW?

Vitamin D

Vitamin D is essential for bone health and is widely used for the prevention and treatment of postmenopausal osteoporosis and renal osteodystrophy. More recently, vitamin D deficiency has been associated with an increased risk for infections, cancer, asthma, heart disease, dementia, diabetes, chronic pain syndromes, and autoimmune disorders. Controversies continue as to whether these associations indicate a direct cause and effect between low levels of vitamin D and the pathophysiology of these diseases, and whether vitamin D supplementation reduces risk or improves outcomes. However, many health organizations recommend increased intake of vitamin D–containing foods (seafood, vitamin D–fortified juices, and milk products), increased exposure to sunlight, and supplementation with vitamin D. The Institute of Medicine currently recommends 400 to 600 IUs of vitamin D per day for adults.

Endocrine Pancreas

The **pancreas** is both an endocrine gland that produces hormones and an exocrine gland that produces digestive enzymes. (The exocrine pancreas is discussed in Chapter 40.) A major disorder of the endocrine pancreas is diabetes mellitus.

The pancreas is located behind the stomach, between the spleen and the duodenum. It houses the **islets of Langerhans.** The islets of Langerhans have four types of hormone-secreting cells: **alpha cells,** which secrete glucagon; **beta cells,** which secrete insulin and amylin; **delta cells,** which secrete gastrin and somatostatin; and **F (or PP) cells,** which secrete pancreatic polypeptide that stimulates gastric secretion and antagonizes cholecystokinin. These hormones regulate carbohydrate, fat,

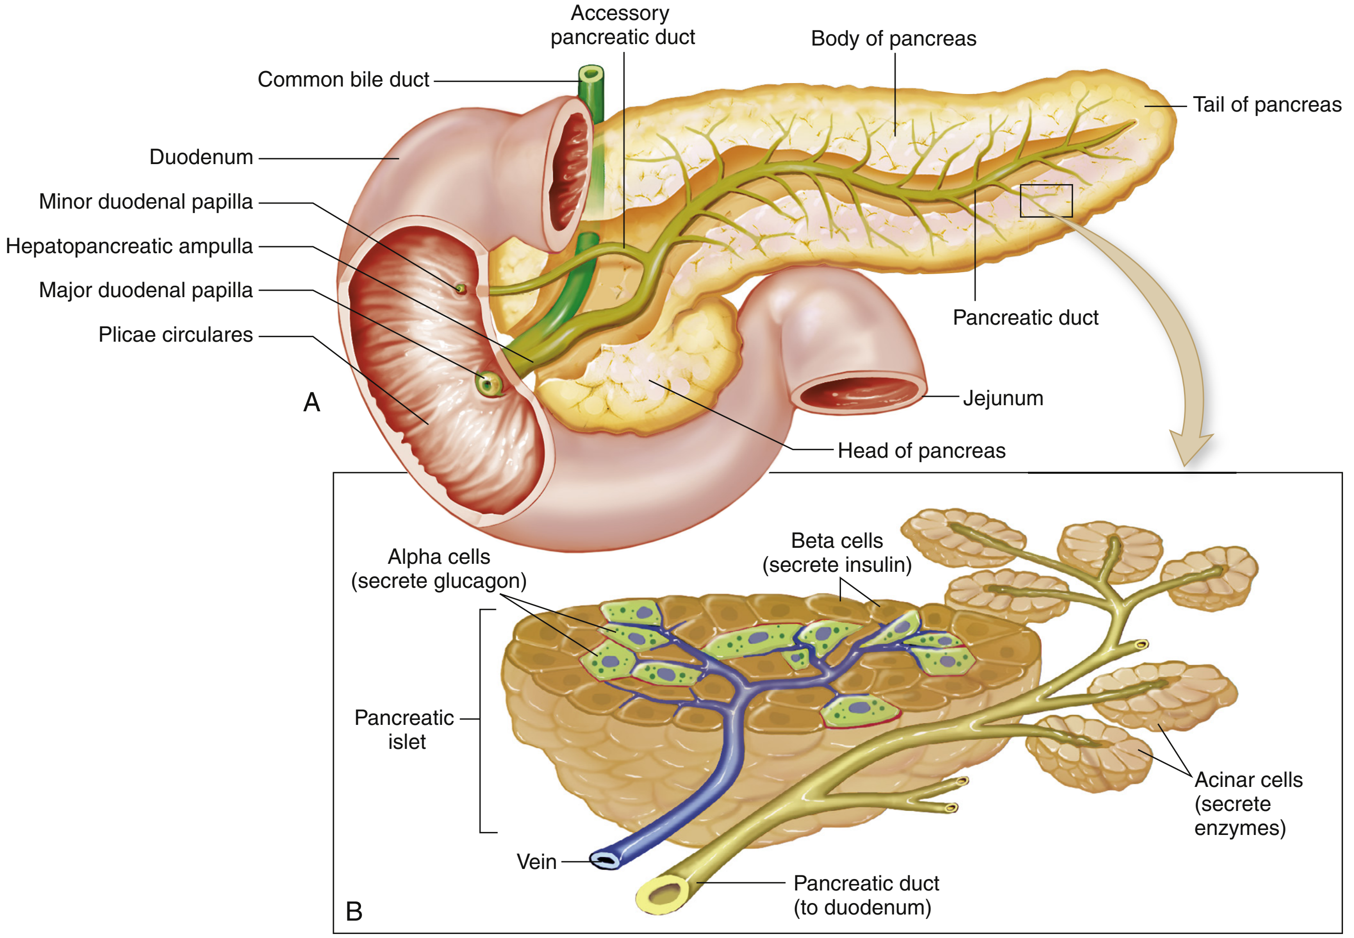

FIGURE 21-14 The Pancreas. **A,** Pancreas dissected to show main and accessory ducts. The main duct may join the common bile duct, as shown here, to enter the duodenum by a single opening at the major duodenal papilla, or the two ducts may have separate openings. The accessory pancreatic duct is usually present and has a separate opening into the duodenum. **B,** Exocrine glandular cells (around small pancreatic ducts) and endocrine glandular cells of the pancreatic islets (adjacent to blood capillaries). Exocrine pancreatic cells secrete pancreatic juice, alpha endocrine cells secrete glucagon, and beta cells secrete insulin. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

and protein metabolism. (The pancreas is illustrated in Figure 21-14.) Nerves from both the sympathetic and the parasympathetic divisions of the autonomic nervous system innervate the pancreatic islets.

The perfusion of the anterior lobe of the pancreas, where alpha, beta, and delta cells are most numerous, comes from branches of the superior mesenteric artery. The posterior lobe is perfused by branches of the celiac artery. The pancreatic islets receive 10% of the pancreatic blood flow but represent only 1% of pancreatic mass. This is necessary for oxygenation and delivery of islet hormones to target cells.

Insulin

The beta cells of the pancreas synthesize **insulin** from the precursor proinsulin. Proinsulin is formed from a larger and earlier precursor molecule, preproinsulin. Proinsulin is composed of an A peptide and a B peptide connected by a C peptide and two disulfide bonds. C peptide is cleaved by proteolytic enzymes, leaving the bonded A and B peptide chains that become insulin. Insulin circulates freely in the plasma and is not bound to a carrier. C peptide can be measured in the blood as an indirect measure of serum insulin synthesis. Recent studies have shown that C peptide has biologic activity and binds to cells through a G-protein receptor, resulting in increased intracellular calcium levels. Its role in diabetic complications is being explored.[34]

Secretion of insulin is regulated by chemical, hormonal, and neural control. Insulin secretion is promoted when blood levels of glucose, amino acids (arginine and lysine), and gastrointestinal hormones (glucagon, gastrin, cholecystokinin, secretin) increase, and when the beta cells are stimulated parasympathetically. Insulin secretion diminishes in response to low blood levels of glucose (hypoglycemia), high levels of insulin (through negative feedback to the beta cells), and sympathetic stimulation of the alpha cells in the islets. Prostaglandin (PGE_2) also inhibits insulin secretion.

Insulin facilitates the rate of glucose uptake into many cells within the body. At the target cell, insulin binds with an enzyme-linked plasma membrane receptor that contains tyrosine kinase on the cytosolic surface. Insulin receptor binding sends a cascade of signals to activate glucose transporters

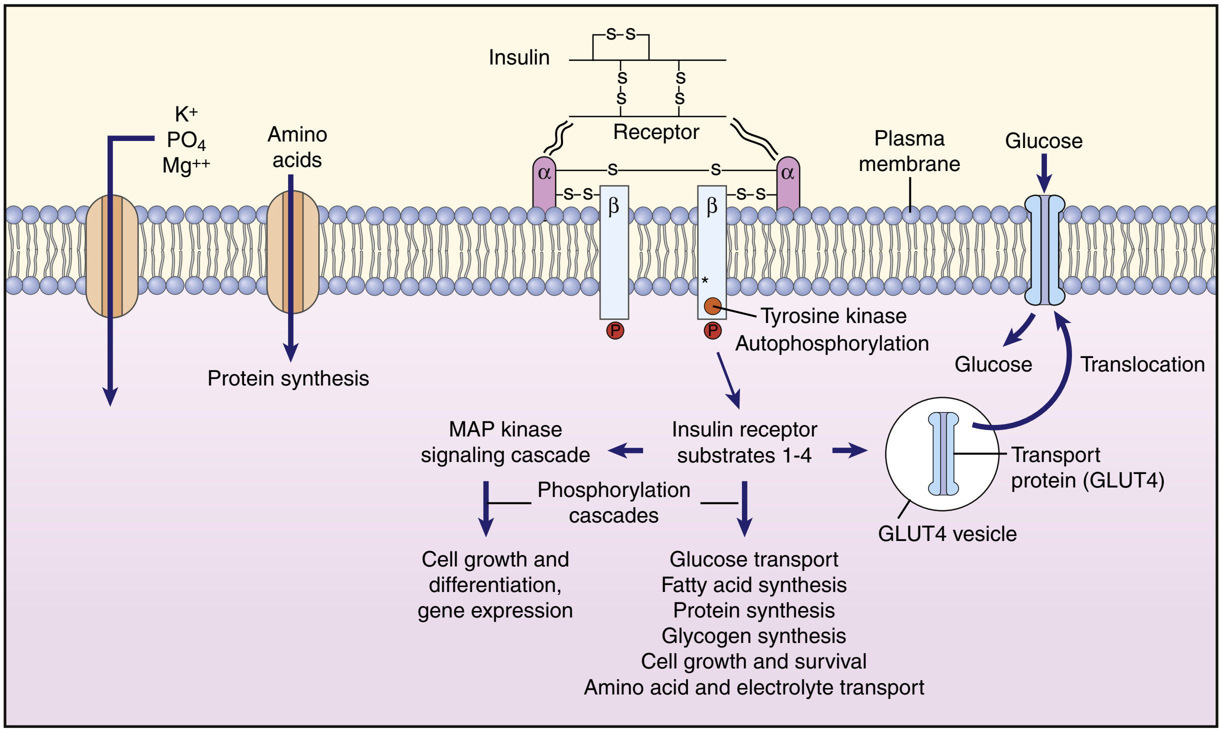

FIGURE 21-15 Insulin Action on Cells. Binding of insulin to its receptor causes autophosphorylation of the receptor, which then itself acts as a tyrosine kinase that phosphorylates insulin receptor substrate 1. Numerous target enzymes, such as protein kinase B and MAP kinase, are activated, and these enzymes have a multitude of effects on cell function. The glucose transporter, GLUT4, is recruited to the plasma membrane, where it facilitates glucose entry into the cell. The transport of amino acids, potassium, magnesium, and phosphate into the cell is also facilitated. The synthesis of various enzymes is induced or suppressed, and cell growth is regulated by signal molecules that modulate gene expression. *MAP,* Mitogen-activated protein. (Redrawn from Levy MN, Koeppen BM, Stanton BA: *Principles of physiology,* ed 4, St Louis, 2006, Mosby.)

(GLUT) for entry of glucose into the cell.[35] The primary GLUT is called GLUT4. It is stored in cellular vesicles until activated by the insulin receptor and is then translocated to the cell surface where it facilitates the diffusion of glucose into the cell. Translocation of GLUT4 to the cell surface is associated with a 10- to 21-fold increase in glucose diffusion into the cell, particularly in skeletal and cardiac muscle, liver, and adipose cells (Figure 21-15). The sensitivity of the insulin receptor is a key component in maintaining normal cellular function, and insulin resistance has been implicated in numerous cardiovascular diseases, including hypertension and diabetes. Adipocytes release a number of hormones that are altered in obesity and have an important effect on insulin sensitivity.

Insulin is an anabolic hormone that promotes not only the uptake of glucose but also the synthesis of proteins, carbohydrates, lipids, and nucleic acids. It functions mainly in the liver, muscle, and adipose tissue. Table 21-7 summarizes the actions of insulin. The net effect of insulin in these tissues is to stimulate protein and fat synthesis and decrease blood glucose level. The brain, red blood cells, kidney, and lens of the eye do not

require insulin for glucose transport. Insulin also facilitates the intracellular transport of potassium (K^+), phosphate, and magnesium. Insulin is metabolized in the liver and kidney by enzymes that split disulfide bonds. Very little insulin is excreted unchanged in the urine.

Glucagon

Glucagon is produced by the alpha cells of the pancreas and by a number of cells lining the gastrointestinal tract. High glucose levels cause glucagon release to be inhibited; low glucose levels and sympathetic stimulation promote glucagon release. Amino acids, such as alanine, glycine, and asparagine, also stimulate glucagon secretion. A protein-rich meal has the same effect.

Glucagon acts primarily in the liver and increases blood glucose level by stimulating glycogenolysis and gluconeogenesis; thus glucagon acts as an antagonist to insulin. Glucagon also stimulates lipolysis, which has a ketogenic effect caused by the metabolism of free fatty acids in the liver. These effects have led to the hypothesis that glucagon excess is as important as insulin insufficiency in the pathogenesis of diabetes.[36]

Incretins

The incretin hormones are secreted from endocrine cells in the gastrointestinal tract in the presence of carbohydrates, proteins, and fats. The major incretin hormones are glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP). They control postprandial glucose levels by promoting glucose-dependent insulin secretion, inhibiting glucagon synthesis, and delaying gastric emptying.[37] Incretins also enhance beta-cell mass and replenish intracellular stores of insulin. Incretins are broken down by an enzyme called dipeptidyl peptidase 4 (DPP IV) and drugs that inhibit this enzyme (called 'gliptins') increase incretin levels. The gliptins and other drugs are incretin agonists used for the treatment of type 2 diabetes.[38,39]

Amylin

Amylin (islet amyloid polypeptide) is a peptide hormone co-secreted with insulin by beta cells in response to nutrient stimuli. It regulates blood glucose level by delaying nutrient uptake and suppressing glucagon secretion after meals. Amylin also has a satiety effect. Through these mechanisms, amylin has an anti-hyperglycemic effect. Aggregated amylin has cytotoxic properties and contributes to the loss of beta cells in type 2 diabetes and in islet cell transplants.[40,41] New drugs that serve as amylomimetics are used for treatment of both type 1 and type 2 diabetes.[42]

Somatostatin

Pancreatic **somatostatin** is produced by delta cells of the pancreas and is a hormone essential in carbohydrate, fat, and protein metabolism (i.e., homeostasis of ingested nutrients). It differs from hypothalamic somatostatin, which inhibits release of growth hormone and TSH. Pancreatic somatostatin is involved in regulating alpha-cell and beta-cell function within the islets by inhibiting secretion of insulin, glucagon, and pancreatic polypeptide.

Ghrelin, Pancreatic Polypeptide, and Gastrin

Ghrelin levels increase before a meal and stimulate appetite, then fall soon after a meal and promote a feeling of satiety.[43] Ghrelin stimulates GH secretion and plays a role in obesity and the regulation of insulin sensitivity.[44] **Pancreatic polypeptide** is released by F cells in response to hypoglycemia and protein-rich meals. It stimulates Y receptors in numerous tissues, including the gallbladder, exocrine pancreas, and parietal cells in the gut. It promotes gastric secretion and antagonizes cholecystokinin and is frequently increased in pancreatic tumors and in diabetes.[45] The function of pancreatic **gastrin** has not been established; however, it likely plays a role in controlling the secretion of glucagon.

Adrenal Glands

The **adrenal glands** are paired pyramid-shaped organs located behind the peritoneum and close to the upper pole of each kidney. Each gland is surrounded by a capsule embedded in fat and well supplied with blood from the phrenic and renal arteries and the aorta. Venous return from the left adrenal gland is to the renal vein and from the right is to the inferior vena cava.

Each adrenal gland consists of two separate portions: an outer cortex and an inner medulla. These two portions have different embryonic origins, different structures, and different hormonal functions. In effect, each adrenal gland functions like two separate glands, although there are interrelationships between functions of each portion (Figure 21-16).

Adrenal Cortex

The **adrenal cortex,** or outer region of the gland, accounts for 80% of the weight of the adult gland. The cortex is histologically subdivided into the following three zones:

1. The **zona glomerulosa,** the outer layer, constitutes about 15% of the cortex and primarily produces the mineralocorticoid aldosterone.
2. The **zona fasciculata,** the middle layer, constitutes 78% of the cortex and secretes the glucocorticoids cortisol, cortisone, and corticosterone.
3. The **zona reticularis,** the inner layer, constitutes 7% of the cortex and secretes mineralocorticoids (aldosterone), adrenal androgens and estrogens, and glucocorticoids.

The cells of the adrenal cortex are stimulated by the anterior pituitary hormone ACTH. The adrenal cortex secretes several steroid hormones, including the glucocorticoids (mainly cortisol), the mineralocorticoids (mainly aldosterone), and the adrenal androgens and estrogens. These hormones are all synthesized from cholesterol. The best-known pathway of steroidogenesis involves the conversion of cholesterol to pregnenolone, which is then converted to the major corticosteroids.[46]

Glucocorticoids. The **glucocorticoids** have metabolic, neurologic, anti-inflammatory, and growth-suppressing effects. They act through nuclear and nongenomic pathways in the cell. The term glucocorticoid refers to those steroid hormones that have direct effects on carbohydrate metabolism. These hormones increase blood glucose concentration by promoting gluconeogenesis in the liver and by decreasing uptake of glucose into muscle cells, adipose cells, and lymphatic

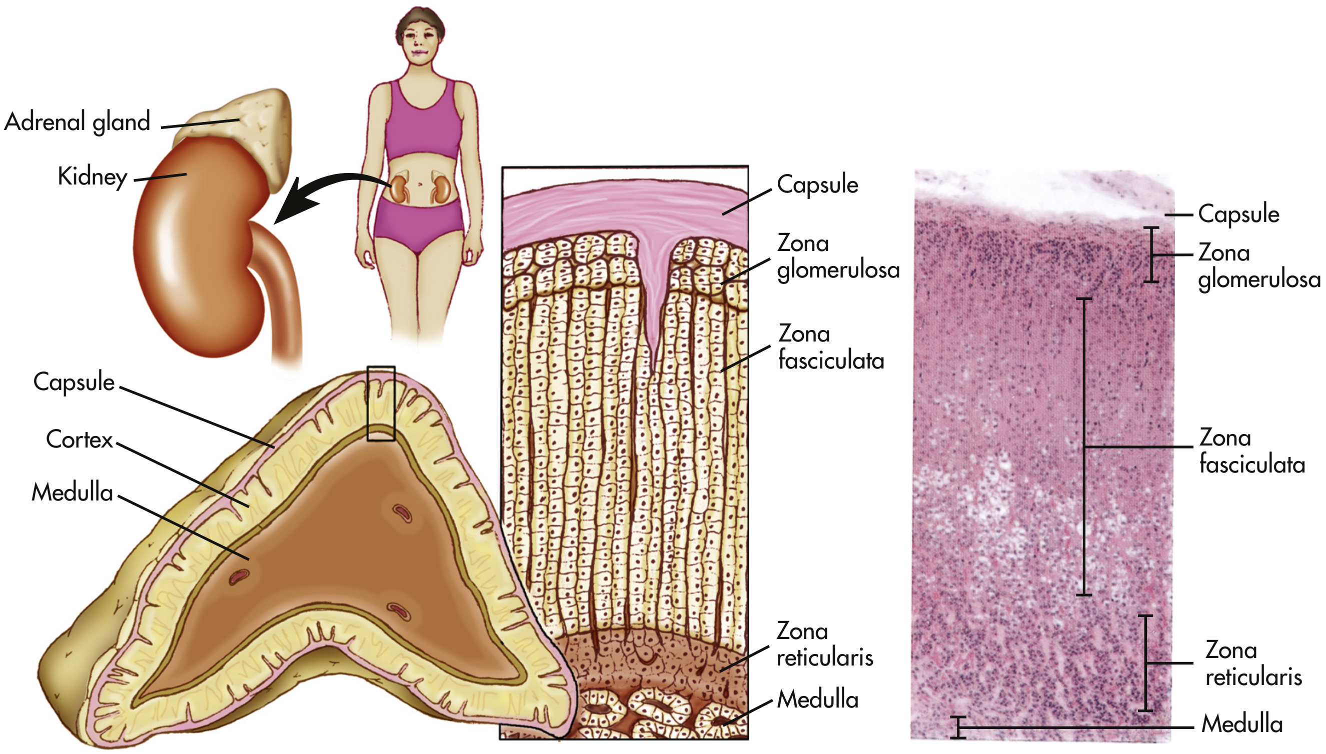

FIGURE 21-16 **Structure of the Adrenal Gland Showing Cell Layers (Zones) of the Cortex.** Zona glomerulosa secretes aldosterone. Zona fasciculata secretes abundant amounts of glucocorticoids, chiefly cortisol. Zona reticularis secretes minute amounts of sex hormones and glucocorticoids. A portion of the medulla is visible at lower right in the photomicrograph (×35) and at the bottom of the drawing. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 6, St Louis, 2007, Mosby.)

cells.[47] In extrahepatic tissues, the glucocorticoids stimulate protein catabolism and inhibit amino acid uptake and protein synthesis. The ultimate effect on the body is protein breakdown (catabolism).

The glucocorticoids act at several sites to influence immune and inflammatory reactions (described in Chapters 7 and 11).[48] They affect innate immunity through several pathways, including decreasing the activity of pattern receptors on the surface of macrophages (see Chapter 7). Another major immune suppressant effect is a glucocorticoid-mediated decrease in the proliferation of T lymphocytes, primarily T-helper lymphocytes.[48] There is a greater effect on T-helper 1 cytokine production (including antiviral interferons) than there is T-helper 2 cytokine production and therefore greater depression of cellular immunity than humoral immunity (see Chapter 8). Glucocorticoids also decrease immune and inflammatory responses by decreasing natural killer cell activity and suppressing the synthesis, secretion, and actions of chemical mediators involved in inflammatory and immune responses. Glucocorticoids suppress the inflammatory response by blocking phospholipase A and the synthesis of prostaglandins, thromboxanes, and leukotrienes; and by inhibiting inflammatory gene expression.[48] In addition, glucocorticoids stimulate anti-inflammatory cytokines (e.g., interleukin-10 [IL-10] and transforming growth factor-beta). Lysosomal membranes are also stabilized, decreasing the release of proteolytic enzymes. This suppression of innate and adaptive immunity by glucocorticoids means that infection and poor wound healing are some of the most problematic complications of the use of glucocorticoids in the treatment of disease. Similarly, psychologic and physiologic stress increases glucocorticoid production, which provides a pathway for the well-described decrease in immunity seen in both acute and chronic stress conditions (see Chapter 11).

Other effects of glucocorticoids include inhibition of bone formation, inhibition of ADH secretion, and stimulation of gastric acid secretion. Glucocorticoids appear to potentiate the effects of catecholamines, including sensitizing the arterioles to the vasoconstrictive effects of norepinephrine. Thyroid hormone and growth hormone effects on adipose tissue also are potentiated by glucocorticoids. A metabolite of cortisol may act like a barbiturate and depress nerve cell function in the brain, accounting for the noted effects on mood associated with steroid level fluctuation in disease or stress.

Pathologically high levels of glucocorticoids increase the number of circulating erythrocytes (leading to polycythemia), increase the appetite, promote fat deposition in the face and cervical areas, increase uric acid excretion, decrease serum calcium levels (possibly by inhibiting gastrointestinal absorption of calcium), suppress the secretion and synthesis of ACTH, and interfere with the action of growth hormone so that somatic growth is inhibited.[49]

The most potent of the naturally occurring glucocorticoids is **cortisol.** It is the main secretory product of the adrenal cortex and is necessary for the maintenance of life and for protection from stress (see Chapter 11, particularly Figure 11-2). Cortisol

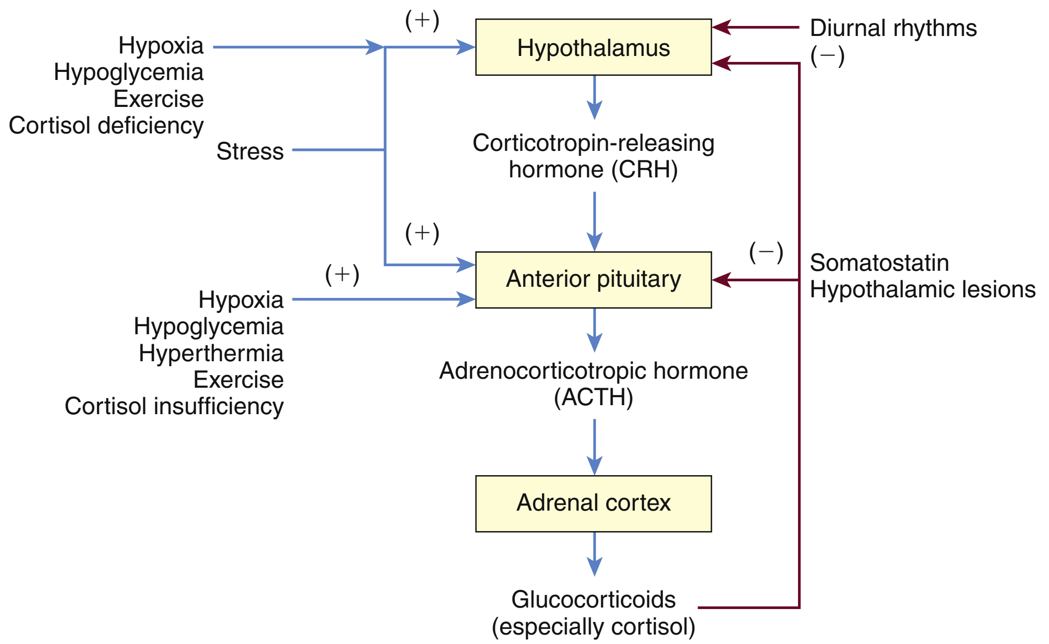

FIGURE 21-17 Feedback Control of Glucocorticoid Synthesis and Secretion.

has a biologic half-life of approximately 90 minutes, with the liver primarily responsible for its deactivation.

The secretion of cortisol is regulated primarily by the hypothalamus and the anterior pituitary gland (Figure 21-17). In the hypothalamus, CRH is produced in several nuclei and stored in the median eminence. Once released, CRH travels through the portal vessels to stimulate the production of ACTH from POMC, β-lipotropin, γ-lipotropin, endorphins, and enkephalins by the anterior pituitary. ACTH is the main regulator of cortisol secretion and adrenocortical growth.

Three factors appear to be primarily involved in regulating the secretion of ACTH: (1) high circulating levels of cortisol and synthetic glucocorticoids suppress CRH and ACTH, whereas low cortisol levels stimulate their secretion; (2) diurnal rhythms affect ACTH and cortisol levels (in persons with regular sleep-wake patterns, ACTH peaks 3 to 5 hours after sleep begins and declines throughout the day; and cortisol levels follow a similar pattern, peaking just before awakening); and (3) psychologic and physiologic (e.g., hypoxia, hypoglycemia, hyperthermia, exercise) stress increases ACTH secretion, leading to increased cortisol levels.[50,51] (Neurologic mechanisms regulating sleep are discussed in Chapter 16.) A form of immunoreactive ACTH (ir ACTH) is produced by the cells of the immune system and may account, in part, for integration of the immune and endocrine systems.

Once ACTH is secreted, it binds to specific plasma membrane receptors on the cells of the adrenal cortex and on other extra-adrenal tissues. Because both adrenal and extra-adrenal tissues have ACTH receptors, a number of effects result from stimulation by ACTH (these effects are summarized in Box 21-1). In addition to increasing adrenocortical secretion of cortisol, ACTH maintains the size and synthetic functions of the adrenal cortex through activation of crucial enzymes and storage of cholesterol for metabolism into steroid hormones.

BOX 21-1 EFFECTS OF ADRENOCORTICOTROPIC HORMONE

Adrenal

Maintenance of gland size
Depletion of ascorbic acid
Activation of adenylyl cyclase
Conversion of cholesterol to pregnenolone
Maintenance of enzymes active in converting pregnenolone to other steroids
Accumulation of cholesterol
Secretion of cortisol and adrenal androgens

Extra-Adrenal

Activation of tissue lipase

Extra-adrenal effects of ACTH include stimulation of melanocytes and activation of tissue lipase.

Once ACTH stimulates the cells of the adrenal cortex, cortisol synthesis and secretion immediately occur. In the healthy person, the secretory patterns of ACTH and cortisol are nearly identical. After secretion, most cortisol circulates in bound form: 15% to 30% is bound to albumin, 55% to 75% is tightly but reversibly bound to a plasma glycoprotein called *transcortin*, and 10% to 15% is unbound. The levels of transcortin play a role in the HPA feedback system controlling cortisol secretion. Transcortin levels are significantly elevated by increased estrogen levels that occur with pregnancy and hormone therapy. The unbound portion is free to diffuse into cells, but only those cells with specific intracellular glucocorticoid receptors respond to cortisol stimulation. ACTH is rapidly inactivated in the circulation, and the liver and kidneys remove the deactivated hormone.

Mineralocorticoids: Aldosterone. **Mineralocorticoid** steroids directly affect ion transport by epithelial cells, causing sodium retention and potassium and hydrogen loss.

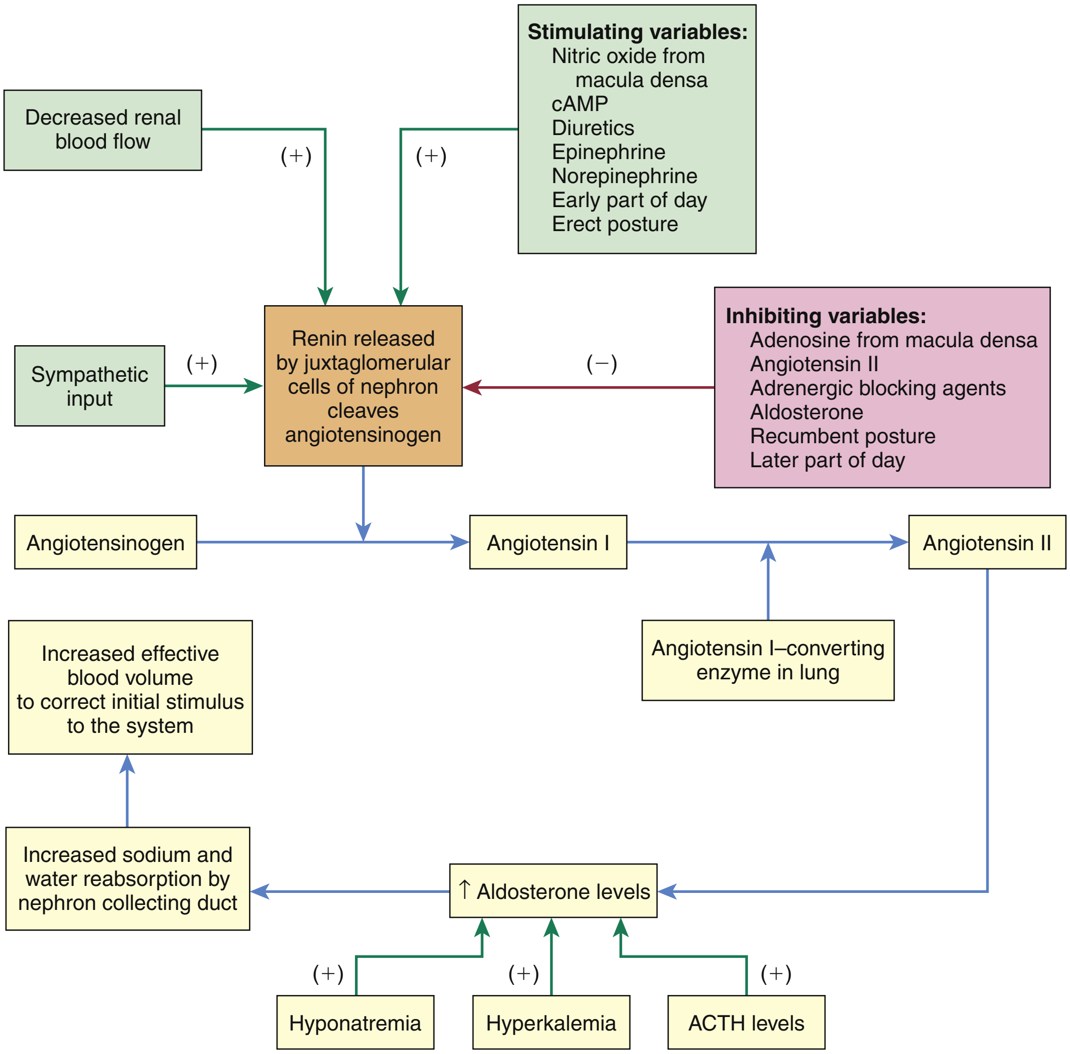

FIGURE 21-18 Feedback Mechanisms Regulating Aldosterone Secretion. *ACTH,* Adrenocorticotropic hormone; *cAMP,* cyclic adenosine monophosphate.

Aldosterone is the most potent of the naturally occurring mineralocorticoids and acts to conserve sodium by increasing the activity of the sodium pump of the epithelial cells in the nephron. (The sodium pump is described in Chapter 1.)

The initial stages of aldosterone synthesis occur in the zona fasciculata and zona reticularis. The final conversion of corticosterone occurs in the zona glomerulosa. Aldosterone synthesis and secretion are regulated primarily by the renin-angiotensin-aldosterone system (described in Chapter 3 and Chapter 37; see Figures 3-4 and 37-10), although other factors also may be involved. The renin-angiotensin system is activated by sodium and water depletion, increased potassium levels, and a diminished effective blood volume (Figure 21-18). Angiotensin II is the primary stimulant of aldosterone synthesis and secretion; however, sodium and potassium levels also may directly affect aldosterone secretion.

When sodium and potassium levels are within normal limits, approximately 50 to 250 mg of aldosterone is secreted daily. Of the secreted aldosterone, 50% to 75% binds to plasma proteins. Aldosterone is degraded in the liver and is excreted by the kidney.

Aldosterone maintains extracellular volume by acting on distal nephron epithelial cells to increase sodium reabsorption and potassium and hydrogen excretion.[52] This renal effect takes 90 minutes to 6 hours. Other effects of aldosterone include enhancement of cardiac muscle contraction, stimulation of ectopic ventricular activity through secondary cardiac pacemakers in the ventricles, stiffening of blood vessels with increased vascular resistance, and decreased fibrinolysis. Pathologically elevated levels of aldosterone have been implicated in the myocardial changes associated with heart failure.[53,54]

Adrenal Estrogens and Androgens. The healthy adrenal cortex secretes small amounts of estrogen and androgens. ACTH appears to be the major regulator. The biologic effects and metabolism of the adrenal sex steroids do not vary from those produced by the gonads (see Chapter 23).

Some of the weak androgenic substances secreted by the cortex (dehydroepiandrosterone [DHEA], androstenedione) are converted by peripheral tissues to stronger androgens, such as testosterone, thus accounting for some androgenic effects initiated by the adrenal cortex. Peripheral conversion of adrenal

androgens to estrogens is enhanced in aging or obese persons, as well as in those with liver disease or hyperthyroidism.

Adrenal Medulla

The **adrenal medulla,** together with the sympathetic division of the autonomic nervous system, is embryonically derived from neural crest cells. The adrenal medulla functions as a sympathetic ganglion without postganglionic processes. **Chromaffin cells (pheochromocytes)** are the cells of the adrenal medulla. The major products stored and secreted by the chromaffin cells are the catecholamines epinephrine (adrenaline) and norepinephrine, which are synthesized from the amino acid phenylalanine (Figure 21-19). Only 30% of circulating epinephrine comes from the adrenal medulla; the other 70% is released from nerve terminals. The medulla is only a minor source of norepinephrine.[55]

Adrenal catecholamines are stored in secretory granules within the chromaffin cells. Physiologic stress to the body (e.g., traumatic injury, hypoxia, hypoglycemia, and many others) triggers release of adrenal catecholamines through acetylcholine (from the preganglionic sympathetic fibers), which depolarizes the chromaffin cells. Depolarization causes exocytosis of the storage granules from the chromaffin cells with release of epinephrine and norepinephrine into the bloodstream; therefore, the catecholamines from the adrenal medulla are hormones and not neurotransmitters.[55] Secretion of adrenal catecholamines is also increased by ACTH and the glucocorticoids.

Once released, the catecholamines remain in the plasma for only seconds to minutes. The catecholamines exert their biologic effects after binding to a plasma membrane receptor (α_1, α_2, β_1, β_2, β_3) in target cells and activating the adenylyl cyclase system (see Table 15-7). Catecholamines are rapidly removed from the plasma by being taken up by neurons for storage in new cytoplasmic granules, or they may be metabolically inactivated and excreted in the urine.

Catecholamines have diverse effects on the entire body. Their release and the body's response have been characterized as the "fight or flight" response (see Chapter 11).

In general, the metabolic effects of catecholamines promote hyperglycemia through a variety of mechanisms and through interference with usual glucose regulatory feedback mechanisms.

Neuroendocrine Response to Stressors

The endocrine system acts together with the nervous system to respond to stressors. The integrated response to stressors also includes the immune system. Hormones of the neuroendocrine system affect components of the immune system, and mediators produced by immune components regulate the neuroendocrine response.

Perception that an event is stressful may be essential to the emotional arousal and initiation of the stress response. Some events, such as bacterial invasion, can activate the stress response without emotional arousal. The hypothalamus receives input from a variety of areas within the brain and ultimately directs the neuroendocrine response to stress through the actions of CRH, the locus ceruleus–norepinephrine autonomic (sympathetic) nervous system, and the pituitary-adrenal axis.[50,56] In addition to the neuroendocrine components of the stress response, the gamma motor neuron system is activated to increase skeletal motor tone. Enhanced availability of vital substrates occurs, and growth and reproduction are inhibited to preserve energy for protective responses. Details of the stress response are presented in Chapter 11.

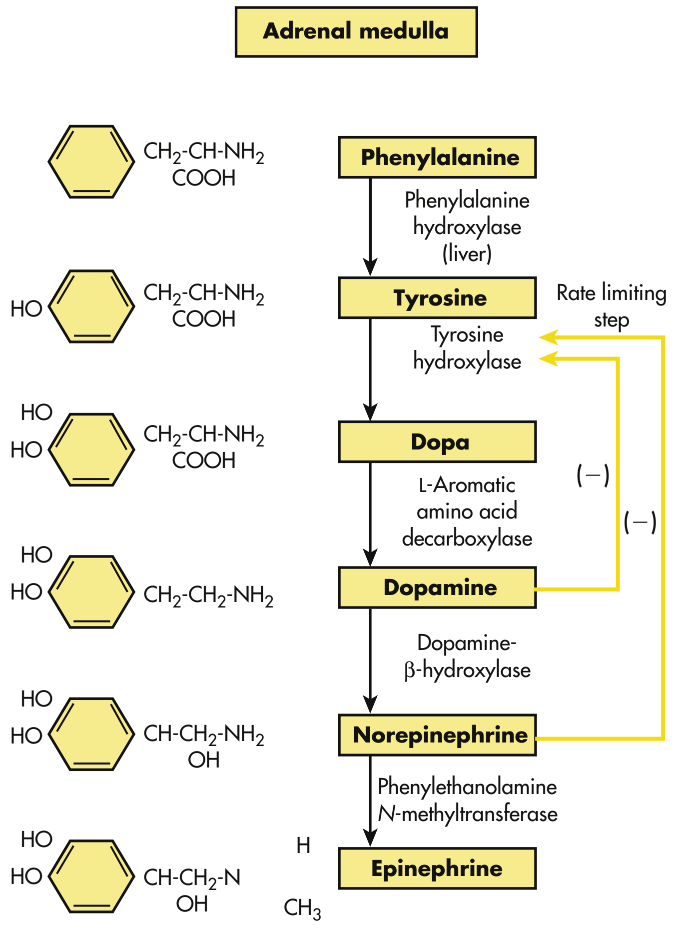

FIGURE 21-19 Synthesis of Catecholamines.

Tests of Endocrine Function

Evaluation of the endocrine system is challenging because of: (1) the complexity of the clinical presentation because of multiple organ system involvement, (2) the nonspecific nature of complaints frequently associated with endocrine dysfunction, and (3) the inappropriate use of laboratory test interpretations.

Tests of the endocrine system involve several general types of clinical evaluation. Measurement of hormone level is accomplished by radioimmunoassay, by enzyme-linked immunosorbent assay, and less commonly by bioassay. **Radioimmunoassay (RIA)** is a technique for measuring the minute quantities of hormones in the blood that uses antibodies and radiolabeled hormones to determine the quantity of hormone in the plasma. **Enzyme-linked immunosorbent assay (ELISA)** also is used to determine circulating hormone levels. This method is similar to that of RIA but is less expensive and easier to conduct. Instead of radiolabeled hormones, an enzyme-labeled hormone is used. A **bioassay** involves the use of graded doses of hormone in a

reference preparation and then comparison of the results with an unknown sample. Bioassays are used more commonly in investigative endocrinology than in clinical laboratories. If the serum level is greater or less than the reference values, more definitive tests are required to determine the source of the problem.

Measurement of individual hormones does not always permit differentiation between normal and abnormal values when hormone levels are changing over time. For an accurate interpretation, the broad normal range of some hormones requires a knowledge of previous hormonal levels and timed sampling. Stimulation and suppression tests that determine the response to exogenous stimulants or inhibitors can help to decipher some of these complexities.

Indirect assessment of hormonal function often includes measurement of concentrations of serum glucose and electrolytes that are affected by the endocrine process. Evaluation of hormonal function also may include radiographic imaging of specific glands.

AGING AND THE ENDOCRINE SYSTEM

The precise relationship between aging and the endocrine system is not clear. Perhaps most important, the question of whether changes in endocrine function are a consequence or a cause of aging has yet to be resolved. These relationships have been difficult to identify, in part because of a number of age-related variables that may coexist, such as acute and chronic non–endocrine disease; use of medications; alterations in diet, body composition, and weight; and changes in sleep-wake cycles. However, the endocrine system is so integral to health that changes in endocrine function have been used as "biomarkers" for unhealthy aging.

Effects of Aging on the Endocrine System

Investigation into the role of the endocrine glands and their interactions in the aging process has generated much data, although the evidence is contradictory. There are complex changes within the HPA; and altered biologic activity of hormones, altered circulating levels of hormones, altered secretory response of the endocrine glands, altered metabolism of hormones, and loss of circadian control of hormone secretion are among the findings. Changes in secretion of hypothalamic regulatory factors and hormones or changes in hypothalamic feedback sensitivity may contribute to alterations in control of an optimal internal environment.[57] The dynamic equilibrium of the endocrine system also may be affected by altered secretion of neurotransmitters within certain areas of the brain, affecting hypothalamic and pituitary function. Such alterations may include an excess or deficit in secretion of pituitary hormones and loss of appropriate secretory pattern of those hormones. Loss of endocrine steady states may be associated with or contribute to aging.

The most studied changes in hormone function with aging affect the levels of reproductive hormones and gonadotropins (menopause and andropause) (discussed in Chapter 23). Two of the most important endocrine changes associated with aging affect the thyroid gland and the pancreas. Other important hormone changes associated with aging include a decline in serum levels of growth hormone and IGF-1, parathyroid hormone, dehydroepiandrosterone, and ADH.

Thyroid Gland. Changes in thyroid structure and function occur with aging.[58] Structurally, some glandular atrophy and fibrosis occur with nodularity and increasing inflammatory infiltrates. These infiltrative changes may reflect age-related autoimmune damage. Clinical signs of thyroid disease are more difficult to detect in older adults. Overall, it is estimated that there is some evidence of thyroid dysfunction in 5% to 10% of older adult women. The presence of thyroid nodules increases after the age of 70 years. Changes relative to thyroid hormone and its function are more difficult to assess and much of the available data are contradictory. Most evidence, however, supports the following age-related changes:

1. Overall TSH secretion is diminished, although centenarians have elevated TSH.[58a]
2. Responsiveness of plasma TSH concentration to TRH administration is reduced, especially in men.
   a. T_4 secretion and degradation are decreased.
   b. Plasma levels of T_3 decline, especially in men, but are generally in the normal range.
   c. Hypothyroidism is seen with increasing frequency as age advances.

Treatment for thyroid deficiency is also affected by aging. The appropriate dose for thyroid hormone (TH) replacement is often lower in older adults because the peripheral metabolism of TH decreases with age. In addition, TH must be replaced slowly in elderly individuals with coronary artery disease to prevent angina and myocardial infarction.[58]

Pancreas. It is estimated that 40% to 50% of individuals older than age 65 have impaired glucose tolerance or diabetes. With aging, the pancreatic cells are increasingly replaced with fat tissue.[59] Dysfunction of the pancreas with decreased insulin secretion of beta cells and insulin receptors and increased insulin resistance have all been documented and may be related to changes in adipokine physiology.[60-62]

These changes have significant implications for many target organs, particularly the cardiovascular system, which is increasingly at risk for both vascular (hypertension, atherosclerosis, glomerulosclerosis) and cardiac (infarction, failure) disorders. Exciting research is exploring the relationship between insulin and activation of genes for the "sirtuins," which are a group of proteins that have been linked with the aging process.[63]

Growth Hormone and Insulin-like Growth Factors. The amounts of GH and IGF decline with aging, a process that has been called the "somatopause."[64] This decline in anabolic stimuli is linked to decreases in muscle size and function, decreased amounts of fat and bone mass, and changes in reproductive and cognitive function[65] (see What's New? Growth Hormone [GH] and Insulin-like Growth Factor [IGF] in Aging).

Parathyroid Glands. An age-related alteration in PTH secretion has been proposed to explain alterations in calcium homeostasis that have been noted in older adults.[66] Calcium intake, especially in women, tends to decrease with aging and may contribute to osteoporosis (see Chapter 44). The average daily intake of 450 to 500 mg/day causes a negative calcium

WHAT'S NEW?

Growth Hormone (GH) and Insulin-like Growth Factor (IGF) in Aging

Aging is a multifactorial process that is influenced by genetic and environmental factors. The aging process is associated with many hormonal and metabolic changes. The amounts of GH and IGF decline with aging, a process that has been called the "somatopause." Clinical findings related to somatotropic hormone changes with aging include increased visceral fat, decreased lean body mass, decreased bone density, and changes in reproductive and cognitive function. The underlying mechanisms of aging and its relationship to GH and IGF are complex. For example, not only do these hormones promote bone and muscle growth, but also a recent study suggests that the brain IGF-1 receptor may be a significant factor in determining overall life span and ability to respond to physiologic stress. GH and IGF effects on inflammation and immunity also are important in the aging process. Unfortunately, there remains much confusion and controversy over the role of these hormones. Although most studies suggest that it is a deficiency of these hormones that leads to an acceleration of the aging process, there are several studies suggesting that lower lifetime levels of these hormones may confer longevity by providing protection from cancer and other age-related diseases. As these hormones are used to treat a wider range of disorders and for different age groups, more information about their safety is emerging. Despite the initial enthusiasm for the use of therapeutic doses of recombinant human growth hormone (rhGH) as a way to slow the aging process, studies have not been consistently positive and the risk for GH- and IGF-mediated oncogenesis is being explored.

Data from Allen DB: *J Clin Endocrinol Metab* 96(10):3042–3047, 2011; Bartke A: *Exp Gerontol* 46(2-3):108–111, 2011; Bartke A: *Trends Endocrinol Metab* 22(11):437–442, 2011; Birzniece V, Nelson AE, Ho KK: *Trends Endocrinol Metab* 22(5):171–178, 2011; Di Somma C et al: *Minerva Endocrinol* 36(3):243–255, 2011; Holzenberger M: *Nestle Nutr Workshop Ser Pediatr Program* 68:237–245, 2011; Kokshoorn NE et al: *Eur J Endocrinol* 164(5):657–665, 2011; Rosenfeld RG et al: *J Clin Endocrinol Metab* 97(1):68–72, 2012.

balance greater than 40 mg/day and may be related to the absolute bone loss of approximately 1.5% per year. Older adults show decreased intestinal adaptation to variations in calcium intake. Hyperparathyroidism may occur secondary to calcium malabsorption and hypocalcemia with increased bone remodeling that results in cortical bone thinning and porosity. Elevated levels of parathyroid hormone have been linked with an increase in mortality in older adults, many of whom also have a mild, persistent hypercalciuria, which indicates a defective renal mechanism for responding to decreased calcium intake. Decreased circulating levels of vitamin D are common in older adults, especially those in long-term care institutions. Vitamin D deficiency has been linked to not only osteoporosis but also cancer, autoimmune diseases, diabetes, cardiovascular disease, and mental health disorders.

Adrenal Glands. The adrenal cortex loses some weight and has more fibrous tissue after the age of 50 years. Age does not appear to affect the feedback mechanisms involved in maintaining glucocorticoid levels, but the decrease in the metabolic clearance rate of the glucocorticoids is age related.

The metabolic clearance of cortisol decreases with an age-related decline in liver and kidney function. Further, less cortisol appears to be used by the body when aging is accompanied by a loss of lean body mass. Decreased clearance and reduced use of cortisol contribute to higher circulating cortisol levels, but diurnal variation is maintained. Because feedback mechanisms are intact, the higher cortisol levels cause a decrease in cortisol secretion. Circadian patterns of ACTH and cortisol secretion may change with aging.

Plasma levels of the adrenal androgens, as well as urinary excretion of the metabolic end products, decrease gradually but dramatically with age, to as much as 50% to 70% of the young adult level. This change in adrenal function has been called the "adrenopause" and is correlated with decreased synthesis activity of dehydroepiandrosterone (DHEA).[67] This change appears to reflect a decline in the function of the zona reticularis. In postmenopausal women, this decline in adrenal androgen secretion is especially important because nearly all sex steroids after menopause come from adrenal and ovarian production of androgen precursors converted to estrogens in the periphery. In older adult men, adrenal androgen production accounts for more than half of circulating testosterone levels.

Antidiuretic Hormone. Although hyponatremia is a common finding in older adults, it appears related to changes in renal function rather than to ADH-related mechanisms. Morphologic studies have not shown significant age-related degenerative changes in the neuroendocrine pathways that regulate the synthesis and secretion of ADH. It appears that ADH secretion is augmented when stimulated by changes in osmotic concentration, whereas baroreceptor-mediated ADH secretion is reduced.

SUMMARY REVIEW

Mechanisms of Hormonal Regulation

1. The endocrine system has diverse functions, including sexual differentiation, growth and development, continuous maintenance of the body's internal environment, and adaptive responses to stress.
2. Hormones are chemical messengers synthesized by endocrine glands and released into the circulation; they work with the nervous system to maintain communication and control.
3. Hormones have specific negative- and positive-feedback mechanisms. Most hormone levels are regulated by negative feedback, in which tropic hormone secretion raises the level of a specific hormone. The elevated level of the specific hormone then causes negative feedback, decreasing secretion of the tropic hormone.
4. Endocrine feedback is described in terms of short and long feedback loops.

SUMMARY REVIEW—cont'd

5. Water-soluble hormones circulate throughout the body in unbound form, whereas lipid-soluble hormones (i.e., steroid and thyroid hormones) circulate throughout the body bound to carrier proteins.
6. Hormones serve as first messengers and affect only target cells with appropriate receptors and then act on those cells to initiate specific cell functions or activities.
7. Hormones have two general types of effects on cells: direct effects, or obvious changes in cell function; and permissive effects, or less obvious changes that facilitate cell function.
8. Receptors for hormones are proteins and may be located on or in the plasma membrane or in the cytosol or nucleus of the target cell. Receptors may be G protein linked, ion channels, or enzyme linked.
9. Water-soluble hormones act as first messengers, binding to receptors on the cell's plasma membrane. The signals initiated by hormone-receptor binding are then transmitted into the cell by the action of second messengers.
10. Second messengers that have been identified include cAMP, cGMP, and calcium, which associates with IP_3 and DAG to produce physiologic effects.
11. For cells that have cAMP as their second messenger, a series of interactions within the plasma membrane must activate adenylyl cyclase.
12. Cells that have cGMP as their second messenger are activated by the enzyme guanylyl cyclase.
13. For cells that have calcium as their second messenger, an increase in intracellular calcium concentration causes calcium to bind with calmodulin, a regulatory protein. This step then initiates other intracellular processes.
14. Lipid-soluble hormones (including steroid and thyroid hormones) may have rapid effects by binding to a plasma membrane or receptor or crossing the plasma membrane through diffusion. These hormones then either bind to cytoplasmic proteins or diffuse directly into the cell nucleus and bind to nuclear receptors.
15. Hormones have direct effects (specific changes in cell function) or permissive effects (facilitate the effects of other hormones).

Structure and Function of the Endocrine Glands

1. The pituitary gland, consisting of anterior and posterior portions, is connected to the central nervous system through the hypothalamus.
2. The hypothalamus regulates anterior pituitary function by secreting releasing hormones into the portal circulation.
3. Hypothalamic hormones include dopamine, which inhibits prolactin secretion; TRH, which affects release of thyroid hormones; CRH, which facilitates release of ACTH and endorphins; and substance P, which inhibits ACTH release and stimulates release of a variety of other hormones. ADH and oxytocin are synthesized in the hypothalamus and stored and secreted by the posterior pituitary.
4. The posterior pituitary stores and secretes ADH, also called arginine-vasopressin, and oxytocin.
5. ADH controls serum osmolality, increases the permeability of the renal tubules to water, and causes vasoconstriction when administered pharmacologically in high doses. ADH also may regulate some central nervous system functions.
6. Oxytocin causes uterine contraction and lactation in women and may have a role in sperm motility in men. In men and women, oxytocin has an antidiuretic effect similar to that of ADH.
7. Hormones of the anterior pituitary are regulated by (a) secretion of hypothalamic-releasing hormones or factors, (b) negative feedback from hormones secreted by target organs, and (c) mediating effects of neurotransmitters.
8. Hormones of the anterior pituitary include ACTH, MSH, somatotropic hormones (GH and prolactin), and glycoprotein hormones (FSH, LH, and TSH).
9. Growth hormone stimulates bone growth, increased protein metabolism in muscles, and lipolysis. Its effects are mediated in part by IGFs.
10. Prolactin functions to produce milk during pregnancy and lactation.
11. The pineal gland produces melatonin, which affects sleep, immune function, and aging.
12. The two-lobed thyroid gland contains follicles, which secrete some of the thyroid hormones, and C cells, which secrete calcitonin and somatostatin.
13. Regulation of TH levels is complex and involves the hypothalamus (TRH), anterior pituitary (TSH), thyroid gland, and numerous biochemical variables.
14. TH secretion is regulated by TRH through a negative-feedback loop that involves the anterior pituitary and hypothalamus.
15. TSH, which is synthesized and stored in the anterior pituitary, stimulates secretion of TH by activating intracellular processes, including uptake of iodine necessary for the synthesis of TH.
16. Synthesis of TH depends on the glycoprotein thyroglobulin, which contains a precursor of TH, tyrosine. Tyrosine then combines with iodide to form precursor molecules of the thyroid hormones T_4 and T_3.
17. When released into the circulation, T_3 and T_4 are bound by carrier proteins in the plasma that store these hormones and provide a buffer for rapid changes in hormone levels.
18. Thyroid hormones alter protein synthesis and have a wide range of metabolic effects on proteins, carbohydrates, lipids, and vitamins. TH also affects heat production and cardiac function.
19. Parafollicular cells or C cells secrete calcitonin and lower serum calcium concentration by inhibiting bone-resorbing osteoclasts.
20. The paired parathyroid glands normally are located behind the upper and lower poles of the thyroid gland. These glands secrete PTH, an important regulator of serum calcium and phosphate levels.

SUMMARY REVIEW—cont'd

21. PTH secretion is regulated by levels of ionized calcium in the plasma and by cAMP within the cell. Some other substances—hormones, neurotransmitters, and ions—affect PTH secretion by inhibiting cAMP or by changing calcium levels.
22. In bone, PTH causes bone breakdown and resorption. In the kidney PTH increases reabsorption of calcium, decreases reabsorption of phosphorus and bicarbonate, and stimulates synthesis of vitamin D.
23. Parathyroid hormone–related peptide (PTHrP) has properties similar to those of PTH and plays a role in placental calcium transport, lactation, and fetal tooth development.
24. The endocrine pancreas contains the islets of Langerhans, which secrete hormones responsible for much of the carbohydrate metabolism in the body.
25. The islets of Langerhans consist of alpha cells, beta cells, delta cells, and F cells.
26. Beta cells synthesize insulin, a hormone that regulates blood glucose concentrations and overall body metabolism of fat, protein, carbohydrates, and amylin.
27. Alpha cells produce glucagon, which is secreted inversely to blood glucose concentrations and stimulates glycogenolysis, gluconeogenesis, and lipolysis.
28. Incretin hormones are produced by endocrine cells of the gastrointestinal tract that promote glucose-dependent insulin secretion, inhibit glucagon synthesis, and delay gastric emptying.
29. Amylin promotes glucose-dependent insulin secretion, inhibits glucagon synthesis, and delays gastric emptying, producing an antihyperglycemic effect.
30. Delta cells secrete somatostatin, which inhibits glucagon, insulin, and polypeptide secretion.
31. F cells secrete pancreatic polypeptide, which stimulates Y receptors, promotes gastric secretion, and antagonizes cholecystokinin.
32. The paired adrenal glands are situated on the kidneys. Each gland consists of an adrenal medulla, which secretes catecholamines, and an adrenal cortex, which secretes steroid hormones.
33. The steroid hormones secreted by the adrenal cortex are all synthesized from cholesterol. These hormones include glucocorticoids, mineralocorticoids, and adrenal androgens and estrogens.
34. Glucocorticoids directly affect carbohydrate metabolism by increasing blood glucose concentration through gluconeogenesis in the liver and by decreasing use of glucose. Glucocorticoids also inhibit immune and inflammatory responses, inhibit bone formation and ADH secretion, and stimulate gastric secretion.
35. Cortisol secretion is related to secretion of ACTH, which is stimulated by CRH. ACTH binds with receptors of the adrenal cortex, which activates intracellular mechanisms (specifically cAMP) and leads to cortisol release.
36. Mineralocorticoids, especially aldosterone, are steroid hormones that directly affect ion transport by epithelial cells, causing sodium retention and potassium and hydrogen loss.
37. Aldosterone secretion is controlled by the renin-angiotensin-aldosterone system and acts by binding to a site on the cell nucleus and altering protein production within the cell. Its principal site of action is the kidney, where it causes sodium reabsorption and potassium and hydrogen excretion.
38. Androgens and estrogens secreted by the adrenal cortex act in the same way as those secreted by the gonads.
39. The adrenal medulla secretes the catecholamines epinephrine and norepinephrine. Catecholamines are synthesized from the amino acid phenylalanine. Their release is stimulated by sympathetic nervous system stimulation, ACTH, and glucocorticoids.
40. Catecholamines bind with various target cells and are taken up by neurons or excreted in the urine. They cause a range of metabolic effects that generally are characterized as the "flight or fight" response.
41. The endocrine system acts together with the nervous and immune systems to respond to stressors, providing an integrated and protective response.
42. Several assay methods are used to measure levels of hormones in the plasma. RIA compares the proportion of radiolabeled and nonradiolabeled hormone against standard reference curves.
43. ELISA is a method similar to RIA, but uses a radiolabeled enzyme rather than a radiolabeled hormone.
44. Bioassays use graded doses of hormone in a reference preparation and then compare the results with an unknown sample to determine the hormone level.

Aging and the Endocrine System

1. Endocrine changes that may be associated with aging include altered biologic activity of hormones, altered circulating levels of hormones, altered secretory responses of endocrine glands, altered metabolism of hormones, loss of circadian control of hormone release, and changes in secretion of hypothalamic regulatory hormones.
2. Cellular damage associated with aging, genetically programmed cell change, and chronic wear and tear may contribute to endocrine gland dysfunction or alterations in the responsiveness of target organs.
3. Aging apparently causes atrophy of the thyroid gland and is associated with infiltrative glandular changes. Secretion of thyroid hormones may diminish with age.
4. Aging causes pancreatic fat deposition and is associated with a decrease both in insulin secretion and in insulin sensitivity.
5. Growth hormone levels decrease with aging, leading to decreased bone and muscle mass.
6. Aging is associated with alterations in calcium steady states, which may be related to alterations in PTH secretion from the parathyroid glands.
7. Age-related changes in adrenal function include decreased clearance of glucocorticoids and a decrease in levels of adrenal androgens. The effects of these changes, however, are offset by feedback mechanisms that maintain glucocorticoid levels and by gonadal secretion of androgens.

CHAPTER OUTLINE

The function of the endocrine system involves complex interrelationships and interactions that maintain dynamic steady-states, provide growth and reproductive capabilities, and allow for adaptive changes in times of stress. Alterations in function were thought only to be caused by either hypersecretion or hyposecretion of the various hormones, leading to abnormal hormone concentrations in the blood. Techniques for studying the various components of the endocrine system have improved, and evidence has shown that dysfunction may also result from abnormal receptor function or from altered intracellular response to the hormone-receptor complex.

MECHANISMS OF HORMONAL ALTERATIONS

Significantly elevated or depressed hormone levels may result from a variety of causes (Table 22-1). Dysfunction of an endocrine gland may involve the gland's failure to produce adequate amounts of biologically free or active hormone forms. This failure may occur when the secretory cells are unable to produce or obtain an adequate quantity of required hormone precursors or when they are unable to convert the precursors to the active hormone. A gland also may synthesize or release excessive amounts of hormone. For example, feedback systems that recognize the need for a particular hormone may fail to function properly or may respond to inappropriate signals. Once hormones are released into the circulation, they may be degraded at an altered rate or they may be inactivated by antibodies before reaching the target cell. Ectopic sources of hormones (hormones produced by nonendocrine tissues) may result also in abnormally elevated hormone levels without benefit of the normal feedback system for hormone control. In these cases the ectopic hormone production is said to be *autonomous*.

Target cells may fail to respond to its hormone *(hormone insensitivity)* (see Table 22-1). The general types of abnormal

TABLE 22-1 MECHANISMS OF HORMONE ALTERATIONS

INAPPROPRIATE AMOUNTS OF HORMONE DELIVERED TO TARGET CELL	INAPPROPRIATE RESPONSE BY TARGET CELL
Inadequate hormone synthesis	**Cell surface receptor–associated disorders**
Inadequate quantity of hormone precursors	Decrease in the number of receptors
Secretory cell unable to convert precursors to active hormone	Impaired receptor function (altered affinity for hormones)
Failure of feedback systems	Presence of antibodies against specific receptors
Do not recognize positive feedback leading to inadequate hormone synthesis	Unusual expression of receptor function
Do not recognize negative feedback leading to excessive hormone synthesis	**Intracellular disorders**
Hormones inactive	Acquired defects in postreceptor signaling cascades
Inadequate biologically free hormone	Inadequate synthesis of a second messenger
Hormone degraded at an altered rate	Intracellular enzymes or proteins are altered
Circulating inhibitors	Alterations in nuclear co-regulators
Dysfunctional delivery system	Altered protein synthesis
Inadequate blood supply	
Inadequate carrier proteins	
Ectopic production of hormones	

target cell responses currently recognized are receptor-associated disorders and intracellular disorders. Receptor-associated disorders have been identified primarily in water-soluble hormones, such as insulin. These types of disorders usually involve one of the following: (1) a decrease in the number of receptors, leading to decreased or defective hormone-receptor binding; (2) impaired receptor function, resulting in insensitivity to the hormone; (3) presence of antibodies against specific receptors that either reduce available binding sites or mimic hormone action; or (4) unusual expression of receptor function, as occurs in some tumor cells.

Intracellular disorders may involve acquired defects in postreceptor signaling cascades or inadequate synthesis of a second messenger, such as cyclic adenosine monophosphate (cAMP), needed to transduce the hormonal signal into intracellular events. The target cell for water-soluble hormones may have a faulty response to hormone-receptor binding and thus fail to generate the required second messenger, or the cell also may have an abnormal response to the second messenger if levels of intracellular enzymes or proteins are altered. (Second messengers for various hormones are listed in Table 21-3.) Both of these pathogenic mechanisms result in failure of the target cell to express the usual hormonal effect. Pathogenic mechanisms affecting target cell response for lipid-soluble hormones, such as thyroid hormone or glucocorticoids, are recognized less often than those affecting the water-soluble hormones. These hormone-resistant states have been generally linked to mutations in the nuclear receptor for the hormone. The number of receptors may be decreased, or those receptors may have an altered affinity or selectivity for hormones.[1] In other cases, hormone responsiveness may be linked to alterations in nuclear co-regulators, which are proteins (such as cAMP response element–binding protein [CREB], see Chapter 21 p. 694) that facilitate or inhibit the transcription of the target gene.[2] Alterations in generation of new messenger ribonucleic acid (mRNA) or absence of substrates for new protein synthesis also may occur, resulting in altered target cell response.

ALTERATIONS OF THE HYPOTHALAMIC-PITUITARY SYSTEM

Perhaps the most common cause of apparent hypothalamic dysfunction is interruption of the pituitary stalk, which can be caused by destructive lesions, rupture after head injury, surgical transection, or tumor. The absence of hypothalamic releasing or inhibiting hormones (Figure 22-1) causes a variety of manifestations that present clinically as pituitary disease. For example, if there is an absence of gonadotropin-releasing hormone (GnRH) from the hypothalamus, then there is a lack of stimulation of gonadotropin follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the pituitary; thus, menses cease in women and spermatogenesis is impaired in men.

Diseases of the Posterior Pituitary

Diseases of the posterior pituitary usually cause abnormal secretion of antidiuretic hormone (ADH, arginine vasopressin). An excess amount of this hormone results in water retention and a hypoosmolar state, whereas deficiency in the amount or response to ADH results in serum hyperosmolarity. These complex pathophysiologic states not only have significant clinical effects on the modulation of body fluids and electrolytes, but also affect cognitive and emotional responses to stress.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

Syndrome of inappropriate antidiuretic hormone (SIADH) secretion is characterized by high levels of ADH in the absence of normal physiologic stimuli for its release. SIADH can complicate malignancies, pulmonary disorders, central nervous system disorders, surgical procedures, and the use of certain medications.[3] SIADH is associated with ectopic secretion of ADH by several types of tumor cells. Tumors that have been reported in association with SIADH include small cell carcinoma of the lung, duodenum, stomach, and pancreas; cancers of the bladder, prostate, and endometrium; lymphomas; and sarcomas. Pulmonary disorders associated with SIADH include pneumonia (e.g., tuberculosis), asthma, cystic fibrosis, and respiratory failure requiring mechanical ventilation. Central nervous system disorders that may cause SIADH include encephalitis, meningitis, intracranial hemorrhage, tumors, and trauma. A nephrogenic form of SIADH has recently been described. In these individuals, mutations in arginine vasopressin (AVP) genes lead to chronic activation of tubular V2 receptor and resulting excessive free water reabsorption.[4] Any surgery can result in postoperative fluid volume shifts and transient SIADH for as long as 5 to 7 days after surgery. The precise

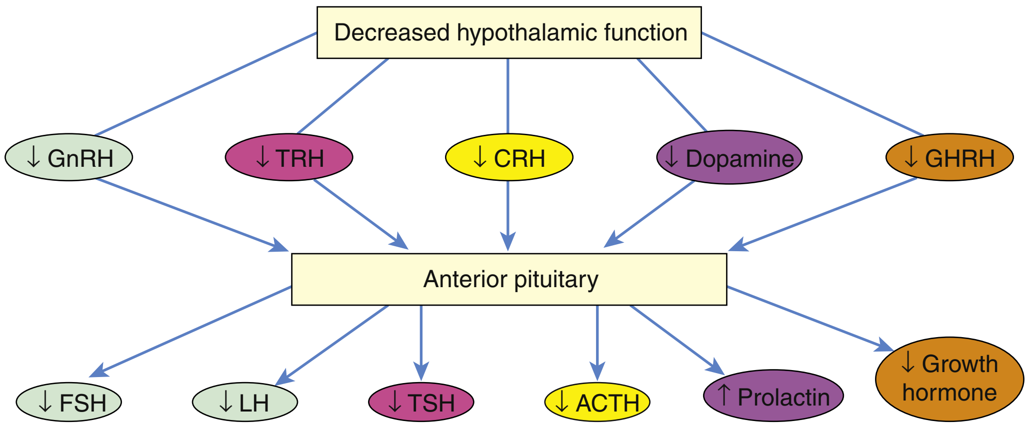

FIGURE 22-1 **Loss of Hypothalamic Hormones.** *ACTH,* Adrenocorticotropic hormone; *CRH,* corticotropin-releasing hormone; *FSH,* follicle-stimulating hormone; *GHRH,* growth hormone–releasing hormone; *GnRH,* gonadotropin-releasing hormone; *LH,* luteinizing hormone; *TRH,* thyrotropin-releasing hormone; *TSH,* thyroid-stimulating hormone.

mechanism is uncertain but is likely related to fluid and volume changes following surgery, the amount and type of intravenous fluids given, and the use of narcotic analgesics. Transient SIADH is especially common after pituitary surgery because stored ADH is released in an unregulated fashion. Medications are an important cause of SIADH, especially in older adults. These include antidepressants, antipsychotics, narcotics, general anesthetics, chemotherapeutic agents, nonsteroidal anti-inflammatory drugs, quinolone antibiotics, and synthetic ADH analogs.[3] These drugs serve either to simulate ADH release, to enhance the physiologic effects of ADH, or to have a biologic action similar to that of ADH.

PATHOPHYSIOLOGY. The pathophysiologic features of SIADH are the result of enhanced renal water retention. Water retention results from the action of ADH on renal collecting ducts, where it increases their permeability to water, thus increasing water reabsorption by the kidneys. (Renal function is discussed in Chapter 37.) This results in an expansion of extracellular fluid volume that leads to dilutional hyponatremia (low serum sodium concentration), hypoosmolarity, and urine that is inappropriately concentrated with respect to serum osmolarity.

CLINICAL MANIFESTATIONS. The symptoms of SIADH result from hypotonic (dilutional) hyponatremia and are associated with hypervolemia and weight gain. The severity and rapidity of onset of the hyponatremia determine the extent of the symptoms. Thirst, impaired taste, anorexia, dyspnea on exertion, fatigue, and dulled sensorium occur when the serum sodium level decreases rapidly from 140 to 130 mEq/L. Peripheral edema is usually absent. Severe gastrointestinal symptoms, including vomiting and abdominal cramps, occur with a drop in sodium concentration from 130 to 120 mEq/L. With a serum sodium level below 115 mEq/L, confusion, lethargy, muscle twitching, and seizures may occur. Even if hyponatremia develops slowly, serum sodium levels below 110 to 115 mEq/L are likely to cause severe and sometimes irreversible neurologic damage. Symptoms resolve with correction of hyponatremia.

EVALUATION AND TREATMENT. A diagnosis of SIADH requires documentation of the following manifestations: (1) serum hypoosmolality (<280 mOsm/kg) and hyponatremia (serum sodium level <135 mEq/L); (2) urine hyperosmolarity (i.e., the osmolality of the urine is always higher than the concurrent serum osmolality); (3) urine sodium excretion that matches sodium intake; (4) normal renal, adrenal, and thyroid function; and (5) absence of conditions that can alter volume status (e.g., recent diuretic use, heart failure, hypervolemia from any cause, or renal insufficiency).[3] Individuals with neurologic injury also may develop hyponatremia caused by cerebral salt wasting syndrome. This can be differentiated from SIADH because cerebral salt wasting is characterized by hypovolemia and weight loss. In addition, urine sodium levels are elevated.[5]

The treatment of SIADH involves the correction of the underlying causal problems; emergency correction of severe hyponatremia by administration of hypertonic saline; and, most importantly, fluid restriction to 800 to 1000 ml/day. Careful monitoring is important. Resolution usually occurs within 3 days, with a 2- to 3-kg weight loss resulting from enhanced free water clearance. If hyponatremia is corrected too rapidly, a severe neurologic syndrome called central pontine myelinolysis can ensue. No drug therapy is available to suppress ectopically produced ADH; however, demeclocycline, which causes the renal tubules to develop resistance to ADH, may be used to treat resistant or chronic SIADH. An ADH receptor agonist, conivaptan, has been approved for the treatment of hospitalized individuals with hyponatremia caused by ADH excess.[6] An oral form of ADH receptor antagonists has been developed.[7]

Diabetes Insipidus

Diabetes insipidus (DI) is an insufficiency of ADH, leading to polyuria (frequent urination) and polydipsia (frequent drinking). There are three forms: neurogenic (hypothalamic), nephrogenic (renal), and polydipsic (polydipsia-polyuria syndrome).

Neurogenic DI is the form encountered most often in clinical practice and is caused by insufficient amounts of ADH. It occurs when any organic lesion of the hypothalamus, pituitary stalk, or posterior pituitary interferes with ADH synthesis, transport, or release.[3] Causative lesions include primary or secondary brain tumors, aneurysms, thrombosis, infections, and

immunologic disorders. DI is a well-recognized complication of closed-head trauma and of pituitary surgery in which DI can be transient or permanent.[8] Neurogenic DI can be a complication of pregnancy. In rare cases, it also can be caused by hereditary disorders that affect ADH genes or result in structural changes in the pituitary gland, such as septo-optic dysplasia (absence of the septum pellucidum in the brain and underdevelopment of the optic nerve).[9]

Nephrogenic DI is associated with an insensitivity of the renal collecting tubules to ADH. The nephrogenic form of DI can be genetic or acquired.[3] This form of DI is often idiopathic, although several genetic abnormalities that affect the vasopressin receptor have been noted. One of the best described is a mutation in the gene that codes for aquaporin-2, which is one of the four water transport channels in the renal tubule.[9]

Acquired nephrogenic DI is generally related to disorders and drugs that damage the renal tubules or inhibit the generation of cAMP in the tubules. These disorders include pyelonephritis, amyloidosis, destructive uropathies, polycystic disease, and intrinsic renal disease, all of which lead to irreversible DI. Drugs that may induce a reversible form of nephrogenic DI include lithium carbonate, colchicine, amphotericin B, loop diuretics, general anesthetics such as methoxyflurane, and demeclocycline.

Dipsogenic DI occurs when excessive fluid intake lowers the plasma osmolarity to the point that it falls below the threshold for ADH secretion.[3] This condition may be associated with psychiatric disorders but also has been found in individuals who have a low osmotic threshold for inducing thirst. Chronic ingestion of extremely large quantities of fluid dilute the renal medullary concentration gradient, which results in a partial resistance to ADH. This condition resolves with effective management of water ingestion.

PATHOPHYSIOLOGY. Neurogenic, nephrogenic, and dipsogenic DI are all characterized by the inability of the kidney to increase permeability to water. This causes excretion of large volumes of dilute urine and an increase in plasma osmolality. In conscious individuals, the thirst mechanism is stimulated and induces polydipsia. For unknown reasons the person usually craves cold drinks. The urine output is varied but can increase from the normal output of 1 to 2 L/day to as much as 8 to 12 L/day. The urine specific gravity is low, from 1.00 to 1.005, which is consistent with the failure to reabsorb water. Dehydration develops rapidly without ongoing fluid replacement. If the individual with DI cannot maintain balance with the urinary loss of water, serum hypernatremia and hyperosmolality occur. Other serum electrolytes generally are not affected.

CLINICAL MANIFESTATIONS. The signs and symptoms of DI include polyuria, nocturia, continuous thirst, and polydipsia. Untreated individuals with long-standing DI may develop a large bladder capacity and hydronephrosis (see Chapter 38). Idiopathic neurogenic DI usually has an abrupt onset, and many individuals can specifically recall the date of onset of their symptoms. Those with posttraumatic or postneurosurgical DI may develop a classic three-phase syndrome: (1) diuresis, (2) antidiuresis, and (3) polyuria/polydipsia.[8] Nephrogenic DI usually has a more gradual onset.

EVALUATION AND TREATMENT. DI must be distinguished from other polyuric states, including diabetes mellitus. The basic criteria for the diagnosis of DI include polyuria, polydipsia, low urine specific gravity (<1.010), low urine osmolality (<200 mOsm/kg), hypernatremia, high serum osmolality (300 mOsm or more depending on adequate water intake), and continued diuresis despite a serum sodium level of 145 mEq/L or greater.

The first step in the diagnosis of DI uses water deprivation with measurement of serum osmolarity and plasma ADH levels. Water restriction is a useful test because individuals without DI respond with a rapid decrease in urine volume and an increase in urine osmolality, whereas those with DI have no decrease in urine volume or increase in urine osmolality. In individuals with severe DI, water deprivation testing can be hazardous. If the individual loses more than 3% of the pretest body weight, circulatory collapse and shock can ensue. Neurogenic DI can be differentiated from nephrogenic DI by measuring the response to administered desmopressin. Neurogenic DI will respond with an increased ability to concentrate the urine, whereas nephrogenic DI will not respond.[3] The diagnosis of dipsogenic DI can be extremely difficult, and differentiation from nephrogenic DI is based on plasma ADH levels. Copeptin, a stable fragment of the ADH precursor molecule, is a reliable surrogate measurement for ADH secretion and can be used for the diagnosis of dipsogenic DI.[10]

Treatment for neurogenic DI is based on the extent of the ADH deficiency and on individual variables such as age, endocrine and cardiovascular status, and lifestyle. Replacement therapy for symptomatic neurogenic DI includes administration of the synthetic vasopressin analog desmopressin acetate (DDAVP) given intranasally or orally.[11]

Treatment for nephrogenic DI requires treatment of any reversible underlying disorders, discontinuation of etiologic medications, and correction of associated electrolyte disorders. Although the use of thiazide diuretics has been implicated as a cause for DI, they improve salt and water absorption at the proximal tubule and may be helpful in moderate DI.[3] New treatments for genetic abnormalities involving the V2 receptor are being evaluated.[9,12]

Diseases of the Anterior Pituitary

Disorders of the anterior pituitary may involve either hypofunction or hyperfunction of the gland.

Hypopituitarism

Hypopituitarism can be characterized by the absence of selective pituitary hormones or the complete failure of all pituitary hormone functions. Hypopituitarism results from either an inadequate supply of hypothalamic-releasing hormones, damage to the pituitary stalk, or an inability of the gland to produce hormones. The most common causes of hypopituitarism lie within the pituitary gland itself. An important cause is pituitary infarction resulting from severe shock, pituitary apoplexy, aneurysms, sickle cell disease, or pregnancy.[13,14] Space-occupying lesions, such as pituitary adenomas or aneurysms, also can compress the gland. Head trauma is another important cause of panhypopituitarism and may be transient or permanent.[15,16] Other causes of

hypopituitarism include surgical removal or destruction of the gland, infections (e.g., meningitis, syphilis, tuberculosis), sarcoidosis, autoimmune hypophysitis, or certain drugs (e.g., bexarotene, carbamazepine).[14] A rare form of hypopituitarism is characterized by combined hormonal deficiencies and is related to mutations of the prophet of pituitary transcription factor *(PROP-1)* gene involved in early embryonic pituitary development.[17,18]

PATHOPHYSIOLOGY. The pituitary gland is highly vascular and is therefore extremely vulnerable to ischemia and infarction. It relies heavily on portal blood flow from the hypothalamus. In traumatic brain injury, disruption of blood flow can cause infarction with subsequent necrosis and fibrosis of pituitary tissue.[14] After tissue necrosis, edema with swelling of the gland occurs. Expansion of the pituitary within the fixed compartment of the sella turcica further impedes blood supply to the pituitary. Over time the pituitary undergoes shrinkage, and symptoms of hypopituitarism develop.

CLINICAL MANIFESTATIONS. The signs and symptoms of hypofunction of the anterior pituitary are variable and depend on which hormones are affected. In **panhypopituitarism,** all hormones are deficient and the individual suffers from multiple complications including cortisol deficiency from lack of adrenocorticotrophic hormone (ACTH), thyroid deficiency from lack of thyroid-stimulating hormone (TSH), and loss of secondary sex characteristics from lack of FSH and LH. Low levels of growth hormone (GH) and insulin-like growth factor 1 (IGF-1) affect growth in children and can cause physiologic and psychologic symptoms in adults. In addition, postpartum women cannot lactate because of decreased or absent prolactin.

ACTH deficiency is a potentially life-threatening disorder because cortisol is required for many aspects of cellular metabolism. ACTH deficiency is usually encountered with generalized pituitary hypofunction and rarely occurs as an isolated event.[19] Within 2 weeks of the complete absence of ACTH, symptoms of cortisol insufficiency develop, including nausea, vomiting, anorexia, fatigue, and weakness. Hypoglycemia is caused by increased insulin sensitivity, decreased glycogen reserves, and decreased gluconeogenesis associated with hypocortisolism. In women, loss of body hair and decreased libido may be caused by decreased adrenal androgen production. ACTH deficiency also limits maximum aldosterone secretion, although the renin-angiotensin system can stimulate some aldosterone secretion with resultant hypotension and decreased urine output.

TSH deficiency also is rarely seen in isolation but most often occurs in conjunction with other pituitary hormone deficiencies. The symptoms of decreased TSH levels may become apparent in 4 to 8 weeks and may include cold intolerance, dryness of skin, mild myxedema, lethargy, and decreased metabolic rate. The symptoms are usually less severe than those associated with primary hypothyroidism, in which lack of thyroxine is related to disease in the thyroid gland (see p. 728).

The onset of **FSH** and **LH deficiencies** in women of reproductive age is associated with amenorrhea and with atrophic changes in the vagina, uterus, and breasts. In postpubertal males, atrophy of the testes and decreased beard growth occur. Men as well as women experience a decrease in body hair and diminished libido.

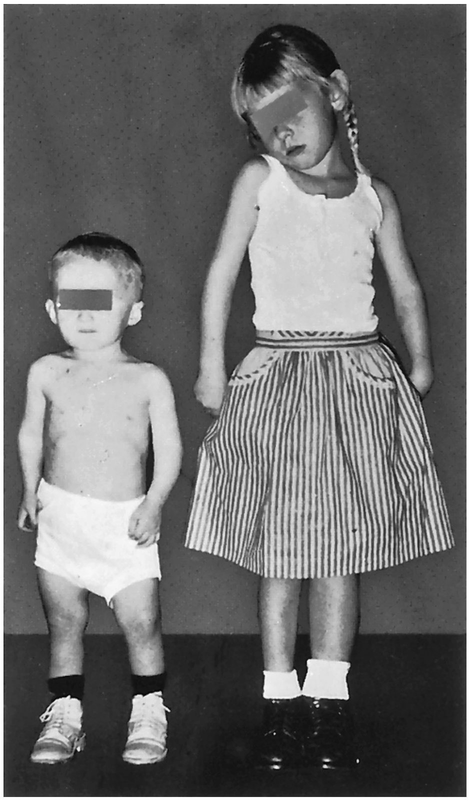

FIGURE 22-2 **Hypopituitary Dwarfism.** A 4-year-old boy whose height is 25 inches. The girl is also 4 years old and has a normal height of 39 inches. Dwarf has a normal face, as well as head, trunk, and limbs of approximately normal proportions. (From Brashear HR, Raney RB: *Shands' handbook of orthopaedic surgery,* ed 10, St Louis, 1986, Mosby.)

GH deficiency occurs in children and adults. As described previously, GH deficiency may result from any of the causes of hypopituitarism. In children it may be genetic or it may be the result of tumors such as craniopharyngiomas. Several genetic defects have been identified in the GH axis that account for impaired GH action. These include a recessive mutation in the *GHRH* gene, resulting in a failure of GH secretion, and mutations that cause GH insensitivity by affecting the GH receptor, insulin-like growth factor 1 (IGF-1) biosynthesis, IGF-1 receptors, or defects in GH signal transduction.[20,21] GH deficiency in children is manifested by growth failure (Figure 22-2). Another feature of GH deficiency in children is fasting hypoglycemia, likely attributable to impaired substrate mobilization for gluconeogenesis and enhanced insulin sensitivity.

In both children and adults, acute GH and IGF-1 deficiency has been implicated in significant metabolic perturbations seen with critical illness.[22] Symptoms of chronic adult GH deficiency syndrome include increased body fat, decreased muscle bulk and strength, reduced sweating, dry skin, and psychologic problems, including depression, social withdrawal, fatigue, loss of motivation, and a diminished feeling of well-being.[14] Several studies also have documented increased mortality in adults who are GH deficient. Osteoporosis and alterations in body composition (i.e., reduced lean body mass) are common concomitants of adult GH deficiency. A decline in GH production is an inevitable consequence of aging.[23]

EVALUATION AND TREATMENT. The diagnostic evaluation of suspected pituitary disease is often challenging and must be carefully interpreted together with the individual's signs and symptoms. Simultaneous measurements of the tropic hormones from the pituitary and target endocrine glands are crucial and, in some cases, dynamic testing of the various axes is indicated.[14] Radiographic assessment of the pituitary (magnetic resonance imaging [MRI] or computed tomography [CT] scans) may demonstrate enlargement of the pituitary, abnormal areas of enhancement suggestive of an adenoma, deviation of the pituitary stalk, or evidence of a locally aggressive tumor.

In general, treatment of hypopituitarism involves replacing target gland hormone(s) that are deficient. In cases of circulatory collapse, immediate therapy with glucocorticoids and intravenous fluids is critical. Thyroid and cortisol replacement therapy must be maintained. Gender-specific sex steroid replacement therapy is also initiated to improve general well-being and to prevent osteoporosis. Recombinant human GH (rhGH) is used for treatment of GH deficiency in children and results in both improved stature and metabolism.[24] Treatment of adult GH deficiency improves quality of life, metabolism, body composition, and physical performance in some individuals.[14,25] The use of GH to treat otherwise healthy aging is more controversial.[23]

Hyperpituitarism: Primary Adenoma

Pituitary adenomas are usually benign slow-growing tumors that arise from cells of the anterior pituitary, most commonly those that secrete GH and prolactin. They are very common in the population with prevalence rates estimated to be around 17%. However, most are microadenomas found incidentally on high-resolution MRI scanning and are hormonally silent and do not pose significant hazards to the individual.[26,27] More significant adenomas are associated with morbidity and mortality attributable to alterations in hormone secretion or to invasion or impingement of surrounding structures. The pathogenesis of pituitary adenomas includes hypothalamic and intrapituitary factors, including altered expression of pituitary cell cycle genes, activation of pituitary selective oncoproteins, or loss of pituitary suppressor factors.[28] Several associated gene mutations have been identified, including those associated with multiple endocrine neoplasia (MEN) syndromes.[29] Primary pituitary carcinomas are rare, representing about 0.2% of all pituitary tumors.

PATHOPHYSIOLOGY. Local expansion of pituitary adenomas may cause both neurologic and secretory defects. Neurologically, the tumor may impinge on the optic chiasm if it extends upward from the sella turcica. This causes a variety of visual disturbances, depending on the area of the optic chiasm that is compressed. If the tumor is locally aggressive, it may invade the cavernous sinus and cause cavernous sinus thrombosis with impairment of the function of the oculomotor, trigeminal, trochlear, and abducens cranial nerves, evoking symptoms relative to their function. Extension also may involve the hypothalamus, disturbing hypothalamic control of wakefulness, thirst, appetite, and temperature.

Hormonal effects of adenomas include hypersecretion from the adenoma itself, and hyposecretion from surrounding pituitary cells. The adenomatous tissue secretes the hormone of the cell type from which it arose, without regard to physiologic needs and without benefit of regulatory feedback mechanisms.

CLINICAL MANIFESTATIONS. The clinical manifestations of pituitary adenomas are related to tumor growth and hormone hypersecretion or hyposecretion. Effects from an increase in tumor size include such nonspecific complaints as headache and fatigue. Visual changes produced by pressure on the optic chiasm include visual field impairments (occasionally beginning in one eye and progressing to the other) and temporary blindness. If the tumor infiltrates other cranial nerves, neurologic function is affected.

Pituitary adenomas arise from hormone-producing cells of the pituitary, and most often are associated with increased secretion of GH and prolactin. Paradoxically, the pressure produced by a pituitary adenoma is also associated with decreased function of neighboring anterior pituitary cells, which results in hyposecretion of other anterior pituitary hormones. For example, gonadotropic hyposecretion often results in menstrual irregularity in women, decreased libido, and receding secondary sex characteristics in men and women. If the tumor exerts sufficient pressure, thyroid and adrenal hypofunction may occur because of lack of TSH and ACTH, respectively. These result in the respective symptoms of hypothyroidism and hypocortisolism.

EVALUATION AND TREATMENT. Diagnosis of pituitary adenoma involves physical and laboratory evaluations, including pertinent hormone assays and radiographic examination of the skull (MRI [preferred] or contrast-enhanced CT). The goal of treatment is to protect the individual from the effects of tumor growth, to control hormone hypersecretion (if present), and to replace deficient hormones while minimizing damage to appropriately secreting portions of the pituitary. Depending on the tumor size and type, individuals may be treated with specific medications to suppress tumor growth, transsphenoidal tumor resection, or radiation therapy. Simple observation and close follow-up is commonly employed for individuals who have no evidence of hormonal hypersecretion and no suggestion of anatomic aggressiveness.[27,30]

Hypersecretion of Growth Hormone: Acromegaly

Acromegaly occurs in adults who are exposed to continuously excessive levels of GH and concomitant elevation of IGF-1. In children and adolescents whose epiphyseal plates have not yet closed, the effect of increased GH levels on long bone growth is termed **giantism** (Figure 22-3).

Approximately 15% of all pituitary tumors release excessive GH. The most common cause of acromegaly is a primary autonomous GH-secreting pituitary adenoma. Acromegaly occurs more often in women than men and is diagnosed most often in adults in their forties and fifties, although the disease is usually present for years preceding the diagnosis.

Acromegaly is a slowly progressive disease that, if untreated, is associated with a decreased life expectancy. The increased number of deaths associated with acromegaly are caused by

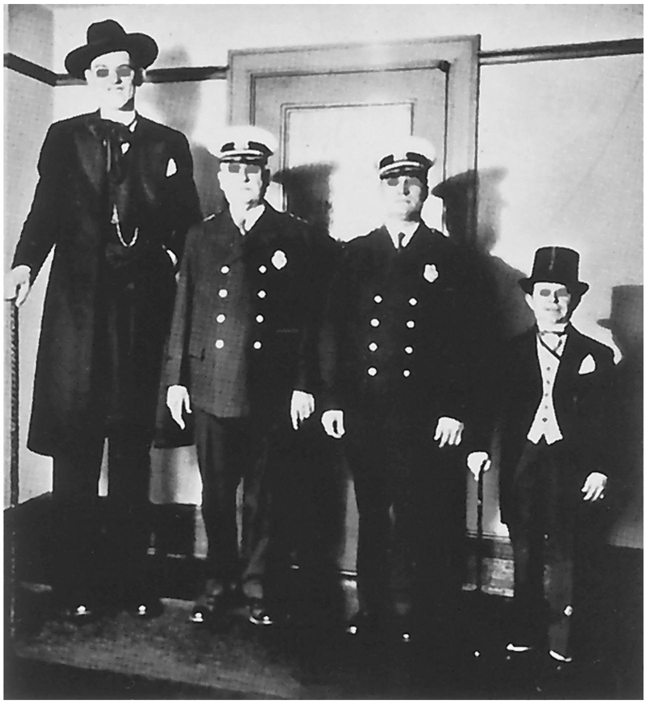

FIGURE 22-3 Giantism. A pituitary giant and dwarf contrasted with normal-size men. Excessive secretion of growth hormone by the anterior lobe of the pituitary gland during the early years of life produces giants of this type, whereas deficient secretion of this hormone produces well-formed dwarfs. (From Patton K, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

FIGURE 22-4 Acromegaly in a female. Chronologic sequence of photographs showing slow development of acromegaly. (From Belchetz P, Hammond P: *Mosby's color atlas and text of diabetes and endocrinology,* Edinburgh, 2003, Mosby.)

cardiac hypertrophy, hypertension, atherosclerosis, and type 2 diabetes mellitus that lead to coronary artery disease. Malignancies, including colon, breast, and lung cancer, are also more common in individuals with acromegaly.

PATHOPHYSIOLOGY. With a GH-secreting adenoma, the usual GH baseline secretion pattern and sleep-related GH peaks are lost, and an unpredictable secretory pattern ensues. With only slight elevations of GH, IGF-1 levels increase, stimulating growth. In children and adolescents whose epiphyseal plates have not yet closed, the effect of increased GH levels causes excessive skeletal growth, with some individuals becoming 8 or 9 feet tall. In the adult, epiphyseal closure has occurred and increased amounts of GH and IGF-1 cause connective tissue proliferation and increased cytoplasmic matrix, as well as bony proliferation that results in the characteristic appearance of acromegaly (Figures 22-4 and 22-5).

GH also has significant effects on glucose, lipid, and protein metabolism.[31] Hyperglycemia results from GH's inhibition of peripheral glucose uptake and increased hepatic glucose production, followed by compensatory hyperinsulinism and, finally, insulin resistance.[32] Excessive levels of GH and IGF-1 also affect the cardiovascular system. Although the associated pathophysiology is not clearly understood, hypertension and left heart failure are seen in one third to one half of individuals with acromegaly. Cardiomyopathy associated with progressive and unrestrained myocardial growth is a significant factor.[33,34]

GH also acts on the renal tubules to increase phosphate reabsorption, leading to mild hyperphosphatemia. The adenoma increasingly becomes a space-occupying lesion and

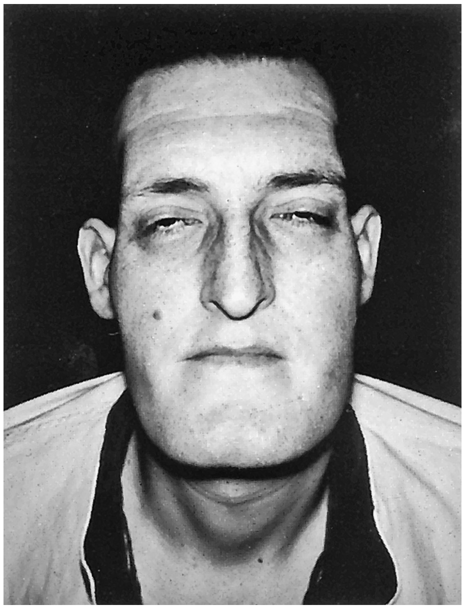

FIGURE 22-5 Acromegaly in a male. Note large head, forward projection of jaw, and protrusion of frontal bone. (Thibodeau GA, Patton K: *The human body in health & disease,* ed 5, St Louis, 2010, Mosby.)

hypopituitarism may occur because of compression of surrounding hormone-secreting cells.

CLINICAL MANIFESTATIONS. As a result of connective tissue proliferation, individuals with acromegaly have enlarged tongues, interstitial edema, increase in the size and function of sebaceous and sweat glands (leading to increased body odor), and coarse skin and body hair. The coarse skin condition becomes very apparent when procedures such as inserting an intravenous needle are performed; the skin is very thick and difficult to penetrate. Bony proliferation results in large joint arthropathy with swelling and decreased range of motion and periosteal vertebral

growth, which causes kyphosis. Enlargement of the facial bones and the bones of the hands and feet result in protrusion of the lower jaw and forehead and a need for increasingly larger sizes of shoes, hats, rings, and gloves (see Figures 22-4 and 22-5).

Because IGF-1 stimulates cartilaginous growth, the increased IGF-1 levels cause elongation of ribs at the bone-cartilage junction, leading to a barrel-chest appearance, and increased proliferation of cartilage in the spine and joints. This in turn causes backache, arthralgia, and arthritis. These are early manifestations of acromegaly. With continued bony and soft tissue overgrowth, entrapment of nerves may occur, leading to peripheral nerve damage as manifested by weakness, muscular atrophy, footdrop, and sensory changes in the hands.

Symptoms of diabetes, such as polyuria and polydipsia, may occur. Acromegaly-associated hypertension is usually asymptomatic until heart failure symptoms develop. Increased tumor size results in central nervous system symptoms of headache, seizure activity, visual disturbances, and papilledema. If compression hypopituitarism occurs, gonadotropin secretion may be affected, causing amenorrhea in women and sexual dysfunction in men. Approximately 20% of growth hormone–secreting tumors also secrete prolactin, resulting in hypogonadism.

EVALUATION AND TREATMENT. Diagnosis of acromegaly is accomplished by documenting elevated IGF-1 levels and GH suppression during oral glucose tolerance testing. The goals of treatment are to normalize GH and IGF-1 serum levels, restoring normal pituitary function and relieving or preventing complications related to tumor expansion. The treatment of choice for acromegaly is transsphenoidal surgery or endonasal endoscopic surgery for removal of the GH-secreting adenoma.[35] Treatment by radiation therapy may be effective when rapid control of GH levels is not essential, when the individual is not a good surgical candidate, or when hyperfunction persists after subtotal resection. Octreotide, octreotide long-acting, and lanreotide are somatostatin analogs that have been shown to be effective in lowering elevated GH levels, reversing many of the clinical manifestations of the disease, and causing tumor shrinkage.[36] Dopaminergic agonists, such as cabergoline, also may be helpful, especially if the tumor also secretes prolactin. Pegvisomant is an effective drug that induces tissue insensitivity to GH by blocking the GH receptor.[37]

Hypersecretion of Prolactin: Prolactinoma

Pituitary tumors that secrete prolactin are called **prolactinomas** and are the most common of the hormonally active pituitary tumors encountered in clinical medicine. These tumors can be classified as microprolactinomas (<1 cm in size) or macroprolactinomas (>1 cm in size). Microprolactinomas are usually encapsulated and noninvasive, whereas macroprolactinomas commonly expand into the optic chasm and invade local structures.[38] The physiologic actions of prolactin include breast development during pregnancy, postpartum milk production, and suppression of ovarian function in nursing women.

In addition to pituitary tumors, many conditions or medications can elevate prolactin level in the absence of pituitary pathologic condition. For example, renal failure, hepatic cirrhosis, polycystic ovarian disease (see Chapter 24), breast stimulation, or chest wall lesions can increase prolactin levels. Because thyrotropin-releasing hormone (TRH) stimulates prolactin secretion, in addition to enhancing TSH release, prolactin level may be elevated in individuals with primary hypothyroidism. Prolactin is under tonic inhibitory hypothalamic control through the secretion of dopamine (prolactin inhibitor factor [PIF]). Thus medications that block the effects of dopamine at the pituitary can increase prolactin production and stimulate proliferation of prolactin-secreting cells (lactotropes). These include antipsychotics (risperidone, chlorpromazine), metoclopramide, tricyclic antidepressants, methyldopa, and estrogens. Any process that interferes with the delivery of dopamine from the hypothalamus to the lactotropes (pituitary stalk tumor, pituitary stalk transection, or compressive pituitary tumor) also results in hyperprolactinemia.

PATHOPHYSIOLOGY. The hallmark of a prolactinoma is sustained increases in serum prolactin concentration. Because the adenoma becomes increasingly a space-occupying lesion, hypopituitarism may occur because of compression of surrounding hormone secreting cells. Central nervous system symptoms may develop because of growth and pressure of the adenoma within the sella turcica.

CLINICAL MANIFESTATIONS. Women with hyperprolactinemia generally present with galactorrhea (nonpuerperal milk production) and menstrual disturbances, including amenorrhea. In susceptible women, hirsutism develops because of estrogen deficiency. If not detected until after many years, this estrogen deficiency also may result in osteoporosis. Men often develop hypogonadism and erectile dysfunction but may not seek care until symptoms related to the increasing size of the adenoma (i.e., headache or visual impairment) develop.[39]

EVALUATION AND TREATMENT. The diagnostic evaluation of hyperprolactinemia starts with a careful history to exclude medications that may cause elevations in prolactin level. A careful search for a nonpituitary cause should be pursued if prolactin concentration is less than 50 ng/ml. Symptoms of hypothyroidism should be elicited, and screening with a serum TSH measurement is indicated. Prolactin levels more than 200 ng/ml are usually associated with a prolactinoma and are an indication for MRI scanning of the pituitary.

Dopaminergic agonists (bromocriptine, cabergoline, and pergolide) are the treatment of choice for prolactinomas, and their use is often associated with both a rapid reduction in the size of the tumor and a reversal of the gonadal effects of hyperprolactinemia.[40] Restoration of fertility in previously anovulatory women is common. Although there is an association between valvular heart disease and cabergoline used in the treatment of parkinsonism, a similar association has not been found when cabergoline is used to treat prolactinoma.[41,42] In individuals resistant or intolerant to these medications, transsphenoidal surgery, endonasal endoscopic surgery, and radiotherapy are options.[38]

ALTERATIONS OF THYROID FUNCTION

Disorders of thyroid function develop as a result of primary dysfunction or disease of the thyroid gland or, secondarily, as a

WHAT'S NEW?

Thyroid Disease and Iodinated Contrast Media (ICM)

Large amounts of circulating iodide can be associated with either hyperthyroidism or hypothyroidism. Iodinated contrast medium is commonly used for both CT and radiographic imaging. A recent case controlled study of 178 and 213 incident hyperthyroid and hypothyroid cases, respectively, was matched to 655 and 779 euthyroid controls, respectively. The cases exposed to ICM did not have preexisting hyperthyroidism or hypothyroidism. Large amounts of iodide inhibit the oxidation of iodide within the thyroid follicle and decrease the release of thyroid hormones into the bloodstream, an autoregulatory process (known as the Wolff-Chaikoff effect), with return of normal thyroid function over weeks to months. This mechanism may explain the incident hypothyroidism found in this study. However, there was no incident hypothyroidism overall.

Normally, uptake of iodide and the subsequent synthesis and release of triiodothyronine and thyroxine are tightly controlled. However, supraphysiologic levels of iodide administered as ICM may overwhelm regulatory capacity and precipitate hyperthyroidism. In this study there was a significant association between ICM exposure and incident hyperthyroidism, and incident overt hyperthyroidism.

Further research is needed to confirm the findings of this study, to establish causality, and to provide guidance for clinical practice. However, individuals unable to tolerate thyroid dysfunction (e.g., unstable cardiovascular disease) should be monitored for thyroid disease after iodide exposure.

Data from Pearce EN: *Arch Intern Med* 172(2):159–161, 2012; Rhee CM et al: *Arch Intern Med* 172(2):153–159, 2012.

result of pituitary or hypothalamic alterations. **Primary thyroid disorders** result in alterations of thyroid hormone (TH) levels with secondary feedback effects on pituitary TSH levels. For example, when there are primary elevations in TH level, TSH level will secondarily decrease because of negative feedback. When TH level is decreased because of a condition affecting the thyroid gland, TSH level will be elevated. Thyroid disease also can present with no or minimal symptoms but with abnormal laboratory values. This is known as **subclinical thyroid disease. Central (secondary) thyroid disorders** are related to disorders of pituitary gland TSH production. When there is excessive TSH production, TH level is elevated secondary to the primary elevation of TSH level. The reverse is true with inadequate TSH production. Exposure to iodinated contrast media has been shown to be associated with development of both hyperthyroidism and hypothyroidism (see What's New? Thyroid Disease and Iodinated Contrast Media [ICM]).

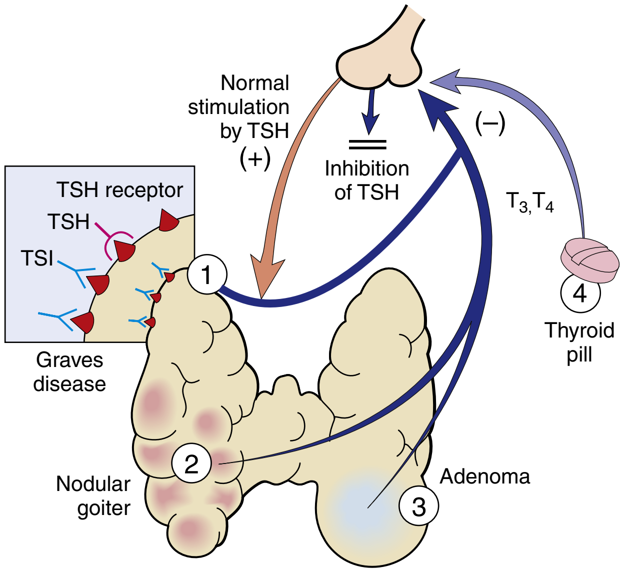

FIGURE 22-6 **Causes of Hyperthyroidism.** Hyperthyroidism may have several causes, among them: **1,** Graves disease; **2,** toxic multinodular goiter; **3,** follicular adenoma; **4,** thyroid medication. *TSH,* Thyroid-stimulating hormone; *TSI,* thyroid-stimulating immunoglobulin. (From Damjanov I: *Pathology for the health professions,* ed 4, St Louis, 2012, Saunders.)

Hyperthyroidism

Thyrotoxicosis

PATHOPHYSIOLOGY. **Thyrotoxicosis** is a condition that results from any cause of increased amounts of TH. Hyperthyroidism is a form of thyrotoxicosis in which excess amounts of TH are secreted from the thyroid gland. The terms *thyrotoxicosis* and *hyperthyroidism* are often used interchangeably. The prevalence of hyperthyroidism is estimated to be 0.7% to 2.1% in the United States, of which 0.7% is subclinical and is more prevalent in women and in iodine-deficient geographical areas.[43] Common diseases that cause **primary hyperthyroidism** include Graves disease, toxic multinodular goiter, a solitary toxic adenoma (Figure 22-6), and, very rarely, follicular thyroid carcinoma. **Central (secondary) hyperthyroidism** is less common and is caused by TSH-secreting pituitary adenomas. Thyrotoxicosis not associated with hyperthyroidism includes subacute thyroiditis, ectopic thyroid tissue, and ingestion of excessive TH. TSH progressively decreases in **subclinical hyperthyroidism** and can be caused by thyroid hormone therapy or iatrogenic exogenous disease. It is more prevalent in iodine-deficient populations.[44] Identifying the cause is important because the treatment and expected outcome vary accordingly. Each condition is associated with specific pathophysiology and manifestations; however, all forms of thyrotoxicosis share some common characteristics.

CLINICAL MANIFESTATIONS. The clinical features of thyrotoxicosis are attributable to the metabolic effects of increased circulating levels of TH (Figure 22-7). This usually results in an increased metabolic rate with heat intolerance and increased tissue sensitivity to stimulation by the sympathetic division of the autonomic nervous system. The major manifestations are summarized in Table 22-2. Enlargement of the thyroid gland (goiter) is common in hyperthyroid conditions caused by stimulation of TSH receptors.

EVALUATION AND TREATMENT. The diagnosis of thyrotoxicosis is based on symptoms of TH excess and documentation of increased circulating thyroid hormone levels. Elevated serum thyroxine (T_4) and triiodothyronine (T_3) levels and decreased serum TSH levels are diagnostic for primary hyperthyroidism. By contrast, central (secondary) hyperthyroidism caused by

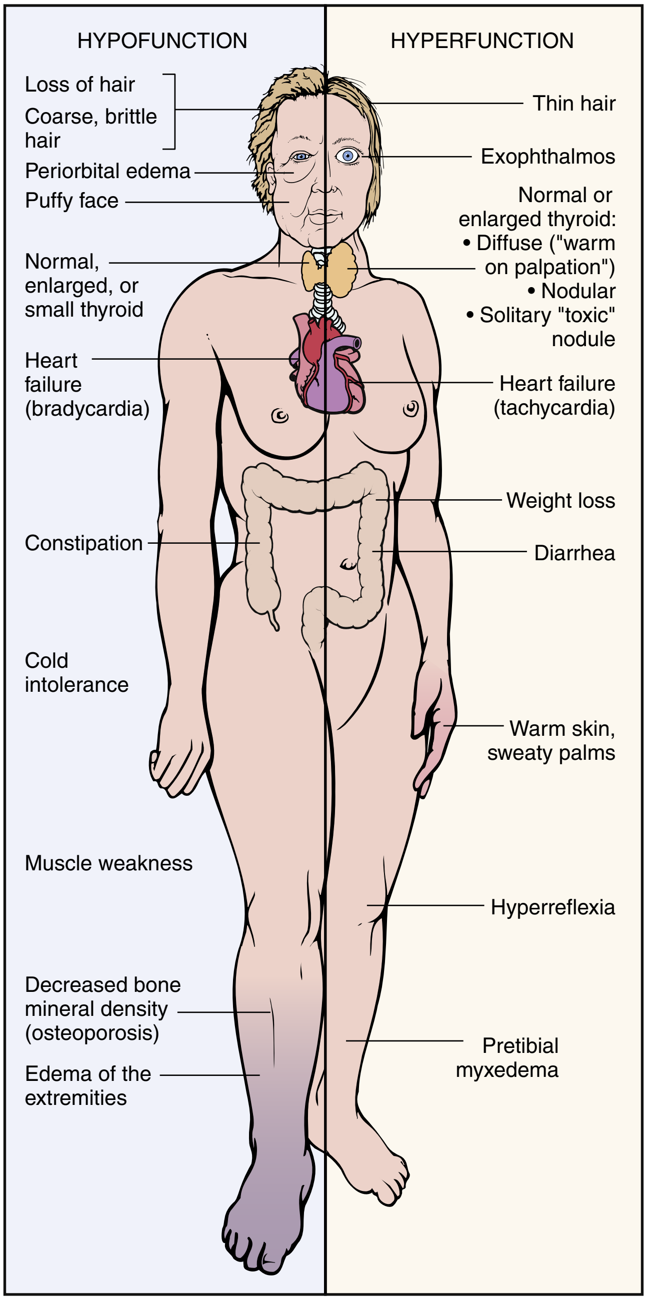

FIGURE 22-7 Clinical Manifestations of Hyperthyroidism and Hypothyroidism. (From Damjanov I: *Pathology for the health professions,* ed 4, St Louis, 2012, Saunders.)

TSH-secreting pituitary tumors is characterized by normal to increased TSH levels in the face of elevated thyroid hormone concentrations. Radioactive iodine is used to test for increased uptake in primary hyperthyroidism (Figure 22-8).

Treatment is directed at controlling excessive TH production, secretion, or action. The major types of therapy currently used to achieve these goals include antithyroid drug therapy (methimazole or propylthiouracil), radioactive iodine therapy, and surgery. Guidelines for the treatment of hyperthyroidism and thyrotoxicosis have been published.[45] Treatment of subclinical hyperthyroidism is based on levels of TSH and clinical symptoms.[44] A major complication of all forms of treatment for hyperthyroidism is hypothyroidism.[46]

Hyperthyroid Conditions

Graves Disease. **Graves disease** is the underlying cause of 50% to 80% of cases of hyperthyroidism and has a prevalence of approximately 0.5% in the U.S. population.[47] It occurs more commonly in women. Although the cause of Graves disease is not known, genetic factors interacting with environmental triggers play an important role in the pathogenesis of this autoimmune thyroid disease. Graves disease results from a form of type II hypersensitivity (see Chapter 9) in which there is stimulation of the thyroid by autoantibodies directed against the TSH receptor. These autoantibodies, called thyroid-stimulating immunoglobulins (TSIs; also called thyroid-stimulating antibodies [TSAbs] or thyroid receptor antibodies [TRAbs]), override normal regulatory mechanisms. The TSI stimulation of TSH receptors in the gland results in hyperplasia of the gland (goiter) and increased synthesis of TH, especially of triiodothyronine (T_3). Increased levels of TH affect every physiologic system and result in the classic signs and symptoms of hyperthyroidism illustrated in Figure 22-8. TSH production by the pituitary is inhibited through the usual negative feedback loop.

TSIs also contribute to two major distinguishing clinical manifestations of Graves disease: ophthalmopathy and pretibial myxedema (Graves dermopathy). Graves ophthalmopathy affects more than half of individuals with Graves disease. There are two categories of ocular manifestations: (1) functional abnormalities resulting from hyperactivity of the sympathetic division of the autonomic nervous system (lag of the globe on upward gaze or a lag of the upper lid on downward gaze) and (2) infiltrative changes involving the orbital contents with enlargement of the ocular muscles. The infiltrative changes result from TSH receptor autoantibodies reacting with receptors on orbital fibroblasts (Figure 22-9). Increased secretion of hyaluronic acid, orbital fat accumulation, inflammation, and edema of the orbital contents result in **exophthalmos** (protrusion of the eyeball). Periorbital edema and extraocular muscle weakness lead to diplopia (double vision). The individual may experience irritation, pain, lacrimation, photophobia, blurred vision, decreased visual acuity, papilledema, visual field impairment, exposure keratosis, and corneal ulceration.[48]

A small number of individuals with Graves disease and very high levels of TSI experience **pretibial myxedema (Graves dermopathy),** characterized by subcutaneous swelling on the anterior portions of the legs and by indurated and erythematous skin (Figure 22-10). Graves dermopathy is associated with thyrotropin receptor antigens on fibroblasts and recruited T lymphocytes that stimulate excess amounts of hyaluronic acid production in the dermis and subcutis. The manifestations occasionally appear on the hands giving the appearance of clubbing of the fingers (thyroid acropachy).[49]

Therapy for Graves disease includes antithyroid drugs, radioactive iodine (used with caution in Graves ophthalmopathy because it may worsen the condition), or surgery. Unfortunately, current treatment for Graves disease does not reverse the infiltrative ophthalmopathy or the pretibial myxedema. Surgical orbital decompression and glucocorticoids can help many individuals with progressive ophthalmopathy.[50] Skin lesions

TABLE 22-2 SYSTEMIC MANIFESTATIONS OF HYPERTHYROIDISM

SYSTEM	CLINICAL MANIFESTATIONS	MECHANISMS UNDERLYING CLINICAL MANIFESTATIONS
Endocrine	Enlarged thyroid gland (goiter) (97-99% of cases); systolic or continuous bruit over thyroid; increased cortisol degradation; hypercalcemia and decreased PTH secretion; diminished sensitivity to exogenous insulin	Hyperactivity of the thyroid gland; excess bone resorption leading to hypercalcemia and a disruption of PTH-regulating mechanisms; increased insulin degradation
Reproductive	Oligomenorrhea or amenorrhea; erectile dysfunction and decreased libido; increased serum estradiol and estrone levels but lower than normal levels of free estradiol and estrone	Menstrual cycle alterations that may be related to hypothalamic or pituitary disturbances; increase in sex hormone–binding globulin
Gastrointestinal	Weight loss; increased peristalsis leading to less formed and more frequent stools; nausea, vomiting, anorexia, abdominal pain; increased use of hepatic glycogen stores and of adipose and protein stores; decrease in serum lipid levels (including triglycerides, phospholipids, and cholesterol); changes in vitamin metabolism leading to decrease in tissue stores of vitamins	Increased catabolism leading to the body's inability to meet its metabolic needs; increased glucose absorption; increase in cholesterol excretion in feces and cholesterol conversion to bile salts; impaired conversion of B vitamins to their coenzymes, causing increased need for water-soluble and fat-soluble vitamins
Integumentary	Excessive sweating, flushing, and warm skin; heat intolerance; hair fine, soft, and straight; temporary hair loss; nails that grow away from nail beds, palmar erythema	Hyperdynamic circulatory state
Sensory (eyes)	Ocular manifestations including elevated upper eyelid leading to decreased blinking and a staring quality; fine tremor of lid; infiltrative ocular changes associated with Graves disease	Overactivity of Müller muscle; inflammation of retroorbital contents
Cardiovascular	Increased cardiac output and decreased peripheral resistance; tachycardia at rest; loud heart sounds; supraventricular dysrhythmias, left ventricular dilation and hypertrophy	Hypermetabolism and need to dissipate heat
Nervous	Restlessness; short attention span; compulsive movement; fatigue; tremor; insomnia; increased appetite; emotional lability	Not clearly defined; alterations in cerebral metabolism resulting from excess thyroid hormone
Pulmonary	Dyspnea; reduced vital capacity	Weakness of respiratory muscles

PTH, Parathyroid hormone.

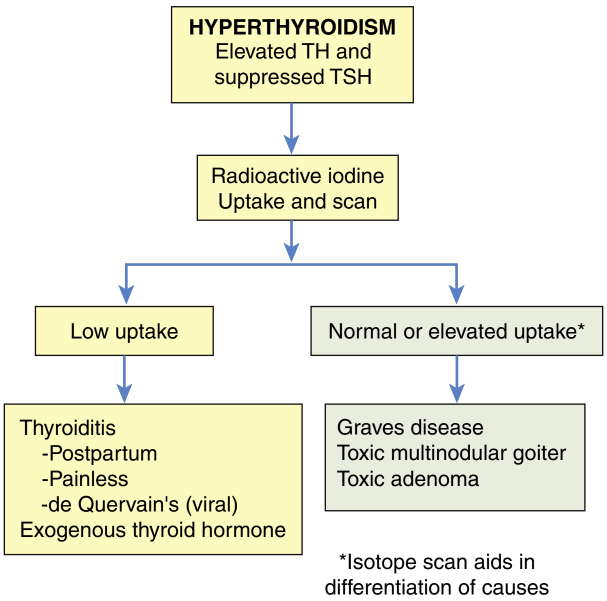

FIGURE 22-8 **Evaluation of Hyperthyroidism.** Radioactive iodine is used in the differential diagnosis of hyperthyroidism. *TH,* Thyroid hormone; *TSH,* thyroid-stimulating hormone.

FIGURE 22-9 **Thyrotoxicosis (Graves Disease).** Note large and protruding eyeballs in association with a large goiter. (From Stein HA, Slatt BJ, Stein RM: *The ophthalamic assistant: fundamentals and clinical practice,* ed 7, Philadelphia, 2000, Mosby.)

FIGURE 22-10 Pretibial Myxedema. Purple-brown edematous plaques on shins of individual with Graves disease. Note orange peel appearance. (From Bolognia JL, Jorizzo JL, Schaffer JV: *Dermatology,* ed 3, New York, 2013, Saunders.)

rarely require treatment, but if they are symptomatic they may respond to topical glucocorticoids.[51]

Hyperthyroidism Resulting from Nodular Thyroid Disease. The thyroid gland normally enlarges in response to an increased secretion of TSH that occurs in puberty, pregnancy, or iodine deficiency, and from immunologic, viral, or genetic disorders. The increased number of follicles is a compensatory mechanism in response to increased TSH levels. When the condition requiring increased TH resolves, TSH secretion normally subsides and the thyroid gland returns to its original size.

Irreversible changes may occur in some follicular cells and these cells function autonomously and produce excessive amounts of TH. On the other hand, some follicular cells may cease to function. The balance between the amount of TH produced by hyperfunctioning nodules and that produced by the remainder of the gland determines whether an individual becomes euthyroid or hyperthyroid. **Toxic multinodular goiter** occurs when there are several hyperfunctioning nodules leading to hyperthyroidism. If only one nodule becomes hyperfunctioning it is termed **solitary toxic adenoma.** This condition is more common in iodine-deficient regions. The classic clinical manifestations of hyperthyroidism (see Figure 22-7) usually develop slowly and exophthalmos and pretibial myxedema do not occur. Nodules may be palpable on physical examination. The incidence of malignancy in toxic multinodular goiter is estimated to be as high as 9% and 10.5%, so most individuals should undergo a fine needle aspiration biopsy of suspicious nodules before treatment.[52] Treatment consists of a combination of radioactive iodine, surgery, or antithyroid drugs. Mutations of the TSH receptor have been found in most solitary toxic adenomas.[53,54]

Thyrotoxic Crisis (Thyroid Storm). **Thyrotoxic crisis (thyroid storm)** is a rare but dangerous worsening of the thyrotoxic state, in which death can occur within 48 hours without treatment. The condition may develop spontaneously, but it occurs in individuals who have undiagnosed or partially treated severe hyperthyroidism and who are subjected to excessive stress from other causes. These causes may include infection, pulmonary or cardiovascular disorders, trauma, burns, seizures, surgery (especially thyroid surgery), obstetric complications, emotional distress, or dialysis. The symptoms of thyroid crisis are caused by the increased action of thyroxine (T_4) and triiodothyronine (T_3) exceeding metabolic demands.[55]

The systemic symptoms of thyrotoxic crisis include hyperthermia; tachycardia, especially atrial tachydysrhythmias; high-output heart failure; agitation or delirium; and nausea, vomiting, or diarrhea, contributing to fluid volume depletion. Treatment includes: (1) the use of drugs that block TH synthesis (i.e., propylthiouracil or methimazole), (2) the use of beta-blockers for control of cardiovascular symptoms, (3) administration of corticosteroids or (4) iodine (e.g., saturated solution of potassium iodide [SSKI]), and (5) supportive care.

Hypothyroidism

Hypothyroidism is caused by a deficient production of TH by the thyroid gland. Hypothyroidism is the most common disorder of thyroid function; it affects between 0.1% and 2% of individuals in the United States and is more common in women and the elderly. It may be primary or secondary. **Primary hypothyroidism** is the most prevalent. **Central (secondary) hypothyroidism,** which is much less common, includes conditions that cause either pituitary or hypothalamic failure with failure to stimulate normal thyroid function. **Subclinical hypothyroidism** is mild thyroid failure and is estimated to occur in 4% to 8% of U.S. adults. It is defined as an elevation in TSH level with normal levels of circulating TH.[44]

PATHOPHYSIOLOGY. In primary hypothyroidism the loss of functional thyroid tissue leads to a decreased production of TH. Causes in adults include autoimmune thyroiditis (Hashimoto disease), iatrogenic loss of thyroid tissue after surgical or radioactive treatment for hyperthyroidism, head and neck radiation therapy, medications, and endemic iodine deficiency. Infants and children may present with hypothyroidism because of congenital defects in the pituitary or thyroid glands.[56] Most states require newborn screening for hypothyroidism. Central (secondary) hypothyroidism is caused by the pituitary's failure to synthesize adequate amounts of TSH or a lack of TRH. Pituitary tumors that compress surrounding pituitary cells or the consequences of their treatment are the most common causes of **secondary hypothyroidism.** Other causes include traumatic brain injury, subarachnoid hemorrhage, or pituitary infarction. Hypothalamic dysfunction results in low levels of TRH, TSH, and TH (Figure 22-11).

CLINICAL MANIFESTATIONS. Hypothyroidism generally affects all body systems and occurs insidiously over months or years. The extent of the symptoms is closely related to the degree of TH deficiency (see Figure 22-7). The lowered levels of TH result in decreased energy metabolism and decreased heat production. The individual develops a low basal metabolic rate, cold intolerance, lethargy, tiredness, and slightly lowered basal body

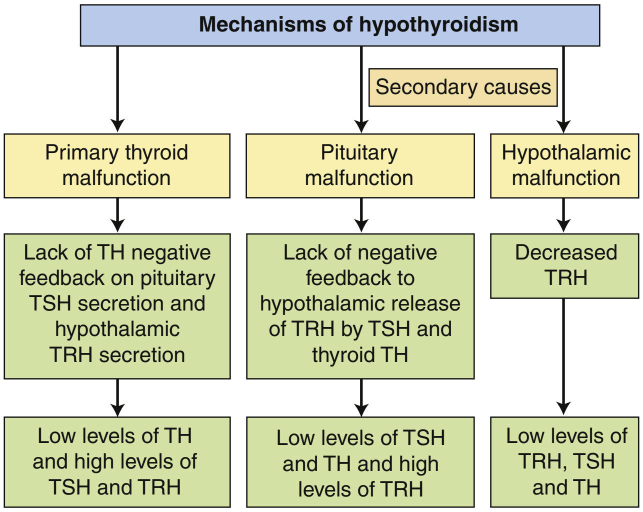

FIGURE 22-11 Mechanisms of Primary and Central (Secondary) Hypothyroidism. *TH,* Thyroid hormone; *TRH,* Thyroid-releasing hormone; *TSH,* Thyroid-stimulating hormone.

temperature and also may have diastolic hypertension. Many organ systems are affected (Table 22-3). The decrease in the level of TH leads to increases in TSH production and may cause goiter.

The characteristic sign of severe or long-standing hypothyroidism is **myxedema,** which is histologically similar to the pretibial myxedema deposits that often occur with Graves disease. Myxedema is a result of an alteration in the composition of the dermis and other tissues. The connective fibers are separated by an increased amount of protein and mucopolysaccharides. This protein-mucopolysaccharide complex binds water, producing nonpitting, boggy edema, especially around the eyes, hands, and feet and in the supraclavicular fossae. Myxedema is also responsible for thickening of the tongue and the laryngeal and pharyngeal mucous membranes. This results in thick, slurred speech and hoarseness, both of which are common in hypothyroidism.

Myxedema coma, a medical emergency, is a diminished level of consciousness associated with severe hypothyroidism. Precipitating events include infections and discontinuation of thyroid supplements, overuse of narcotics or sedatives, or a consequence of an acute illness in individuals who have hypothyroidism. Older individuals with severe vascular disease and with moderate or untreated hypothyroidism are particularly at risk for developing myxedema coma. Signs and symptoms include hypothermia without shivering, hypoventilation, hypotension, hypoglycemia, lactic acidosis, and coma.[57] Symptoms of hypothyroidism in older adults should not be attributed to normal aging changes.

EVALUATION AND TREATMENT. The diagnosis of primary hypothyroidism is made by documentation of the clinical symptoms of hypothyroidism, and by measurement of increased levels of TSH and decreased levels of TH (total T_3 and both total and free T_4). When hypothyroidism is caused by pituitary deficiencies, serum TSH levels are decreased or are inappropriately normal in the face of low levels of TH. Hormone replacement therapy is the treatment of choice for hypothyroidism. Levothyroxine (a synthetic hormone) is preferred over desiccated thyroid (the crude extract from animal thyroid glands). Treatment of myxedema coma with TH, combined with circulatory and ventilatory support and management of hyponatremia and hypothermia, is usually effective. Mortality can be as high as 25%.[55] Treatment of subclinical hypothyroidism is related to elevated levels of TSH and clinical symptoms.[58] The goal of treatment is maximal metabolic restoration consistent with the individual's overall well-being and normalization of TSH levels in primary hypothyroidism or normalization of TH levels in central hypothyroidism.

Hypothyroid Conditions

Primary Hypothyroidism. **Primary hypothyroidism** has several causes. **Iodine deficiency (endemic goiter)** is the most common cause worldwide, but is relatively rare in the United States because of the use of iodized table salt and fortified foods. The most common cause of hypothyroidism in the United States is **autoimmune thyroiditis (Hashimoto disease,** chronic **lymphocytic thyroiditis),** which results in gradual inflammatory destruction of thyroid tissue by infiltration of lymphocytes and circulating thyroid autoantibodies (antithyroid peroxidase and antithyroglobulin antibodies). Autoreactive T lymphocytes, antibody activation of natural killer cells (antibody-dependent cell-mediated cytotoxicity), cytokines, and induction of apoptosis also are involved in the tissue destruction seen in Hashimoto thyroiditis.[59] Variants in major histocompatibility complex (MHC) antigens have been associated with autoimmune thyroiditis that are different from those found in Graves disease. Hashimoto disease occurs in genetically predisposed individuals and is associated with high iodine intake, selenium deficiency, smoking, chronic hepatitis C, and interferon-alpha (IFN-α).[60] Epigenetic mechanisms are probably involved.[61] Goiter formation is commonly observed.

Spontaneous recovery of thyroid function is seen in three conditions: subacute thyroiditis, painless thyroiditis, and postpartum thyroiditis.[62] **Subacute thyroiditis (subacute granulomatous thyroiditis,** or **de Quervain thyroiditis)** is an uncommon nonbacterial inflammation of the thyroid often preceded by a viral infection. It is accompanied by fever, tenderness, and enlargement of the thyroid. The inflammatory process initially results in elevated levels of TH caused by release of stored thyroglobulin, and then is associated with transient hypothyroidism before the gland recovers normal activity. Symptoms may last 2 to 4 months and nonsteroidal anti-inflammatory agents, corticosteroids, beta-blockers, and, possibly, TH supplementation may be required during the course of the illness. **Painless thyroiditis (silent** or **subacute lymphocytic thyroiditis)** has a course similar to that of subacute thyroiditis but is pathologically identical to Hashimoto disease. **Iatrogenic hypothyroidism** results from radioiodine thyroid ablation, thyroidectomy, and medications (lithium and amiodarone). **Postpartum thyroiditis** generally occurs within 6 to 12 months of delivery, develops in up to 5.4% of all women, and has a course similar to that of painless thyroiditis. Pathologic specimens suggest it is related to Hashimoto disease. Spontaneous recovery is seen in most women affected with this form of thyroiditis; however, persistent hypothyroidism does occur.[63,64]

TABLE 22-3 SYSTEMIC MANIFESTATIONS OF HYPOTHYROIDISM

SYSTEM	CLINICAL MANIFESTATIONS	MECHANISMS UNDERLYING CLINICAL MANIFESTATIONS
Neurologic	Confusion, syncope, slowed speech and thinking, memory loss; lethargy, headaches, hearing loss, night blindness; slow, clumsy movements; cerebellar ataxia; slow alpha-wave activity and loss of amplitude in EEG; reduced cAMP response to epinephrine, glucagons, and PTH stimulation; decreased appetite	Decreased cerebral blood flow leading to cerebral hypoxia; reduced intracellular processes caused by decreased β-adrenergic activity that may be related to a decrease in the number of β-adrenergic receptor sites
Endocrine	Increased TSH production in primary hypothyroidism; enlarged pituitary thyrotropes, increase in serum prolactin levels with galactorrhea; decreased rate of cortisol turnover but with normal serum cortisol levels	Impaired TH synthesis or defects in iodide trapping leading to compensatory TSH production; chronic overstimulation of thyrotropes of TRH and by TSH synthesis; stimulation of lactotropes by TRH related to increased prolactin levels; decreased deactivation of cortisol
Reproductive	Decreased androgen secretion in men, increased estriol formation in women; low total hormone values but with increased amounts of unbound hormone; anovulation, decreased libido, menorrhagia, and a high incidence of spontaneous abortion in women; erectile dysfunction, decreased libido, and oligospermia in men	Altered metabolism of estrogens and androgens; decreased levels of sex hormone–binding globulin
Hematologic	Decrease in red cell mass leading to normocytic, normochromic anemia; macrocytic anemia associated with vitamin B_{12} deficiency and inadequate folate or iron absorption in the gastrointestinal tract	Decreased basal metabolic rate and reduced oxygen requirements; decreased production of erythropoietin; possible relationship between TH and optimal hematologic response to vitamin B_{12}
Cardiovascular	Reduction in stroke volume and heart rate causing lowered cardiac output; increased peripheral vascular resistance to maintain systolic blood pressure can cause hypertension; normal response to exercise but with alterations in circulatory system at rest (prolonged circulation time and decreased blood flow to tissues); cool skin and cold tolerance; enlarged heart; decreased intensity of heart sounds and variety of ECG changes (sinus bradycardia, prolonged PR interval, depressed P waves, flattened or inverted T waves, and low-amplitude QRS complexes); cardiac tamponade (although rare) (see Chapter 32)	Decreased metabolic demands and loss of regulatory and rate-setting effects of TH; protein-mucopolysaccharide–rich fluid in the pericardial sac associated with enlarged heart; pericardial effusions associated with heart sounds and ECG changes Increases in peripheral vascular resistance and increased blood volume can cause hypertension
Pulmonary	Dyspnea; myxedematous changes in respiratory muscles leading to hypoventilation and carbon dioxide retention, which contribute to myxedema coma	Pleural effusions associated with dyspnea, although effusions may be asymptomatic
Renal	Reduced renal blood flow and glomerular filtration rate leading to decreased renal excretion of water; increase in total body water and dilutional hyponatremia; reduced production of erythropoietin	Hemodynamic alterations associated with reduced blood flow and filtration; increased total body water related to decreased excretion and mucinous deposits in tissue
Gastrointestinal	Constipation, weight gain, and fluid retention; decreased absorption of most nutrients; decreased protein metabolism leading to retarded skeletal and soft tissue growth and slightly positive nitrogen balance; edema; decreased glucose absorption and delayed glucose uptake; elevated serum lipid values	Reduced intake and reduced peristaltic activity that may progress to fecal impaction; water absorption related to prolonged transit time; fluid retention associated with myxedematous changes; edema associated with high concentrations of exchangeable albumin in the extravascular space caused by increased capillary permeability to proteins; depressed insulin degradation; depressed lipid synthesis and degradation
Musculoskeletal	Muscle aching and stiffness; slow movement and slow tendon jerk reflexes; decreased bone formation and resorption, increased bone density; aching and stiffness in joints	Decreased rate of muscle contraction and relaxation contributing to slow movement and reflexes
Integumentary	Dry, flaky skin; dry, brittle head and body hair; reduced growth of nails and hair; slow wound healing	Reduced sweat and sebaceous gland secretion
	Myxedema	Accumulation of hyaluronic acid, which binds water and causes a puffy appearance
	Cool skin	Decreased circulation to skin

Congenital Hypothyroidism. **Congenital hypothyroidism (CH)** is thyroid hormone deficiency present at birth. It occurs as a result of absent thyroid tissue (thyroid agenesis) or with hereditary defects in TH synthesis. Thyroid agenesis occurs more often in female infants, with permanent abnormalities in 1 of every 3000 to 4000 live births.[65] Because TH is essential for embryonic growth, particularly of brain tissue, the infant will be mentally retarded if there is no T_4 available during fetal life.

Clinical manifestations at birth are not the typical signs of hypothyroidism and this is most likely caused by transplacental passage of some maternal thyroid hormone in addition to some residual neonatal thyroid function. Without treatment, symptoms may not be evident until after 4 months of age. Hypothyroidism is difficult to identify at birth, but high birth weight, hypothermia, delay in passing meconium, and neonatal jaundice are suggestive signs. Without treatment, symptoms include difficulty eating, hoarse cry, and protruding tongue caused by myxedema of oral tissues and vocal cords; hypotonic muscles of the abdomen with constipation, abdominal protrusion, and umbilical herniation; subnormal temperature; lethargy; excessive sleeping; slow pulse rate; and cold, mottled skin. Skeletal growth is stunted because of impaired protein synthesis, poor absorption of nutrients, and lack of bone mineralization. The individual will become dwarfed, with short limbs, if not treated (cretinism) (Figure 22-12). Dentition is often delayed. Mental retardation is a function of the severity of hypothyroidism and the delay before initiation of treatment.

Cord blood can be screened in the first days of life for T_4 and TSH levels. Neonatal screening has resulted in eradication of mental retardation related to CH where screening is available. Treatment is administration of T_4. The probability of normal growth and intellectual function is high if treatment is started within 2 weeks and before the child is 3 or 4 months old. The earlier TH replacement is initiated, the better the child's outcome. Permanent congenital hypothyroidism will require treatment for life.[66]

Thyroid Carcinoma. **Thyroid carcinoma** is the most common endocrine malignancy, accounting for 60,220 estimated new cases and 1850 estimated cancer deaths in 2013 in the United States, less than 4% of all neoplasms.[67] Exposure to ionizing radiation, especially during childhood, is the most consistent causal factor. Papillary and follicular thyroid carcinomas are the most frequent, and medullary and anaplastic thyroid carcinomas are less common. Most tumors are well differentiated.[68]

Most individuals with thyroid carcinoma have normal T_3 and T_4 levels and are therefore euthyroid. Thyroid cancer typically is discovered as a small thyroid nodule or as a metastatic tumor most commonly occurring in the regional lymph nodes, lungs, brain, or bone. Changes in voice and swallowing and difficulty in breathing are related to tumor growth impinging on the trachea or esophagus. The diagnosis of thyroid carcinoma is generally made by fine-needle aspiration of a thyroid nodule. Ultrasonographic characteristics may be suggestive of malignancy, and staging requires appropriate imaging.[69]

Treatment for well-differentiated thyroid carcinoma remains somewhat controversial mainly because of its protracted nature and the relatively low mortality regardless of the method of treatment. Treatment of well-differentiated tumors includes surgical dissection (e.g., a near-total or total thyroidectomy), postoperative radioactive iodine therapy to treat any microscopic residual tumor, and suppression of TSH with levothyroxine to replace TH and suppress TSH on any tumor cells.[68] Anaplastic thyroid carcinoma carries a grave prognosis, and palliation with surgical debulking, external beam radiotherapy, and chemotherapy may be offered.[70]

ALTERATIONS OF PARATHYROID FUNCTION

Hyperparathyroidism

Hyperparathyroidism is characterized by greater than normal secretion of parathyroid hormone (PTH) and hypercalcemia. Hyperparathyroidism is classified as primary, secondary, or tertiary. Calcium levels are either low or normal in secondary hyperparathyroidism. Normocalcemic hyperparathyroidism is characterized by increased levels of intact PTH, normal total and ionized serum calcium concentrations, and no underlying etiology. Increased PTH screening for osteoporosis has led to the development of this diagnosis. There may be tissue resistance to PTH or the elevated level of PTH may represent an early phase of primary hyperparathyroidism.[71]

PATHOPHYSIOLOGY. Primary hyperparathyroidism is usually a sporadic disease characterized by inappropriate excess secretion of PTH by one or more of the parathyroid glands. PTH secretion

TABLE 22-4 **MANIFESTATIONS OF PRIMARY HYPERPARATHYROIDISM**

SYMPTOMS	RESPONSIBLE DERANGEMENTS	MECHANISMS
Renal colic, nephrolithiasis, recurrent urinary tract infections, renal failure	Hypercalciuria, hyperphosphaturia, proximal renal tubular bicarbonate leak, urine pH >6	Calcium phosphate salts precipitate in alkaline urine, renal pelvis, and collecting ducts; calcium oxalate stones also formed
Abdominal pain, peptic ulcer disease	Hypercalcemia-stimulated hypergastrinemia	Elevated hydrochloric acid secretion
Pancreatitis	Hypercalcemia	Etiology of relationship unknown
Bone disease, osteitis fibrosa and osteitis cystica, osteoporosis	PTH-stimulated bone resorption, metabolic acidosis	Osteoporosis now more commonly encountered, but other disorders are more specific for hyperparathyroidism
Muscle weakness, myalgia	PTH excess, possible direct effect on striated muscle and on nerves	Characteristic myopathic changes in muscle histology (neuropathy of type I and type II muscle fibers)
Neurologic and psychiatric problems (impaired memory, confusion, depression, anxiety, psychosis)	Hypercalcemia	Neuropathy; electroencephalographic changes present
Polyuria, polydipsia	Hypercalcemia	Direct effect on renal tubule to decrease responsiveness to antidiuretic hormone
Constipation	Hypercalcemia	Decreased peristalsis of gastrointestinal tract
Anorexia, nausea, and vomiting	Hypercalcemia	Central stimulation of vomiting center
Hypertension	Renal disease, direct effect of calcium on arterial smooth muscle, pheochromocytoma	Plasma rennin activity elevated or normal
Arthralgia and arthritis	Gout, pseudogout, periarticular classification	Hyperuricemia, chronic renal failure with high calcium- phosphate product

Data from Flint PW et al: *Cummings otolaryngology: head & neck surgery,* ed 5, St Louis, 2010, Mosby.
PTH, Parathyroid hormone.

is increased and is not under the usual feedback control mechanisms. The calcium level in the blood increases because of increased bone resorption and gastrointestinal absorption of calcium, but fails to inhibit PTH secretion.

Primary hyperparathyroidism is one of the most common endocrine disorders: 80% to 85% of cases are caused by parathyroid adenomas, another 10% to 15% result from parathyroid hyperplasia, and approximately 1% are caused by parathyroid carcinoma.[72] Normal feedback mechanisms, such as elevated serum levels of ionized calcium, fail to normally inhibit PTH secretion by the parathyroid gland.

The cause of primary hyperparathyroidism is unknown; however, recent data suggest that there are two mechanisms for the development of this condition. The first is a monoclonal proliferation of parathyroid cells with a higher threshold for calcium feedback, and the second is generalized growth of parathyroid tissue. The former is most likely the cause of adenomas, and the latter is probably the cause for hyperplasia. There is also a familial form of the disease that includes a wide range of inherited endocrine disorders including multiple endocrine neoplasia syndromes (MEN-1 and MEN-2a).[73] Hypercalcemia and hypophosphatemia are the hallmarks of primary hyperparathyroidism. The effects of excessive PTH secretion and primary hyperparathyroidism on various organ systems are summarized in Table 22-4.

Secondary hyperparathyroidism is caused by an increase in PTH secondary to a chronic disease state, such as chronic kidney disease or intestinal malabsorption, which causes a decrease in serum ionized calcium levels (hypocalcemia) or chronic vitamin D deficiency. Hypercalcemia does not occur in secondary hyperparathyroidism because the parathyroid tissue is not autonomous and is only responding to a physiologic stimulus of hypocalcemia.

The most common cause of secondary hyperparathyroidism is chronic kidney disease (with failure of glomerular filtration), which results in hyperphosphatemia, reduced levels of activated vitamin D, and hypocalcemia, which stimulates PTH secretion. Disturbances in calcium and vitamin D metabolism that arise in chronic renal disease diminish activation of the parathyroid calcium-sensing receptor leading to increases in PTH secretion. Because vitamin D metabolism is impaired in kidney failure, eucalcemia cannot be restored unless vitamin D supplements are administered.[74] Other causes of secondary hyperparathyroidism include chronic vitamin D or calcium deficiency; decreased intestinal absorption of vitamin D or calcium; and ingestion of drugs, such as phenytoin, phenobarbital, and laxatives, which either accelerates the metabolism of vitamin D or decreases intestinal absorption of calcium.

Tertiary hyperparathyroidism is excessive secretion of PTH and hypercalcemia that occurs after long-standing secondary hyperparathyroidism. The etiology is unknown but represents autonomous secretion of PTH from persistent parathyroid stimulation even after withdrawal of calcium and calcitriol therapy. It develops in individuals with chronic secondary hyperparathyroidism and after renal transplantation.

Two other conditions must be differentiated from primary and secondary hyperparathyroidism. **Pseudohypoparathyroidism** is an inherited condition that presents with increased PTH levels, hypocalcemia, and hyperphosphatemia. These individuals are resistant to PTH and cannot produce cAMP in response

to PTH (a postreceptor defect in PTH action).[75] **Familial hypocalciuric hypercalcemia (FHH)** is a benign autosomal dominant condition that can mimic hyperparathyroidism and is characterized by a high serum calcium level, low serum phosphate level, and low urine calcium excretion. It is caused by a mutation in the calcium-sensing receptor in the parathyroid gland. It can be differentiated from primary hyperparathyroidism by measurement of 24-hour urine calcium excretion.[76]

CLINICAL MANIFESTATIONS. Most individuals with primary hyperparathyroidism are asymptomatic. Hypercalcemia and hypophosphatemia commonly occur in primary hyperparathyroidism. Hypercalcemia may be asymptomatic or affected individuals may present with symptoms related to the muscular, nervous, and gastrointestinal systems, including fatigue, headache, depression, anorexia, and nausea and vomiting. There also is an increased risk for cardiovascular disease including hypertension.[77] Excessive osteoclastic and osteocytic activity resulting in bone resorption may cause pathologic fractures, kyphosis of the dorsal spine, and compression fractures of the vertebral bodies. (Bone resorption is discussed in Chapter 43.)

In primary hyperparathyroidism, hypercalcemia affects proximal renal tubular function, causing hypercalciuria, metabolic acidosis, and production of abnormally alkaline urine. PTH also enhances the renal excretion of phosphate, which results in hypophosphatemia (low serum phosphate concentration) and hyperphosphaturia (increased urine phosphate level). The combination of these three variables—hypercalciuria, alkaline urine, and hyperphosphaturia—predisposes the individual to the formation of calcium stones. Kidney stones are often formed in the renal pelvis or in the renal collecting ducts and may be associated with infections. Kidney stones and renal infection may lead to impaired renal function.[78] Hypercalcemia also impairs the concentrating ability of the renal tubule by decreasing its response to ADH. Chronic hypercalcemia of hyperparathyroidism is associated with mild insulin resistance, necessitating increased insulin secretion to maintain normal glucose levels. Hypercalcemia also affects the muscular, nervous, and gastrointestinal systems. Elevated levels of PTH increase the risk for cardiovascular disease.[79]

Secondary hyperparathyroidism caused by renal disease presents clinically not only with bone resorption but also with the symptoms of hypocalcemia and hyperphosphatemia. Hypocalcemia can cause many significant clinical problems (see Chapter 3). Hyperphosphatemia can cause deleterious effects on the cardiovascular system.[80]

EVALUATION AND TREATMENT. The concurrent findings of increased ionized calcium concentration in the face of elevated intact PTH level (which documents an abnormal feedback mechanism) are suggestive of primary hyperparathyroidism. Sestamibi (a radioisotope) scanning, CT, or ultrasound is used to localize adenomas before surgery.[81] Definitive treatment of severe primary hyperparathyroidism involves surgical removal of the solitary adenoma or, in the case of hyperplasia, complete removal of three and partial removal of the fourth hyperplastic parathyroid glands. In those individuals who fail surgery, other treatments such as bisphosphonates, corticosteroids, and calcimimetics (e.g., cinacalcet) may be considered. Calcimimetics increase the parathyroid calcium receptor sensitivity, thus lowering PTH levels.[82]

If hypercalcemia is documented but PTH levels are low, the differential diagnosis shifts to hypercalcemia of malignancy, granulomatous diseases (sarcoidosis), excessive calcium ingestion, or to hypervitaminosis A or D. Treatment of these conditions depends on the underlying cause.

If serum calcium level is low but PTH level is elevated, secondary hyperparathyroidism is likely. Evaluation for renal function frequently documents chronic renal disease. Treatment for secondary hyperparathyroidism in chronic kidney disease requires calcium replacement, dietary phosphate restriction and phosphate binders, and vitamin D replacement. Treatment also may include calcimimetics.[83]

Hypoparathyroidism

Hypoparathyroidism (abnormally low PTH levels) most commonly is caused by damage to the parathyroid glands during thyroid surgery and occurs because of the anatomic proximity of the parathyroid glands to the thyroid. Hypoparathyroidism also is associated with genetic syndromes, including familial hypoparathyroidism and DiGeorge syndrome (velocardiofacial syndrome) and an idiopathic or autoimmune form of the disease.[84] Hypomagnesemia also can cause a decrease in PTH secretion and function.[85]

PATHOPHYSIOLOGY. A lack of circulating PTH causes depressed serum calcium levels and increased serum phosphate levels. In the absence of PTH, resorption of calcium from bone and regulation of calcium reabsorption from the renal tubules are impaired. The phosphaturic effects of PTH are lost, resulting in hyperphosphatemia.

The effects of hypomagnesemia on the peripheral metabolism and clearance of PTH are not clearly understood. Once serum magnesium levels return to normal, however, PTH secretion returns to normal, as does the responsiveness of peripheral tissues to PTH. Hypomagnesemia may be related to chronic alcoholism, malnutrition, malabsorption, increased renal clearance of magnesium caused by the use of aminoglycoside antibiotics or certain chemotherapeutic agents, or prolonged magnesium-deficient parenteral nutritional therapy.

CLINICAL MANIFESTATIONS. Symptoms associated with hypoparathyroidism are related to hypocalcemia. Hypocalcemia causes a lowering of the threshold for nerve and muscle excitation so that a nerve impulse may be initiated by a slight stimulus anywhere along the length of a nerve or muscle fiber. This creates tetany manifested as muscle spasms, hyperreflexia, tonic-clonic convulsions, laryngeal spasms, and, in severe cases, death from asphyxiation. Chvostek and Trousseau signs may be used to evaluate for neuromuscular irritability. Chvostek sign is elicited by tapping the cheek, resulting in twitching of the upper lip. Trousseau sign is elicited by sustained inflation of a sphygmomanometer placed on the upper arm to a level above the systolic blood pressure with resultant painful carpal spasm.[85] Other symptoms of hypocalcemia are caused by mechanisms that are not yet understood. These symptoms include dry skin, loss of body and scalp hair, hypoplasia of developing teeth, horizontal ridges on the nails, cataracts, basal ganglia calcifications

(which may be associated with a parkinsonian syndrome), and bone deformities, including brachydactyly and bowing of the long bones.

Phosphate retention caused by increased renal reabsorption of phosphate is associated also with hypoparathyroidism. Hyperphosphatemia is associated with inhibition of the renal enzyme necessary for the conversion of vitamin D to its most active form. This enzyme, 25-hydroxy-vitamin D 1α-hydroxylase, also is required by PTH. This tends to depress serum calcium levels further by reducing gastrointestinal absorption of calcium.

EVALUATION AND TREATMENT. A low serum calcium level and a high phosphorous level in the absence of renal failure, intestinal disorders, or nutritional deficiencies suggest hypoparathyroidism. Intact PTH levels are low in hypoparathyroidism, and measurement of serum magnesium and urinary calcium excretion can help in diagnosis.[85]

The treatment of hypoparathyroidism is directed toward the alleviation of hypocalcemia. In acute states this involves parenteral administration of calcium, which allows correction of serum calcium deficit within minutes. Maintenance of serum calcium level is achieved with pharmacologic doses of an active form of vitamin D and oral calcium. PTH hormone replacement therapy is being evaluated and results are encouraging.[86] Hypoplastic dentition, cataracts, bone deformities, and basal ganglia calcifications do not respond to the correction of hypocalcemia; however, the other symptoms of hypocalcemia are reversible.

As serum calcium levels return to normal, phosphaturia usually is stimulated. This leads to a return to normal serum phosphate levels. In some individuals, however, the absence of the phosphaturic effect of PTH causes a persistent hyperphosphatemia. Significant elevations of phosphorous concentration should be treated with drugs that inhibit gastrointestinal absorption of phosphate (phosphate binders).[85]

DYSFUNCTION OF THE ENDOCRINE PANCREAS: DIABETES MELLITUS

Diabetes mellitus (DM) is a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both. It affects 8.3% of the U.S. population and 27% of Americans older than age 65.[87] The American Diabetes Association (ADA) classifies four categories of diabetes mellitus[88] (Table 22-5):

1. Type 1 (beta-cell destruction, usually leading to absolute insulin deficiency)
2. Type 2 (ranging from predominantly insulin resistance with relative insulin deficiency to predominantly an insulin secretory defect with insulin resistance)
3. Other specific types
4. Gestational diabetes

The diagnosis of diabetes mellitus is based on glycosylated hemoglobin (HbA_{1c}) levels, fasting plasma glucose (FPG) levels, 2-hour plasma glucose level during oral glucose tolerance testing (OGTT) using a 75-g oral glucose load, or random glucose

TABLE 22-5 CLASSIFICATION AND CHARACTERISTICS OF DIABETES MELLITUS

NAME	CHARACTERISTICS
Type 1	Cellular-mediated autoimmune destruction of pancreatic beta cells
Beta-cell destruction leading to absolute insulin deficiency; immune-mediated diabetes is most common form (≈90%)	Individual prone to ketoacidosis Little or no insulin secretion Insulin dependent 75% of individuals develop before 30 years of age; can occur up to the tenth decade Usually not obese
Idiopathic (≈10%)	No defined etiologies; absolute requirement for insulin replacement therapy in affected individuals may be sporadic
Type 2	Usually not insulin dependent but may be insulin requiring
May range from predominantly insulin resistant with relative insulin deficiency to predominantly secretory defect with insulin resistance	Individual not ketosis prone (but may form ketones under stress) Obesity common in the abdominal region Generally occurs in those older than 40 years, but the frequency is rapidly increasing in children Strong genetic predisposition Often associated with hypertension and dyslipidemia
Other Specific Types	
Genetic defects of beta-cell function	Genetic abnormalities that decrease the ability of the beta cell to secrete insulin: 1. Maturity-onset diabetes of youth (MODY) includes 6 specific autosomal dominant mutations including genes for hepatocyte nuclear factor-1α (HNF-1α; MODY 3), glucokinase (MODY 2), HNF-4α (MODY 1), insulin-promoter factor-1(IPF-1; MODY 4), HNF-1β (MODY 5), and NeuroD1 (MODY 6) 2. Defects in mitochondrial deoxyribonucleic acid (DNA) 3. Other (including an inability to convert proinsulin to insulin)
Genetic defects in insulin action	Mutations in the insulin receptor with hyperinsulinism or hyperglycemia or severe diabetes
Diseases of the exocrine pancreas	Any process that diffusely injures the pancreas, including pancreatitis, neoplasia, and cystic fibrosis
Endocrinopathies	Endocrine disorders including acromegaly, Cushing syndrome, glucagonoma, pheochromocytoma, hyperthyroidism, somatostatinoma, and aldosteronoma
Drug- or chemical-induced beta-cell dysfunction	Commonly associated drugs include glucocorticoids and thiazide diuretics, although many others may be implicated

TABLE 22-5 CLASSIFICATION AND CHARACTERISTICS OF DIABETES MELLITUS—cont'd

NAME	CHARACTERISTICS
Infections	Beta-cell destruction by viruses including cytomegalovirus, congenital rubella
Uncommon forms of immune-mediated diabetes mellitus	Anti–insulin receptor antibodies Reported with "stiff man syndrome" and individuals receiving interferon-α
Other genetic syndromes sometimes associated with diabetes mellitus	Down, Klinefelter, Turner, and Wolfram syndromes
Gestational Diabetes Mellitus (GDM)	
Any degree of glucose intolerance with onset or first recognition during pregnancy	Insulin resistance combined with inadequate insulin secretion in relation to hyperglycemia Women who are obese, older than 25 years of age, have a family history of diabetes, have a history of previous GDM, or are of certain ethnic groups (Hispanic, Native American, Asian, or African American) are at increased risk of developing GDM The metabolic stress of pregnancy may uncover a genetic tendency for type 2 diabetes mellitus

Data from Agency for Healthcare Research & Quality, U.S. Preventive Services Task Force (USPSTF): *Screening for gestational diabetes mellitus recommendation statement,* May 2008. Available at www.ahrq.gov/clinic/uspstf08/gestdiab/gdrs.htm; American Diabetes Association (Committee Report): *Diabetic Care* 26(Suppl 1):S5–S20, 2003.

BOX 22-1 DIAGNOSTIC CRITERIA FOR DIABETES MELLITUS

1. HbA_{1c} (as measured in a DCCT-referenced assay) ≥6.5%*

OR

2. FPG ≥126 mg/dl (7.0 mmol/L); fasting is defined as no caloric intake for at least 8 hr*

OR

3. 2-hr plasma glucose ≥200 mg/dl (11.1 mmol/L) during an OGTT*

OR

4. In a patient with classic symptoms of hyperglycemia or hyperglycemic crisis, a random plasma glucose ≥200 mg/dl (11.1 mmol/L)

Categories of Increased Risk for Diabetes

1. FPG 100 to 125 mg/dl
2. 2-hr PG in the range of 75 to 199 mg/dl during an OGTT
3. HbA_{1c} 5.7% to 6.4%

From American Diabetes Association: *Diabetes Care* 33:S62–S69, 2010.

*In the absence of unequivocal hyperglycemia, criteria 1 through 3 should be confirmed by repeat testing.

DCCT, Diabetes Control and Complications Trial; *FPG,* fasting plasma glucose; *HbA_{1c},* hemoglobin A_{1c}; *hr,* hour(s); *OGTT,* oral glucose tolerance test; *PG,* plasma glucose.

levels in an individual with symptoms (Box 22-1). Glycosylated hemoglobin refers to the permanent attachment of glucose to hemoglobin molecules and reflects the average plasma glucose exposure over the life of a red blood cell (approximately 120 days).

The ADA classification "…categories at increased risk for diabetes…"[88] describes nondiabetic elevations of HbA_{1c}, FPG, or the 2-hour plasma glucose value during OGTT (see Box 22-1). This classification includes impaired glucose tolerance (IGT), which results from diminished insulin secretion, and impaired fasting glucose (IFG), which is caused by enhanced hepatic glucose output. Individuals with IGT and IFG are at increased risk of cardiovascular disease and premature death and carry a 3% to 7% yearly risk of developing diabetes.[88]

Types of Diabetes Mellitus

Type 1 Diabetes Mellitus

Although type 2 diabetes affects a larger percentage of children and adolescents each year, **type 1 diabetes mellitus** remains the most common form of diabetes in those under age 12, affecting 1 in 300 individuals in the United States. Diagnosis is rare during the first 9 months of life and peaks at 12 years of age. It is the result of a loss of beta cells in the pancreatic islets. Table 22-6 summarizes the epidemiology of diabetes mellitus (DM).

PATHOPHYSIOLOGY. Two distinct types of type 1 diabetes have been identified: autoimmune and nonimmune. In autoimmune-mediated diabetes mellitus, environmental-genetic factors are thought to trigger cell-mediated destruction of pancreatic beta cells. Autoimmune type 1 diabetes is called *type 1A.* Nonimmune type 1 diabetes is far less common than autoimmune. It occurs secondary to other diseases, such as pancreatitis, or to a more fulminant disorder termed *idiopathic (type 1B) diabetes.* Type 1B diabetes occurs mostly in people of Asian or African descent and affected individuals have varying degrees of insulin deficiency.

Genetic Susceptibility. Between 10% and 13% of individuals with newly diagnosed type 1 diabetes have a first-degree relative (parent or sibling) with type 1 diabetes. There is a 50% concordance rate in twins.[89] The exact nature of genetic susceptibility to type 1A diabetes is not clearly understood. The strongest association is with major histocompatibility complex, or MHC (histocompatibility leukocyte antigen [HLA] class II alleles HLA-DQ and HLA-DR). Numerous other mutations involving single genes both within and outside of the MHC complex have been associated with an increased risk of type 1 DM.[90]

Environmental Factors. Environmental factors are thought to have a significant contribution to the development of type 1 diabetes mellitus. Several types of viral infections have been implicated with autoimmune damage to beta cells, especially enteroviruses, although a cause-and-effect relationship has not yet been proven[91,92] (see What's New? The Role of Viruses in the Etiology of Type 1 Diabetes). Exposure to other infectious

TABLE 22-6 EPIDEMIOLOGY AND ETIOLOGY OF DIABETES MELLITUS IN THE UNITED STATES

	TYPE 1 DIABETES: PRIMARY BETA-CELL DEFECT OR FAILURE	TYPE 2 DIABETES: INSULIN RESISTANCE WITH INADEQUATE INSULIN SECRETION
Incidence		
Frequency	One of the most common childhood diseases (5-10% of all cases of diabetes mellitus) Prevalence rate is 0.17%	Accounts for most cases (≈90-95%) Prevalence rate for ages 45-64 yr is 10.5%, for ages 65-74 yr is 18.4%
Change in incidences	No documented increase in incidence in the United States	Incidence in all age groups has doubled since 1980
Characteristics		
Age at onset	Peak onset at age 11-13 yr (slightly earlier for girls than for boys) Rare in children younger than 1 yr and adults older than 30 yr	Risk of developing diabetes increases after age 40 yr; in general, incidence increases with age into the 70s; among Pima Indians, incidence peaks between ages 40 and 50 yr, then falls
Gender	Similar in males and females	Similar in males and females overall, although black females have the highest incidence and prevalence of all groups
Racial distribution	Rates for whites 1.5-2 times higher than those for nonwhites Higher rates for those of Scandinavian descent than for those of central or southern European descent	Risk is highest for blacks and Native Americans
Obesity	Generally normal or underweight	Frequent contributing factor to precipitate type 2 diabetes among those susceptible; a major factor in populations recently exposed to westernized environment Increased risk related to duration, degree, and distribution of obesity
Etiology		
Common theory	*Autoimmune:* Genetic and environmental factors, resulting in gradual process of autoimmune destruction in genetically susceptible individuals *Nonautoimmune:* Unknown Strong association with *HLA-DQA* and *HLA-DQB* genes	Disease results from genetic susceptibility (polygenic) combined with environmental determinants and other risk factors; inherited defects in beta-cell mass and function combined with peripheral tissue insulin resistance Associated with long-duration obesity
Heredity	Risk to sibling: 5-10% Risk to offspring: 2-5%	Risk to first-degree relative (child or sibling): 10-15%
Presence of antibody	Islet cell autoantibodies (ICAs) and/or autoantibodies to insulin, and autoantibodies to glutamic acid decarboxylase (GAD_{65}) and tyrosine phosphatases IA-2 and IA-2β are present in 85-90% of individuals when fasting; hyperglycemia is initially detected	Islet cell antibodies not prevalent
Insulin resistance	Insulin resistance at diagnosis is unusual, but insulin resistance may occur as the individual ages and gains weight	Insulin resistance is generally caused by altered cellular metabolism and an intracellular postreceptor defect
Insulin secretion	Severe insulin deficiency or no insulin secretion at all	Typically increased at time of diagnosis, but progressively declines over the course of the illness

Data from American Diabetes Association: *Diabetic Care* 30(Suppl 1):S42–S47, 2007.

WHAT'S NEW?

The Role of Viruses in the Etiology of Type 1 Diabetes

The etiology of type 1 diabetes is believed to be the result of genetic and environmental interactions. The role of viral infection in the etiology of type 1 diabetes continues to be debated. The most recent studies focus on the association between type 1 diabetes and enteroviruses, especially coxsackieviruses B (CV-B). Enteroviruses have been implicated both epidemiologically and immunologically. In one recent study, type 1 diabetes incidence was found to have increased after epidemics because of enteroviruses; in addition, enteroviral RNA can be detected in the blood of more than half of individuals with type 1 diabetes at the time of diagnosis. Enteroviruses can infect pancreatic beta cells and establish persistent infection. This is postulated to initiate both innate and adaptive immune responses with consequent effects ranging from functional damage to cell death. T-cytotoxic T cells play an important role in the autoimmune destruction of beta cells, and enteroviruses are potent stimulators of T-cytotoxic cell activation. Another postulated mechanism by which enteroviral infection might induce beta-cell autoimmunity is by infecting thymic epithelial cells, resulting in an increase in autoreactive thymocytes. Further investigation into the relationship between viral infection and type 1 diabetes may lead to prevention or treatment through vaccination or immune modulation.

microorganisms (such as *Helicobacter pylori*), exposure to cow's milk proteins, and a relative lack of vitamin D also have been implicated.[93,94] Despite intensive research, the number of identified possible environmental factors remains small.

Immunologically Mediated Destruction of Beta Cells. Type 1 diabetes mellitus is a slowly progressive autoimmune T cell–mediated disease that occurs in genetically susceptible individuals (Figure 22-13 and see Chapter 9). The destruction of beta cells progresses through the following stages:

1. *Lymphocyte and macrophage infiltration of the islets resulting in inflammation (insulinitis) and islet beta-cell death.* Autoantigens are expressed on the surface of pancreatic islet cells and circulate in the bloodstream and lymphatics (see Figure 22-13). Circulating autoantigens are ingested by antigen-presenting cells that activate CD4+ T helper 1 (Th1) lymphocytes.[95] The activated T helper lymphocytes secrete interleukin-2 (IL-2) that activates beta-cell autoantigen-specific T cytotoxic lymphocytes, causing them to proliferate and attack islet cells through secretion of toxic perforins and granzymes.[96] T helper lymphocytes also secrete interferon that activates macrophages and stimulates the release of inflammatory cytokines (including IL-1 and tumor necrosis factor [TNF]), which cause further beta-cell destruction and apoptosis.[97]
2. *Production of autoantibodies against islet cells, insulin, glutamic acid decarboxylase (GAD), and other cytoplasmic proteins.* Activated T helper 2 (Th2) lymphocytes produce IL-4, which stimulates B lymphocytes to proliferate and produce antibodies (see Figure 22-13). Islet cell autoantibodies (ICAs) precede evidence of beta-cell deficiency and can be found in the serum years before symptoms occur.[98] Anti–glutamic acid decarboxylase (antiGAD_{65}) antibodies (an enzyme in beta cells that is involved in coordinating insulin release) are more persistent, which makes them clinically useful in differentiating the etiology of diabetes in a given individual. Autoantibodies against insulin (insulin autoantibodies [IAAs]) also have been noted. It is likely that IAAs may form during the process of active islet cell and beta-cell destruction.[99] Finally, another islet antigen against which antibodies are produced in type 1 diabetes can now be measured in the serum. It is called the zinc transporter 8 (Znt8) protein and is associated with variation in disease progression.[100,101]

An additional autommune mechanism being explored in the pathogenesis of type 1 diabetes is a relative inactivity of T regulatory cells. These T lymphocytes normally serve to inhibit the immune response and maintain self tolerance.[102] Over time these immune mechanisms lead to a decrease in beta-cell mass and insulin production.

Hyperglycemia, Glucagon, and Hyperketonemia. Before hyperglycemia occurs, 80% to 90% of the function of the insulin-secreting beta cells in the islet of Langerhans must be lost. Beta-cell abnormalities are present long before the acute clinical onset of type 1 diabetes.

A disequilibrium of hormones produced by the islets of Langerhans occurs in diabetes mellitus. Alpha-cell and beta-cell functions are abnormal. Lack of insulin and amylin (produced by beta cells) and a relative excess of glucagon (produced by alpha cells) exist in type 1 diabetes. The ratio of insulin to glucagon in the portal vein controls hepatic glucose and fat metabolism. The paracrine action of insulin and amylin normally suppresses secretion of glucagon. Considerable data have documented that high levels of glucagon relative to insulin levels contribute to the generation of hyperglycemia and hyperketonemia. Thus, both alpha-cell and beta-cell functions are abnormal and both a lack of insulin and amylin and a relative excess of glucagon contribute to hyperglycemia in type 1 diabetes. Relative hyperglucagonemia occurs in every form of diabetes mellitus, leading some researchers to suggest that it is important in propagating the metabolic abnormalities in diabetes.[103-105]

CLINICAL MANIFESTATIONS. Historically, type 1 diabetes mellitus has been thought to have an abrupt onset. It is now known, however, that the natural history involves a long preclinical

TABLE 22-7 CLINICAL MANIFESTATIONS AND RATIONALE FOR TYPE 1 DIABETES MELLITUS

MANIFESTATIONS	RATIONALE
Polydipsia	Because of elevated blood glucose levels, water is osmotically attracted from body cells, resulting in intracellular dehydration and hypothalamic stimulation of thirst
Polyuria	Hyperglycemia acts as an osmotic diuretic; the amount of glucose filtered by the glomeruli of the kidneys exceeds the amount that can be reabsorbed by the renal tubules; glycosuria results, accompanied by large amounts of water lost in the urine
Polyphagia	Depletion of cellular stores of carbohydrates, fats, and protein results in cellular starvation and a corresponding increase in hunger
Weight loss	Weight loss occurs because of fluid loss in osmotic diuresis and the loss of body tissue as fat and proteins are used for energy as a result of the effects of insulin deficiency
Fatigue	Metabolic changes result in poor use of food products, contributing to lethargy and fatigue; sleep loss from severe nocturia also contributes to fatigue

WHAT'S NEW?

Immunomodulation in the Prevention and Treatment of Type 1 Diabetes

Many different kinds of immunologic approaches are being tested to prevent the autoimmune destruction of beta cells in type 1 diabetes. These treatments are aimed at preserving insulin synthesis early in the course of disease. Some of these interventions create generalized immunosuppression, including mycophenolate mofetil, monoclonal antibodies to B cells (rituximab), monoclonal antibodies to T cells (otelixizumab, teplizumab), interleukin-1 blockade, and cyclosporine. Studies document their effectiveness in stabilizing beta-cell function but, unfortunately, they also cause many side effects. More focused immunologic therapies are "antigen specific," which means they suppress only the parts of the immune response that are attacking the beta cells. One approach that has shown some promising (but mixed) results has been the use of vaccines to induce T-regulatory cells that suppress the immune attack on specific antigens. Vaccines that have been tested so far include insulin, glutamic acid decarboxylase 65 (GAD-Alum), and heatshock proteins (DiaPep277). Another ambitious new approach to preserving beta-cell function is through the introduction of stem cells, which decrease autoimmune responses and may engraft and become insulin-producing beta cells.

Data from Chen W, Xie A, Chan L: *Transl Res* 161(4):217–229, 2013; Godfrey KJ et al: *Diabetic Med* 29(1):14–23, 2012; Li CR, Baaten BJ, Bradley LM: *J Mol Cell Biol* 4(1):38–47, 2012; Ludvigsson J et al: *N Engl J Med* 366(5):433–442, 2012; Miller SA, St Onge E: *Exp Opin Biol Ther* 11(11):1525–1532, 2011; Pozzilli P et al: *Curr Pharm Design* 17(29):3224–3228, 2011; Sherry N et al: *Lancet* 378:487–497, 2011; Tooley JE, Waldron-Lynch F, Herold KC: *Trends Mol Med* 18(3):173–181, 2012; Zhao Y et al: *BMC Med* 10:3, 2012.

period with gradual destruction of beta cells, eventually leading to insulin deficiency and hyperglycemia. Generally, this latent period is longer in older individuals with type 1 diabetes and often results in misclassification of those affected as having type 2 diabetes.

Type 1 diabetes mellitus affects the metabolism of fat, protein, and carbohydrates. Glucose accumulates in the blood and appears in the urine as the renal threshold for glucose is exceeded, producing an osmotic diuresis and symptoms of polyuria and polydipsia. Wide fluctuations in blood glucose levels occur. In addition, protein and fat breakdown occur because of the lack of insulin, resulting in weight loss (Table 22-7).

Insulin normally stimulates lipogenesis and inhibits lipolysis, thus preventing fat catabolism. With insulin deficiency, lipolysis is enhanced and there is an increase in the amount of nonesterified fatty acids delivered to the liver. The consequence is increased glyconeogenesis contributing to hyperglycemia. In the absence of insulin, the release of free fatty acids from adipocytes increases production of ketone bodies (acetoacetate, hydroxybutyrate, and acetone) by the mitochondria of the liver at a rate that exceeds peripheral use. Accumulation of ketone bodies causes a drop in pH and triggers the buffering system associated with metabolic acidosis. Diabetic ketoacidosis (DKA), caused by increased levels of circulating ketones in the absence of the antilipolytic effect of insulin, may occur (p. 744).

EVALUATION AND TREATMENT. The criteria for diagnosis of type 1 diabetes are the same as those for type 2 diabetes (see Box 22-1). The diagnosis of diabetes is not difficult when the symptoms of polydipsia, polyuria, polyphagia, weight loss, and hyperglycemia are present in fasting and postprandial states. C-peptide, a component of proinsulin released during insulin production, can be measured in the serum as a surrogate for insulin levels and is indicative of residual beta-cell mass and function. Other important aspects of evaluation include assessing for evidence of the chronic complications of type 1 diabetes, including renal, nervous system, cardiac, peripheral vascular, retinal, and bony tissue damage.

Nearly half of children aged 4 years and younger and nearly one fourth of those between the ages of 5 and 15 with type 1 diabetes are first diagnosed when they present with the signs and symptoms of DKA.[106] In DKA, acetone (a volatile form of ketones) is exhaled by hyperventilation and gives the breath a sweet or "fruity" odor. Occasionally, diabetic coma is the initial symptom of the disease.

Many different kinds of approaches are being tested to prevent the autoimmune destruction of beta cells that is characteristic of type 1 diabetes. Avoidance of cow's milk, utilization of a gluten-free diet, and increased intake of omega-3 fatty acids and vitamin D are all being explored.[107] Pharmacologic prevention trials include immunosuppression with antirejection drugs (e.g., mycophenolate mofetil, rituximab, monoclonal antibodies to CD3, and cyclosporine), immunomodulation therapies, and oral or intranasal insulin[108] (see What's New? Immunomodulation in the Prevention and Treatment of Type 1 Diabetes).

Treatment regimens are designed to achieve optimal glucose control (as measured by the HbA_{1c} value) without causing episodes of significant hypoglycemia. Successful management

BOX 22-2 CRITERIA FOR THE DIAGNOSIS OF METABOLIC SYNDROME

Three of the following five traits:

- Increased waist circumference (>40 inches in men; >35 inches in women)
- Plasma triglycerides ≥150 mg/dl
- Plasma high-density lipoprotein (HDL) cholesterol <40 mg/dl (men) or <50 mg/dl (women)
- Blood pressure ≥130/85 mmHg
- Fasting plasma glucose ≥100 mg/dl

Data from Grundy SM et al: *Circulation* 109:433–438, 2004.

requires individual planning according to type of disease, age, and activity level. All individuals with type 1 diabetes require some combination of insulin supplementation, meal planning, exercise program, and self-monitoring of blood glucose level. Several different types of insulin preparations are available, as well as new technologies for more physiologic insulin delivery systems, such as modern insulin pumps.[109] The use of pramlintide, a synthetic analog of amylin, can replace this hormone in individuals with type 1 and type 2 diabetes.[110] Blood glucose monitoring is an essential part of management and there are numerous types of monitoring devices for both self and "real-time" blood glucose monitoring.[111] Individuals also should be screened at least yearly for complications of diabetes. Finally, islet cell and whole pancreas transplantation has been successful in selected individuals.

Type 2 Diabetes Mellitus

Type 2 diabetes mellitus is much more common than type 1 and has been rising in incidence since 1940. In the United States, type 2 diabetes affects 10.5% of those aged 45 to 64 years and 18.4% of those aged 65 to 74 years, and has doubled in all adult age groups in the past two decades.[112] Prevalence varies by ethnic group and gender and is highest in African American women with an overall prevalence of 34% in those aged 65 to 74. There also is a greatly increased prevalence of type 2 diabetes in children, especially in Native American and obese children (see Table 22-6).

An environmental-genetic interaction appears to be responsible for type 2 diabetes.[113] The most well-recognized risk factors are age, obesity, hypertension, physical inactivity, and family history. The *metabolic syndrome* is a constellation of disorders (central obesity, dyslipidemia, prehypertension, and an elevated fasting blood glucose level) that together confer a high risk of developing type 2 diabetes and associated cardiovascular complications (Box 22-2). The metabolic syndrome develops during childhood and is highly prevalent among overweight children and adolescents and affects approximately 55 million Americans. These individuals should be screened on a regular basis for diabetes mellitus. Early recognition and treatment, including vigorous lifestyle changes, are critical to reducing cardiovascular events and improving clinical outcomes.[114] Polycystic ovary syndrome (PCOS) also is associated with insulin resistance and risk of diabetes seven times the average risk for women without PCOS.[115]

PATHOPHYSIOLOGY. Many organs contribute to the insulin resistance and chronic hyperglycemia associated with type 2 diabetes mellitus (Figure 22-14). Additionally, genes have been identified that are associated with type 2 diabetes, including those that code for beta-cell mass, beta-cell function (ability to sense blood glucose levels, insulin synthesis, and insulin secretion), proinsulin and insulin molecular structure, insulin receptors, hepatic synthesis of glucose, glucagon synthesis, and cellular responsiveness to insulin stimulation. Genetic abnormalities also are the result of epigenetic changes that occur in response to environmental influences that span generations.[116,117] The combination of genetic, epigenetic, and environmental influences results in the basic pathophysiologic mechanisms of type 2 diabetes: insulin resistance and decreased insulin secretion by beta cells (Figure 22-15). All of these mechanisms are essential to the development of type 2 diabetes. Although many individuals with risk factors for type 2 diabetes (including obesity, metabolic syndrome, and hypertension) are insulin resistant, only those individuals who are genetically predisposed to beta-cell dysfunction (and therefore a relative deficiency in insulin) will develop type 2 diabetes.[118]

Insulin resistance is defined as a suboptimal response of insulin-sensitive tissues (especially liver, muscle, and adipose tissue) to insulin. Several mechanisms are involved in abnormalities of the insulin signaling pathway and contribute to insulin resistance. These include an abnormality of the insulin molecule, high amounts of insulin antagonists, down-regulation of the insulin receptor, decreased or abnormal activation of post-receptor kinases, and alteration of glucose transporter (GLUT) proteins. Obesity is present in 60% to 80% of those with type 2 diabetes and is a major contributor to insulin resistance through several important mechanisms:

1. Adipokines are hormones produced in adipose tissue. A nuclear receptor, called peroxisome proliferator–activated receptor gamma (PPARγ), is highly expressed in adipose cells and is responsible for modulating changes in adipokines in obese individuals, including increased serum levels of leptin (leptin resistance) and resistin and decreased levels of adiponectin. Changes in adipokines have effects not only on tissues but also on hypothalamic and pancreatic function.[119,120] A group of insulin-sensitizing drugs, called the thiazolidinediones that modulate PPARγ activity, have been used in the treatment of type 2 diabetes for many years.
2. Elevated levels of serum free fatty acids (FFAs) and intracellular deposits of triglycerides and cholesterol are found in obese individuals who have what has been termed "metabolic overload" (high caloric and lipid intake). FFAs bind to G-protein–coupled receptors, which modulate several responses. These changes interfere with intracellular insulin signaling, decrease tissue responses to insulin, cause alterations in insulin incretin and glucagon secretion, and promote inflammation.[121]
3. Obesity causes release of inflammatory cytokines (TNF-α, IL-6) from intra-abdominal adipocytes or adipocyte-associated mononuclear cells and from activated macrophages in other tissues. These cytokines

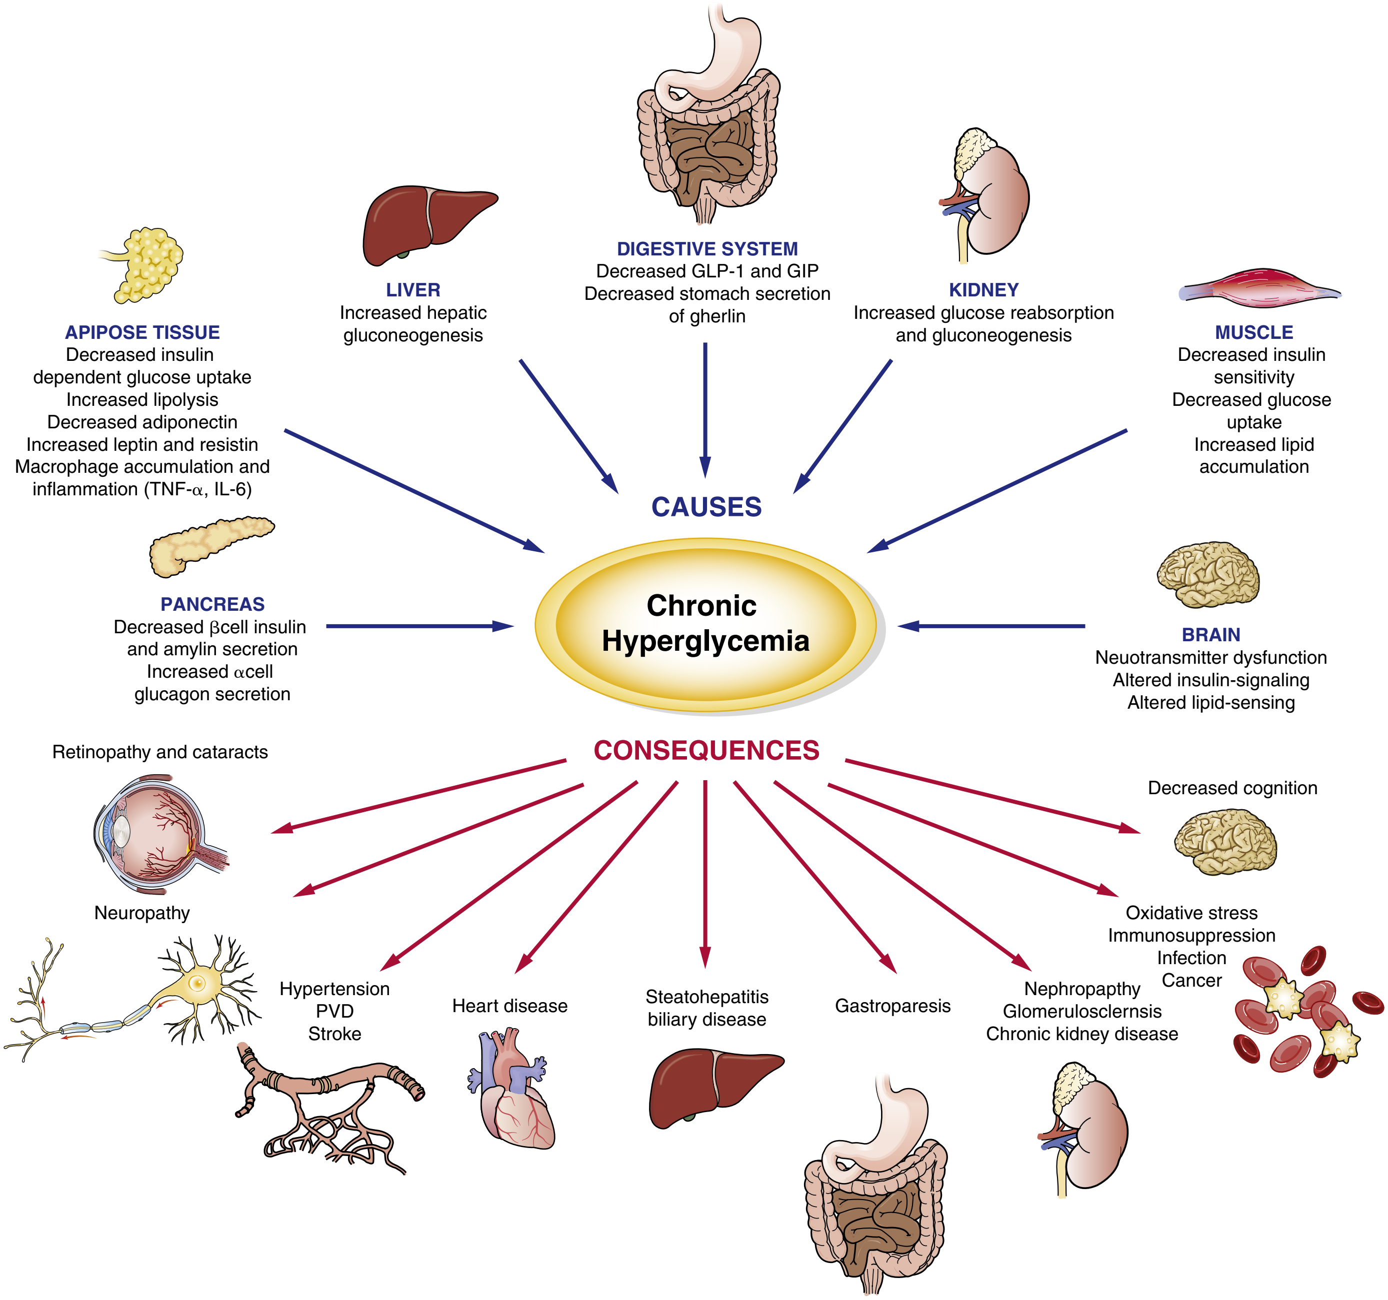

FIGURE 22-14 Multiorgan Causes and Common Consequences of Chronic Hyperglycemia in Type 2 Diabetes Mellitus. *IL,* Interleukin; *PVD,* Peripheral vascular disease; *TNF,* Tumor necrosis factor.

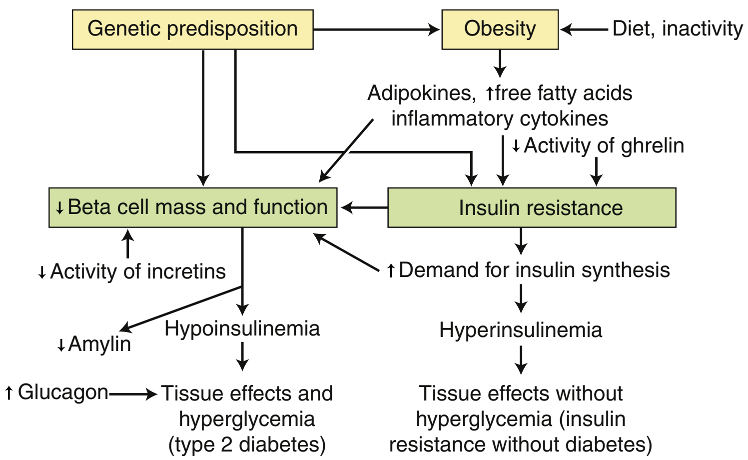

FIGURE 22-15 Pathophysiology of Type 2 Diabetes Mellitus.

induce insulin resistance through a postreceptor mechanism and play an important role in the genesis of fatty liver, atherosclerosis and dyslipidemia.[122,123]

4. Alterations in oxidative phosphorylation in cellular mitochondria have been documented, resulting in reduced insulin-stimulated mitochondrial activity and insulin resistance, especially in skeletal muscle and hepatocytes.[124,125]
5. Obesity is correlated with hyperinsulinemia and decreased insulin receptor density.

In most individuals with type 2 diabetes, compensatory hyperinsulinemia prevents the clinical appearance of diabetes for many years. Eventually, however, islet cell dysfunction develops and leads to a relative deficiency of insulin activity. **Beta-cell dysfunction** is caused, in part, by a decrease in beta-cell mass. A progressive decrease in the weight and number of beta cells occurs in type 2 diabetes, and several different mechanisms have been implicated. Beta cells are extremely sensitive to high levels of glucose and free fatty acids and, under these so-called glucolipotoxic conditions, beta-cell endoplasmic reticulum function is interrupted and beta cells undergo apoptotic cell death.[126] Beta-cell dysfunction also is caused by inflammation and changes in adipokines. A variety of inflammatory cytokines, including TNF-α, IL-1β, and IL6, also have been shown to be toxic to beta cells, and autoimmune beta-cell destruction has been described in type 2 diabetes.[127] The adipokine leptin decreases insulin synthesis in the beta cell. Thus many of the obesity-related causes of insulin resistance (elevated free fatty acid [FFA] hyperglycemia, adipokines, and inflammatory cytokines) also promote programmed cell death in beta cells.

Glucagon is a hormone produced by the alpha cells of the pancreas and acts primarily in the liver to increase blood glucose level by stimulating glycogenolysis and gluconeogenesis. Glucagon acts as an antagonist to insulin. In healthy individuals, high glucose levels cause glucagon release to be inhibited. As in type 1 diabetes, pancreatic alpha cells in type 2 diabetes are less responsive to glucose inhibition, resulting in increased glucagon secretion. These abnormally high levels of glucagon have long been known to play a role in the increased hepatic production of glucose and resultant hyperglycemia seen in type 2 diabetes.[103,128]

Amylin (islet amyloid polypeptide) is another beta-cell hormone that is decreased in both type 1 and type 2 diabetes. Amylin increases satiety and suppresses glucagon release from the alpha cells. It also contributes to islet cell destruction through the deposition of abnormal (misfolded) amyloid polypeptide in the pancreas.[129,130] Pramlintide, a synthetic analog of amylin, is used for treatment in both type 1 and type 2 diabetes.[104,131]

The **incretins, glucagon-like peptide-1 (GLP-1)** and **glucose-dependent insulinotropic polypeptide (GIP),** are a class of peptides released from the gastrointestinal tract in response to food intake. They increase the sensitivity of beta cells to circulating glucose levels, thus improving insulin responsiveness to meals. They are then inactivated by the enzyme **dipeptidyl peptidase IV (DPP-IV)**. These peptides are important in maintaining glycemic control, and currently two GLP-1 agonists and four DPP-IV inhibitors are approved for use in the United States[131,132] (see What's New? Incretin-Based Therapies for Diabetes Mellitus).

Ghrelin is a peptide produced in the stomach and pancreatic islets. Hyperinsulinemia and hyperleptinemia are associated with decreased levels of ghrelin in type 2 diabetes.[133] Decreased levels of circulating ghrelin have been associated with alterations in insulin secretion, insulin resistance, and obesity. Its use as a potential treatment for type 2 diabetes is being investigated.[134,135]

CLINICAL MANIFESTATIONS. Clinical manifestations of type 2 diabetes are nonspecific. The affected individual often is overweight, dyslipidemic, hyperinsulinemic, and hypertensive. Classic symptoms of polyuria and polydipsia may present, but more often individuals will complain of nonspecific symptoms such as fatigue, pruritus, recurrent infections, visual changes, or symptoms of neuropathy (paresthesias or weakness). In those whose diabetes has progressed without treatment, symptoms related to coronary artery, peripheral artery, and cerebrovascular disease may develop (Table 22-8).

EVALUATION AND TREATMENT. The diagnostic criteria for type 2 diabetes are the same as those for type 1 (see Box 22-1). Prevention of type 2 diabetes hinges on diet and exercise to reduce weight. Pharmacologic therapy may be considered for those at highest risk for diabetes, especially if HbA_{1c} levels continue to rise despite lifestyle modifications. Annual monitoring for diabetes is indicated in those with prediabetes.[136]

WHAT'S NEW?

Incretin-Based Therapies for Diabetes Mellitus

The incretin hormone system is being explored as a possible therapeutic target in diabetes. Incretin hormones are secreted by enteroendocrine cells of the large and small intestines. The major component of this system, glucagon-like peptide-1 (GLP-1), has many positive effects on glucose metabolism. GLP-1 augments glucose-dependent insulin secretion without causing hypoglycemia, stimulates insulin gene expression, inhibits glucagon secretion, delays gastric emptying, and induces a feeling of satiety through an effect on the central nervous system. GLP-1 also has been shown to induce new beta-cell differentiation (neogenesis) from pancreatic ductal cells and to protect beta cells from apoptosis (programmed cell death). There are two classes of incretin-related therapies: GLP-1 receptor agonists (GLP-1 RAs) and dipeptidyl peptidase IV (DPP-IV) inhibitors. Two incretin GLP-1 RAs (exenatide and liraglutide) are approved for use in the United States and three are in development. They lower postprandial plasma glucose level with little risk of hypoglycemia, assist individuals with weight loss, and augment endogenous insulin secretion. A recent study documented that nearly two thirds of persons treated with GLP-1 RAs alone achieved target HbA_{1c} levels after 12 weeks of therapy. The available DPP-IV inhibitors (sitagliptin, saxagliptin, vildagliptin, and linagliptin) also improve metabolic control but to a lesser degree than the GLP-1 RAs; however, they have been shown to improve levels of serum lipids. Both classes are well tolerated: GLP-1 RAs are associated with nausea and DPP-IV inhibitors are associated with headaches and certain infections. Pancreatitis has been reported in both but appears to be a rare complication.

Data from Blonde L, Montanya E: *Diabetes Obes Metab* 14(Suppl 2):20–32, 2012; Esposito K et al: *Diabetes Obes Metab* 14(3):228–233, 2012; Israili ZH: *Am J Ther* 18(2):117–152, 2011; Karagiannis T et al: *BMJ* 344:e1369, 2012; Monami M et al: *Adv Therapy* 29(1):14–25, 2012; Scheen AJ: *Exp Opin Pharmacol* 13(1):81–99, 2012.

TABLE 22-8 CLINICAL MANIFESTATIONS AND RATIONALE FOR TYPE 2 DIABETES MELLITUS

MANIFESTATION	RATIONALE
Recurrent infections (e.g., boils and carbuncles; skin infections) and prolonged wound healing	Growth of microorganisms is stimulated by increased glucose levels; impaired blood supply hinders healing
Genital pruritus	Hyperglycemia and glycosuria favor fungal growth; candidal infections, resulting in pruritus, are a common presenting symptom in women
Visual changes	Blurred vision occurs as water balance in the eye fluctuates because of elevated blood glucose levels; diabetic retinopathy is another cause of visual loss
Paresthesias	Paresthesias are common manifestations of diabetic neuropathies
Fatigue	Metabolic changes result in poor use of food products, contributing to lethargy and fatigue

WHAT'S NEW?

Bariatric Surgery in the Treatment of Diabetes

The American Diabetes Association has endorsed bariatric surgery for the treatment of type 2 diabetes in individuals with body mass indexes (BMIs) ≥35 kg/m^2. Gastric bypass surgery is now the procedure of choice, although gastric banding procedures also have beneficial results. There is current powerful evidence that bariatric surgery improves glycemic control in up to 80% of individuals with type 2 diabetes, even before there is any significant weight loss. The proposed mechanisms for these effects continue to be researched. Current hypotheses relate to changes in neuroendocrine control involving the hypothalamus, pancreas, liver, and gut. Hormones that have been implicated include changes in the concentrations of ghrelin, leptin, and the incretins. Long-term studies are now confirming the safety and efficacy of bariatric surgery in achieving persistent glycemic control and reduced risk for diabetes-associated cardiovascular complications. Further study is needed to determine the mechanisms by which bariatric surgery has such profound effects on type 2 diabetes, and whether similar outcomes might be achieved with less-invasive techniques.

Data from Dixon JB et al: *Obes Rev* 13(1):57–67, 2012; Ismail-Beigi F: *N Engl J Med* 366(14):1319–1327, 2012; Li Q et al: *Diabetes Obes Metab* 14(3):262–270, 2012; McKenney RL, Short DK: *Surg Clin North Am* 91(6):1139–1148, vii, 2011; Noria SF, Grantcharov T: *Can J Surg* 56(1):47–57, 2013; Park CW, Torquati A: *Surg Clin North Am* 91(6):1149–1161, vii, 2011; Sala PC et al: *Obes Surg* 22(1): 167–176, 2012.

The first step in management is to establish an appropriate glycemic goal. Although treatment regimens that reduce HbA_{1c} to around 7% have been shown to reduce long-term complications, intensive lowering of glucose concentration to near-normal levels through the use of multiple agents is not correlated with better outcomes and is associated with a greater risk for hypoglycemic episodes and weight gain.[136-140]

Dietary measures, including restriction of the total caloric intake, are of primary importance in both the prevention and the treatment of type 2 diabetes.[136] As the obese individual loses weight, the body's resistance to insulin often diminishes. Nonobese individuals with type 2 diabetes should consume calories consistent with their ideal weight and pattern of activity. The emphasis of medical nutrition therapy (MNT) in type 2 diabetes mellitus should be focused on achieving glucose, lipid, and blood pressure goals.[141]

Exercise is an important aspect of prevention and treatment of type 2 diabetes.[136] Exercise reduces postprandial blood glucose levels, diminishes insulin requirements, lowers triglyceride and cholesterol levels, and increases the level of high-density lipoprotein (HDL) cholesterol. In addition, exercise is a valuable adjunct to weight loss for the overweight individual. Hypoglycemia may result, however, when the exercising individual receives sulfonylurea or insulin therapy.

In those individuals with morbid obesity unresponsive to diet and exercise interventions, bariatric surgery may be indicated. Studies suggest that gastric bypass surgery is associated with marked improvements in glycemic control in those with established diabetes[138] (see What's New? Bariatric Surgery in the Treatment of Diabetes).

For most individuals with type 2 diabetes, medications are needed for optimal management. Although many older individuals continue to use insulin injections, oral hypoglycemic agents are the treatment of choice for most people.[142] There are currently nine classes of oral agents available[139] (Table 22-9). Insulin therapy may be needed in the later stages of type 2 diabetes because of loss of beta-cell function; however, the risks of treatment-related hypoglycemia must be considered.[143]

Other Specific Types of Diabetes Mellitus and Gestational Diabetes Mellitus

As described in Table 22-5 (p. 734), the American Diabetes Association (ADA) classification of diabetes mellitus encompasses not only the most common forms of diabetes (type 1 and type 2) but also "other specific types of diabetes mellitus" and "gestational diabetes mellitus." Other specific types of diabetes include genetic defects in beta-cell function, genetic defects in insulin action, diseases of the exocrine pancreas, endocrinopathies, drug- or chemical-induced beta-cell dysfunction, infections, and other uncommon autoimmune and inherited disorders that are associated with diabetes.

The most well described of these other specific types of diabetes is termed **maturity-onset diabetes of youth (MODY).** MODY accounts for 1% to 2% of diabetes and should be considered in children who lack beta-cell antibodies. It also may account for up to 5% of individuals diagnosed with gestational diabetes.[144] MODY includes six specific autosomal dominant mutations including genes for hepatocyte nuclear factor-1α (HNF-1α; MODY 3), glucokinase (MODY 2), HNF-4α (MODY 1), insulin promoter factor-1 (IPF-1; MODY 4), HNF-1β (MODY 5), and NeuroD1 (MODY 6).[145] Interestingly, the gene mutations found in MODY are not commonly found in type 2 diabetes. The clinical diagnosis of MODY is based on the following criteria: family history of diabetes with an autosomal

TABLE 22-9 TYPES OF ORAL HYPOGLYCEMIC DRUGS

DRUG TYPE	MECHANISMS OF METABOLIC CONTROL
α-Glycosidase inhibitor (miglitol and voglibose)	Delays carbohydrate absorption in gut by inhibiting disaccharidases
Biguanide (metformin)	Decreases hepatic glucose production and increases insulin sensitivity and peripheral glucose uptake
Meglitinides (glinides) (repaglinide and nateglinide)	Stimulate insulin release from pancreatic beta cells
Sulfonylureas (glyburide, glipizide, gliclazide, glimepiride)	Stimulate insulin release from pancreatic beta cells
Peroxisome proliferator-activated-receptor-gamma agonists (thiazolidinediones, pioglitazone, and rosiglitazone)	Increase insulin sensitivity, particularly in adipose tissue
Bile acid sequestrant (colesevelam)	Unknown; theories include decreased hepatic glucose production, increased insulin secretion, and increased incretin release
GLP-1 receptor agonists (exenatide and liraglutide)	Increase insulin secretion, decrease glucagon secretion, decrease rate of gastric emptying, decrease appetite, weight loss
DPP-IV inhibitors (sitagliptin, saxagliptin, vildagliptin, and linagliptin)	Increase insulin secretion, decrease glucagon secretion, decrease rate of gastric emptying, decrease appetite
Amylin mimetics (pramlintide)	Decrease glucagon secretion, decrease rate of gastric emptying, and decrease appetite
SGLT2 inhibitor (sodium-glucose co-transporter 2) In clinical trials: canagliflozin, dapagliflozin, empagliflozin	Inhibits proximal tubular renal transport of glucose, decreasing glucose reabsorption and increasing renal excretion of glucose independent of insulin

Data from Ismail-Beigi F: *N Engl J Med* 366(14):1319–1327, 2012; Misra M: *J Pharm Pharmacol*, published online August 9, 2012.

dominant mode of inheritance, insulin independence (nonketotic diabetes mellitus), and age at onset younger than 25 years. Genetic testing confirms the diagnosis. It is important to identify those with MODY because many can be effectively treated with an oral hypoglycemic agent (sulfonylureas) rather than with injections of insulin.[145,146]

Gestational diabetes mellitus (GDM) has long been defined as any degree of glucose intolerance with onset or first recognition during pregnancy. However, the recent dramatic increase in type 2 diabetes prevalence has led to the recommendation that high-risk women found to have diabetes at their initial prenatal visit receive a diagnosis of overt diabetes.[88] GDM complicates approximately 7% of all pregnancies. The exact mechanism of GDM is unknown, but insulin resistance and inadequate insulin secretion are contributing factors. The American Diabetes Association recommends that pregnant women with risk factors be screened for type 2 diabetes at their first prenatal visit. Those without a history of DM also should be screened with an oral glucose tolerance test at 24 to 28 weeks' gestation. Women with GDM should be monitored after delivery.[136] Often there are no symptoms and careful glucose level control prenatally, during pregnancy, and after delivery is essential to both the short-term and the long-term health of mother and baby.[147] There is an increased risk for type 2 diabetes and associated complications later in life in women who develop gestational diabetes.[148]

Acute Complications of Diabetes Mellitus

Hypoglycemia

Hypoglycemia is a lowered plasma glucose level. In general, hypoglycemia occurs when blood glucose levels are less than 35 mg/dl in newborns for the first 48 hours of life and less than 45 to 60 mg/dl in children and adults. Its causes may be exogenous (medications, alcohol, or exercise), endogenous (tumors of the pancreas or inherited disorders), or functional (hyperalimentation, spontaneous, or liver disease). Hypoglycemia in diabetes is sometimes called *insulin shock* or *insulin reaction.* Individuals with type 2 diabetes are at less risk for hypoglycemia than those with type 1 diabetes because they retain relatively intact glucose counterregulatory mechanisms. However, hypoglycemia does occur in type 2 diabetes when treatment involves insulin secretogogues (e.g., sulfonylureas) or exogenous insulin (Table 22-10).

Symptoms of hypoglycemia result either from activation of the sympathetic nervous system (neurogenic adrenergic symptoms) or from an abrupt cessation of glucose delivery to the brain (neuroglycopenic symptoms), or both.[149,150]

Neurogenic reactions occur when the decrease in blood glucose level is rapid and present with tachycardia, palpitations, diaphoresis, tremors, pallor, and arousal anxiety. Neuroglycopenia causes further symptoms including headache, dizziness, irritability, fatigue, poor judgment, confusion, visual changes, hunger, seizures, and coma. Hypoglycemia unawareness is a phenomenon that occurs in individuals without appropriate autonomic warning symptoms. Autonomic symptoms are blunted, symptoms are reduced, and recovery from hypoglycemia may be delayed because of impaired glycogenolysis and hampered delivery of gluconeogenic substrates to the liver.

The American Diabetes Association recommends that glucose (15 to 20 g) be given to the conscious individual with hypoglycemia. Doses of glucagon should be prescribed for emergency use for all individuals at significant risk of severe hypoglycemia, and caregivers should be instructed in their use. Individuals with hypoglycemia unawareness or who have had episodes of severe hypoglycemia should raise their glycemic treatment targets to reduce risk of future episodes.[136]

TABLE 22-10 **COMMON ACUTE COMPLICATIONS OF DIABETES MELLITUS (DM)**

HYPOGLYCEMIA IN PERSONS WITH DM	DIABETIC KETOACIDOSIS	HYPERGLYCEMIC NONKETOTIC SYNDROMES
Synonyms		
Insulin shock, insulin reaction	Diabetic coma syndrome	Hyperosmolar hyperglycemia nonketotic coma
Persons at Risk		
Individuals taking insulin Individuals with rapidly fluctuating blood glucose levels Individuals with type 2 diabetes taking sulfonylurea agents	Individuals with type 1 diabetes Individuals with nondiagnosed diabetes	Older adults or very young individuals with type 2 diabetes, nondiabetic individuals with predisposing factors, such as pancreatitis; individuals with undiagnosed diabetes
Predisposing Factors		
Excessive insulin or sulfonylurea agent intake, lack of sufficient food intake, excessive physical exercise, abrupt decline in insulin needs (e.g., renal failure, immediately postpartum), simultaneous use of insulin-potentiating agents or beta-blocking agents that mask symptoms	Stressful situation such as infection, accident, trauma, emotional stress; omission of insulin; medications that antagonize insulin	Infection, medications that antagonize insulin, comorbid condition
Typical Onset		
Rapid	Slow	Slowest
Presenting Symptoms		
Adrenergic reaction: pallor, sweating, tachycardia, palpitations, hunger, restlessness, anxiety, tremors Neurogenic reaction: fatigue, irritability, headache, loss of concentration, visual disturbances, dizziness, hunger, confusion, transient sensory or motor defects, convulsions, coma, death	Malaise, dry mouth, headache, polyuria, polydipsia, weight loss, nausea, vomiting, pruritus, abdominal pain, lethargy, shortness of breath, Kussmaul respirations, fruity or acetone odor to breath	Polyuria, polydipsia, hypovolemia, dehydration (parched lips, poor skin turgor), hypotension, tachycardia, hypoperfusion, weight loss, weakness, nausea, vomiting, abdominal pain, hypothermia, stupor, coma, seizures
Laboratory Analysis		
Serum glucose <30 mg/dl in newborn (first 2-3 days) and <55-60 mg/dl in adults	Glucose levels >250 mg/dl, reduction in bicarbonate concentration; increased anion gap; increased plasma levels of β-hydroxybutyrate, acetoacetate, and acetone	Glucose levels >600 mg/dl, lack of ketosis, serum osmolarity >320 mOsm/L, elevated blood urea nitrogen and creatinine

Diabetic Ketoacidosis

Ketoacidosis, a serious complication of diabetes mellitus, is a common cause for hospital admissions. **Diabetic ketoacidosis (DKA)** develops when there is an absolute or relative deficiency of insulin and an increase in the levels of insulin counterregulatory hormones.[151] This is most common in individuals with type 1 diabetes but can occur in those with type 2 diabetes as well. In addition, a syndrome called *ketosis-prone diabetes (KPD)* has been described and occurs most frequently in obese, middle-aged men with a strong family history of type 2 diabetes. These individuals do not fit the criteria for diagnosis of type 1 or type 2 diabetes but exhibit significantly impaired insulin secretion spontaneously or in response to physiologic stress such as infection.[152] The most common precipitating factor for DKA is intercurrent illness, such as infection, trauma, surgery, or myocardial infarction. Interruption of insulin administration also may result in DKA. Factors associated with increased risk are younger or older age, diagnostic error, ethnic minority, lack of health insurance in the United States, lower body mass index, preceding infection, and delayed treatment.[153]

PATHOPHYSIOLOGY. In a state of relative insulin deficiency there is an increase in the concentrations of insulin counterregulatory hormones including catecholamines, cortisol, glucagon, and GH. These counterregulatory hormones antagonize insulin by increasing glucose production and decreasing tissue use of glucose. Profound insulin deficiency results in decreased glucose uptake, increased fat mobilization with release of fatty acids, and accelerated gluconeogenesis and ketogenesis (Figure 22-16).[151] Relatively increased glucagon levels also contribute to activation of the gluconeogenic (glucose-forming) and ketogenic (ketone-forming) pathways in the liver. Because of the insulin deficiency, hepatic overproduction of β-hydroxybutyrate and acetoacetic acids causes increased ketone concentrations. Ordinarily ketones are used by tissues as an energy source to regenerate bicarbonate. This balances the loss of bicarbonate, which occurs when the ketone is formed. Hyperketonemia (increased blood ketone levels) may be a result of impairment in the use of ketones by peripheral tissue, which permits strong organic acids to circulate freely. Bicarbonate buffering then does not occur, and the individual develops a metabolic acidosis.

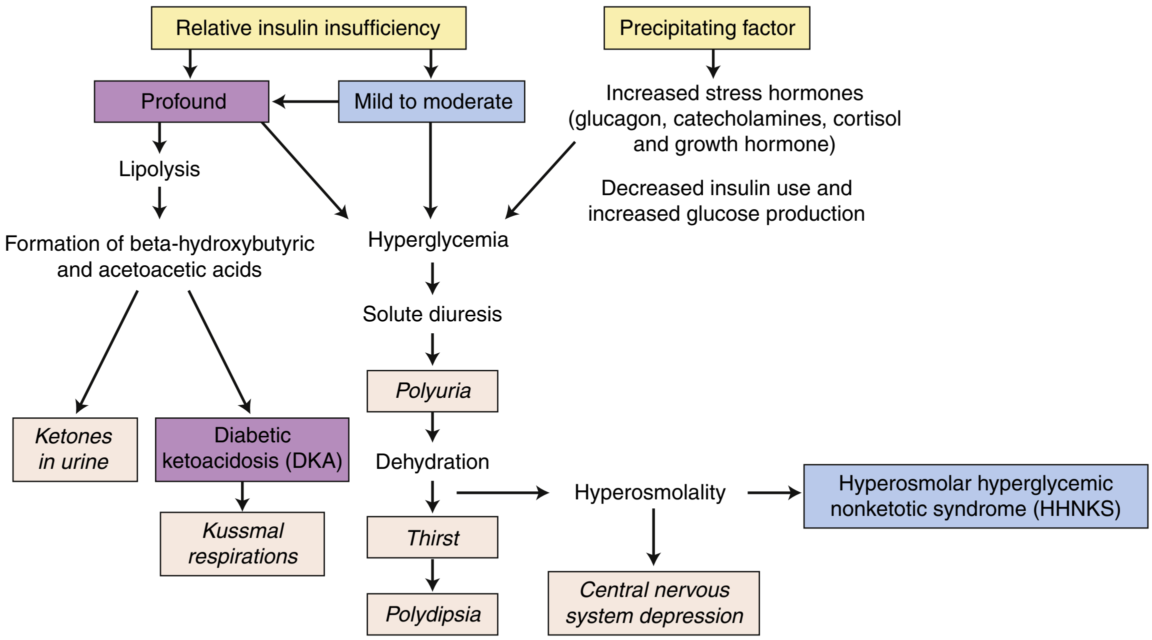

FIGURE 22-16 Pathophysiology of DKA and HHNKS in Diabetes Mellitus.

CLINICAL MANIFESTATIONS. The signs and symptoms of DKA are nonspecific. Polyuria and dehydration result from the osmotic diuresis associated with hyperglycemia. In this case, the plasma glucose level is higher than the individual's renal threshold, allowing significant amounts of glucose to be lost in the urine. Deficits of sodium, phosphorus, and magnesium are common. The most important electrolyte disturbance, however, is a marked deficiency in the level of total body potassium. Although the serum potassium concentration may appear normal or elevated because of volume contraction and a shift of potassium out of the cell and into the blood caused by metabolic acidosis, the total body deficiency of potassium may reach 3 to 5 mEq/kg. Symptoms of diabetic ketoacidosis include Kussmaul respirations (hyperventilation in an attempt to compensate for the acidosis), postural dizziness, central nervous system depression, ketonuria, anorexia, nausea, abdominal pain, thirst, and polyuria (see Table 22-10).

EVALUATION AND TREATMENT. The diagnosis of ketoacidosis is suggested when individuals have symptoms of vomiting, abdominal pain, dehydration, an acetone odor on the breath, and change in sensorium. The American Diabetes Association criteria for the diagnosis of DKA are: (1) a serum glucose level >250 mg/dl, (2) a serum bicarbonate level <18 mg/dl, (3) a serum pH <7.30, (4) the presence of an anion gap, and (5) the presence of urine and serum ketones.[154]

Treatment of DKA involves administration of insulin to decrease glucose levels. Fluids are administered to replace lost fluid volume. Electrolyte deficits become apparent as fluid volume is replaced, and intravenous sodium, potassium, and phosphorus are administered as needed. Fluids and electrolytes should be monitored closely.[155] After the administration of insulin, the concentration of β-hydroxybutyrate promptly begins to decrease, and after a slight increase, acetoacetate concentration also begins to decrease. A persistent ketonuria may be observed for several days after treatment. Continuous monitoring of the individual is essential to ensure an uncomplicated recovery from DKA. Health teaching emphasizes predisposing factors and strategies for avoiding DKA.

Hyperosmolar Hyperglycemic Nonketotic Syndrome

Hyperosmolar hyperglycemic nonketotic syndrome (HHNKS), or **hyperglycemic hyperosmolar state (HHS),** is a life-threatening emergency most often precipitated by infections, medications, nonadherence to diabetes treatment, or coexisting disease.[151] HHNKS is more commonly seen with type 2 diabetes. It can also occur in individuals with pancreatic destruction from other causes such as chronic pancreatitis.

PATHOPHYSIOLOGY. HHNKS differs from DKA in the degree of insulin deficiency (which is more profound in DKA) and the degree of fluid deficiency (which is more marked in HHNKS) (see Figure 22-16). HHNKS is characterized by a lack of ketosis. Because the amount of insulin required to inhibit fat breakdown is less than that needed for effective glucose transport, insulin levels are sufficient to prevent excessive lipolysis but not to use glucose properly.[151] Glucose levels are considerably higher in HHNKS than in DKA because of volume depletion.

CLINICAL MANIFESTATIONS. Glycosuria and polyuria in HHNKS result from the extreme serum glucose level elevation. As much as 19 g of glucose per hour may be lost in diuresis, which also causes severe volume depletion, increased serum osmolarity, intracellular dehydration, and loss of electrolytes including potassium. Neurologic changes, such as stupor, correlate with the degree of hyperosmolarity and are common in HHNKS; thus, this syndrome is sometimes called *hyperosmolar hyperglycemic coma*.

EVALUATION AND TREATMENT. The diagnostic features of HHNKS include a very high serum glucose concentration

(often more than 600 mg/dl), a near-normal serum bicarbonate level and pH, a serum osmolarity that is usually greater than 320 mOsm/L, and either absent or low levels of ketones in the urine and serum.[151] DKA and HHNKS show considerable overlap in symptoms and treatment. Insulin infusion should be combined with fluid repletion over 24 hours.[156] An important distinction, however, is that the dehydration in HHNKS is far more severe than that in DKA. Thus fluid replacement, with both crystalloids and colloids, is more rapid. Potassium deficits may be extreme and require several days of treatment. Phosphorus and sodium also may be needed. HHNKS is a significant risk factor for infection, sepsis, and venous thrombosis.[151] Mortality also is high in HHNKS, and is related to the age of the individual and comorbid conditions including the severity of the precipitating illness (see Table 22-10 for a comparison of the three acute complications described thus far).

Somogyi Effect

The **Somogyi effect** is a unique combination of hypoglycemia followed by rebound hyperglycemia. The rise in blood glucose concentration occurs because counterregulatory hormones (epinephrine, GH, corticosteroids), which are stimulated by hypoglycemia, cause gluconeogenesis. Excessive carbohydrate intake may contribute to the rebound hyperglycemia. The clinical occurrence of Somogyi effect is controversial.

Dawn Phenomenon

The **dawn phenomenon** is an early morning rise in blood glucose concentration with no hypoglycemia during the night. It is related to nocturnal elevations of GH, which decrease metabolism of glucose by muscle and fat. Increased clearance of plasma insulin also may be involved. Altering the time and dose of insulin administration manages the problem.

Chronic Complications of Diabetes Mellitus

A number of serious complications are associated with any type of DM, including microvascular (e.g., retinopathy, nephropathy, and neuropathy) and macrovascular disease (e.g., coronary artery disease, stroke, and peripheral vascular disease), and infection. Most complications are associated with chronic hyperglycemia (see Figure 22-14). Strict control of blood glucose level significantly reduces some complications, particularly microvascular events. Oxidative stress (overproduction of reactive oxygen species) and activation of several complex metabolic pathways have been associated with persistent hyperglycemia and the chronic complications of DM. They include shunting of glucose into the polyol pathway, activation of protein kinase C isoforms, increased formation of advanced glycation end products (AGEs), increased expression of the receptor for AGEs (RAGE), and increased activation of the hexosamine pathway.[157] It has been proposed that hyperglycemia induces mitochondrial overproduction of oxygen free radicals and this is a key pathologic mechanism for the activation of the metabolic pathways associated with the chronic complications of DM.[158,159] Genetic and epigenetic factors contribute to the etiology of diabetic complications.[160,161]

Oxidative Stress

Chronic hyperglycemia, insulin resistance, hyperinsulinemia, and dyslipidemia contribute to the production of reactive oxygen species (ROS) and the detrimental effects of oxidative stress. Increased formation of AGEs, defects in the polyol pathway, and uncoupling of nitric oxide synthase, xanthine oxidase, and nicotinamide adenine dinucleotide phosphate (NADPH) oxidase generate ROS, which damage large and small vessels and contribute to atherogenesis and to micro- and macrovascular disease. Direct cellular injury, as well as the formation of gene products that cause endothelial cellular injury, contributes to these late complications of diabetes mellitus.[157]

Hyperglycemia and the Polyol Pathway

Tissues that do not require insulin for glucose transport, such as the kidney, red blood cells (RBCs), blood vessels, eye lens, and nerves, cannot down-regulate the cellular uptake of glucose. Consequently, intracellular glucose is shunted into an alternate metabolic pathway for glucose metabolism known as the **polyol pathway**. Overactivation of the polyol pathway results in two processes that may contribute to the complications of diabetes. One is the excessive accumulation of sorbitol (a polyol-sugar alcohol) through the action of the enzyme **aldose reductase.** The accumulated sorbitol increases intracellular osmotic pressure and attracts water in tissue. Swelling occurs along with visual changes and predisposition to cataracts in the lens of the eye. Sorbitol interferes with ion pumps in the nerves, damages Schwann cells, and disrupts nerve conduction. RBCs become swollen and stiff and interfere with perfusion. Second, activation of the polyol pathway reduces glutathione, an important antioxidant, contributing to oxidative injury in cells and tissues, particularly blood vessels. Aldose reductase inhibitors are being evaluated for treatment of these complications.[162]

Hyperglycemia and Protein Kinase C

Protein kinase C (PKC) is a family of intracellular signaling proteins that can become inappropriately activated in different tissues by hyperglycemia. Intracellular hyperglycemia increases the second-messenger diacylglycerol (DAG)-PKC pathway, which in turn activates protein kinase C. Various consequences have been observed, including insulin resistance, extracellular matrix and cytokine production, vascular cell proliferation, enhanced contractility, angiogenesis, and increased permeability. These effects may contribute to the microvascular complications of diabetes. Specific PKC inhibitors are under investigation and have shown some promise in stabilizing or preventing retinopathy, nephropathy, and neuropathy.[163]

Hyperglycemia and Glycation

Glycation is a normal non-enzymatic process that involves the *reversible* attachment of glucose to proteins, lipids, and nucleic acids without the action of enzymes. With recurrent or persistent hyperglycemia, glucose becomes *irreversibly* bound to collagen and other proteins in red blood cells (e.g., glycated hemoglobin), blood vessel walls, interstitial tissue, and within cells. The products of this binding are known as **advanced glycation end products (AGEs),** and their receptor (RAGE). They

have a number of properties that may cause tissue injury or pathologic conditions associated with diabetes[164,165]:

1. Cross-linking and trapping of proteins, including albumin, low-density lipoprotein (LDL), immunoglobulin, and complement, with thickening of the basement membrane or increased permeability in small blood vessels and nerves
2. Binding to cell receptors, such as macrophages and glomerular mesangial cells, and inducing release of inflammatory cytokines and growth factors that stimulate cellular proliferation in the glomeruli, smooth muscle of blood vessels, and collagen synthesis with fibrosis
3. Induction of lipid oxidation, oxidative stress, and inflammation
4. Inactivation of nitric oxide with loss of vasodilation and diminished endothelial function
5. Procoagulant changes on endothelial cells with promotion of platelet adhesion and reduced fibrinolysis

Pharmacologic agents that inhibit AGE formation or block their receptor (RAGE) are being evaluated.[166]

Hyperglycemia and the Hexosamine Pathway

Chronic intracellular hyperglycemia causes shunting of excess intracellular glucose into the hexosamine pathway and leads to O-linked glycosylation (an enzymatic process) of several proteins with alteration in signal transduction pathways and oxidative stress. The O-linked attachment of *N*-acetylglucosamine (O-GlcNAc) on serine and threonine residues of nuclear and cytoplasmic proteins is associated with insulin resistance and cardiovascular complications of diabetes mellitus.[167]

Microvascular Disease

Diabetic microvascular complications (disease in capillaries) are a leading cause of blindness, end-stage renal failure, and various neuropathies. Thickening of the capillary basement membrane, endothelial cell hyperplasia, thrombosis, and pericyte degeneration are characteristic of diabetic microangiopathy and emerge over a period of 1 to 2 years. The thickening eventually results in decreased tissue perfusion. Hyperglycemia is a prerequisite for these microvascular changes and may be related to glycation of structural proteins, which results in the accumulation of AGEs. The frequency and severity of the lesions appear to be proportional to the duration of the disease and blood glucose control. In the Diabetes Control and Complications Trial—the Epidemiology of Diabetes Intervention and Complications Study (DCCT-EDIC), the intensively treated cohort continued to have significantly fewer complications (metabolic memory) even though their HbA_{1c} values were essentially equivalent to those of the conventional therapy group.[168,169] Hypoxia and ischemia accompany microangiopathy, particularly in the retina, the kidney, and nerves. Many individuals with type 2 diabetes present with microvascular complications because of the long duration of asymptomatic hyperglycemia that generally precedes diagnosis. This underscores the need for diabetes screening.

Diabetic Retinopathy. The retina is the most metabolically active structure per weight of tissue in the body. Thus the retina is a vulnerable target for microvascular disease in diabetes mellitus. **Diabetic retinopathy** is a leading cause of blindness worldwide and in U.S. adults younger than age 60.[170] In comparison to type 1 diabetes, retinopathy seems to develop more rapidly in individuals with type 2 diabetes because of the likelihood of long-standing hyperglycemia before diagnosis. Most individuals with diabetes will eventually develop retinopathy and they also are more likely to develop cataracts and glaucoma (see Chapter 16). Diabetic retinopathy is associated with increased risk of life-threatening systemic vascular complications, including stroke, coronary heart disease, and heart failure.[171] The prevalence and severity of the retinopathy are strongly related to the age of the individual, the duration of diabetes, and the extent of glycemic control.

Diabetic retinopathy results from relative hypoxemia, damage to retinal blood vessels and vasoconstriction, red blood cell (RBC) and platelet aggregation, influence of vascular endothelial growth factors and growth hormone, and angiogenesis. The following three stages of retinopathy lead to loss of vision: stage I: *nonproliferative*—characterized by thickening of the retinal capillary basement membrane and an increase in retinal capillary permeability, vein dilation, microaneurysm formation, and superficial (flame-shaped) and deep (blot) hemorrhages; stage II: *preproliferative*—progression of retinal ischemia with areas of poor perfusion that culminate in infarcts; and stage III *proliferative*—neovascularization (angiogenesis) and fibrous tissue formation within the retina or optic disc (see Figures 22-17 and 22-18, and Table 22-11 for details). Traction of the new vessels on the vitreous humor may cause retinal detachment or hemorrhage into the vitreous humor. **Maculopathy** is a progressive process that may accompany the increased retinal capillary permeability, vessel occlusion, and ischemia. If formation of exudates, edema, or ischemia occurs near the fovea, serious loss of vision may result. **Macular edema** (fluid accumulation and retinal thickening near the center of the macula) is the leading cause of vision loss among persons with diabetes. Blurring of vision also can be a consequence of hyperglycemia and sorbitol accumulation in the lens. Dehydration of the lens, aqueous humor, and vitreous humor also reduces visual acuity.[172] Cataracts, optic neuropathy, and defects in eye muscle function also are associated with the chronic complications of hyperglycemia and diabetes mellitus.

Laser treatments are used to reduce the rate of vision loss from diabetic macular edema and neovascularization. Vitrectomy is a surgical procedure used to treat an intravitreal hemorrhage secondary to rupture of a neovascular capillary tuft. Intravitreal delivery of steroids, antivascular endothelial growth factor preparations, and renin-angiotensin system (RAS) inhibitors is being evaluated.[173]

Diabetic Nephropathy. Diabetes is the most common cause of end-stage kidney disease in the Western world. Without appropriate management, approximately 30% of individuals with type 1 and 40% of those with type 2 diabetes develop nephropathy.[174] The early phases of nephropathy are asymptomatic and begin to develop after 10 years with type 1 diabetes or after 5 to 8 years with type 2 diabetes. There are some differences in renal lesions in type 1 and type 2 diabetes,

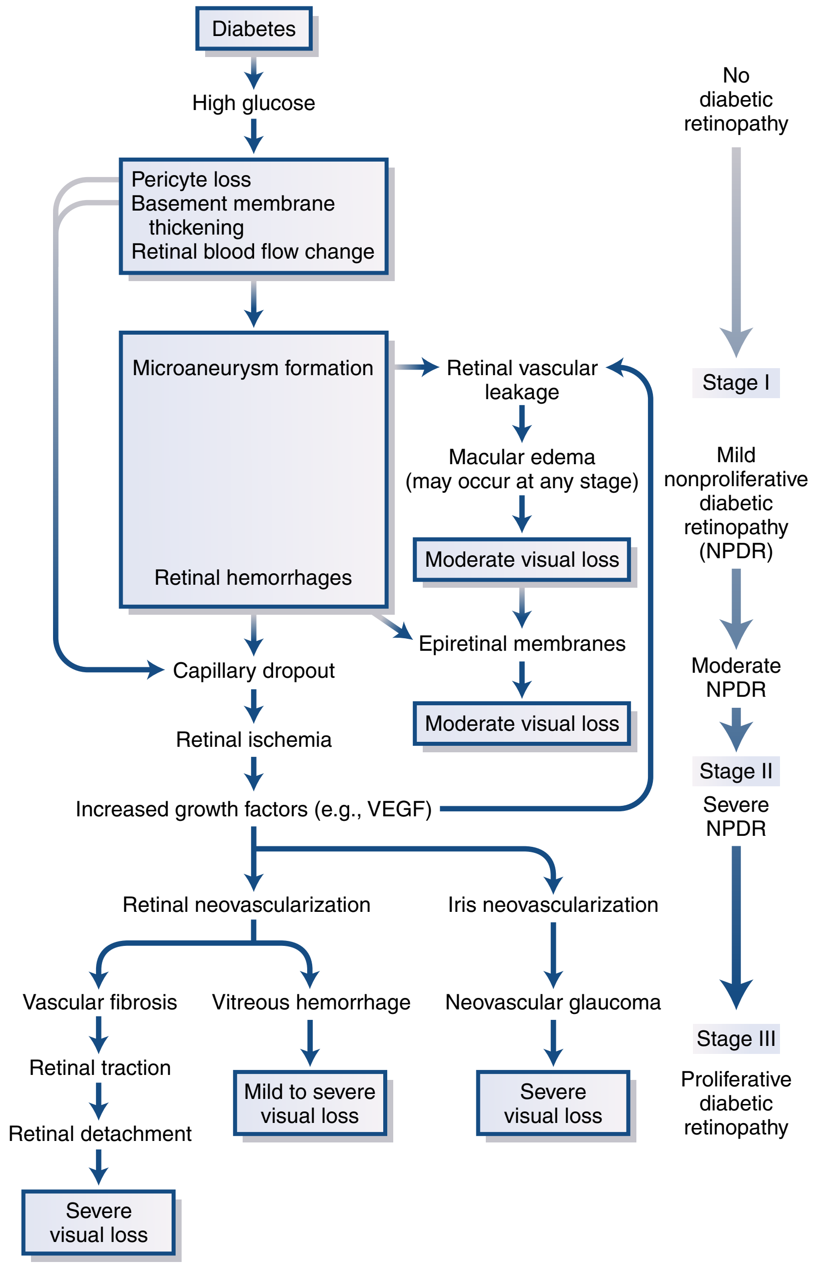

FIGURE 22-17 Pathophysiology of Diabetic Retinopathy. *VEGF,* Vascular endothelial growth factor. (From Mehlmed S et al: *Williams textbook of endocrinology,* ed 12, Philadelphia, 2012, Saunders.)

with glomerular changes and earlier microalbuminuria in type 1 being most prominent; however, hyperglycemia is the major initiating factor in both types.

The exact process responsible for destruction of the kidneys in diabetes is unknown. Multiple mechanisms contribute to nephropathy, including chronic hyperglycemia, systemic hypertension, hyperperfusion, hyperfiltration, increased blood viscosity, increased glomerular pressure, albuminuria, protein kinase C, growth factors, advanced glycation end products, the polyol pathway, inflammatory cytokines, oxidative stress, the renin-angiotensin-aldosterone system, and hypercholesterolemia.[175-178]

The glomeruli are injured by protein denaturation, hyperglycemia with high renal blood flow (hyperfiltration), and intraglomerular hypertension exacerbated by systemic hypertension. Renal glomerular changes can occur early in diabetes mellitus and occasionally may precede the overt manifestations of the disease (Figure 22-19). Progressive changes include glomerular enlargement, glomerular basement membrane thickening with proliferation of mesangial cells, and proliferation of the mesangial matrix. This results in diffuse and nodular glomerulosclerosis (Kimmelstiel-Wilson nodule), loss of podocytes, resistance to glomerular capillary blood flow, and decreased glomerular filtration rates (GFRs). Alterations in glomerular membrane permeability occur with loss of negative charge and albuminuria. Tubular and interstitial fibrosis contributes to loss of function.[179]

Microalbuminuria is usually the first manifestation of kidney dysfunction (30 to 300 mg/day). Continuous untreated proteinuria generally heralds a life expectancy less than 10 years.

Microalbuminuria is an independent risk factor for cardiovascular disease and progressive renal impairment.[180] The determinants of proteinuria in diabetic nephropathy are not completely understood.[181] Glycated albumin generates ROS and directly damages glomerular membrane epithelial cells, vascular smooth muscle, and mesangial cells. Glomerular endothelial dysfunction also promotes albuminuria.[182] As renal failure progresses, extensive vascular and extravascular changes occur.

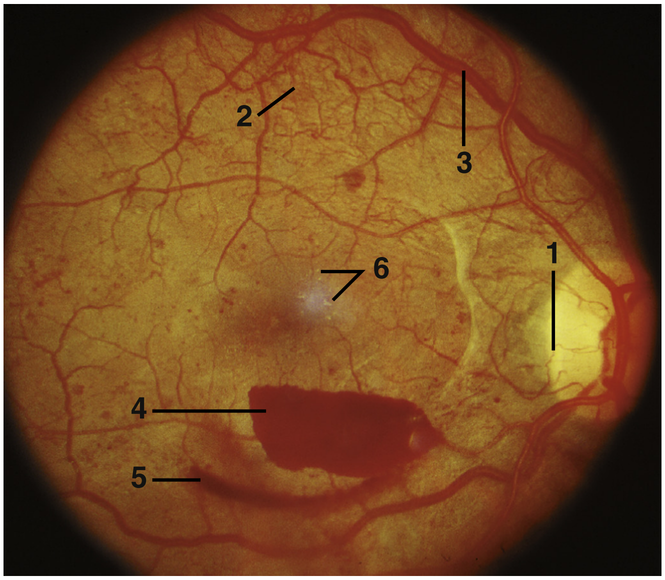

FIGURE 22-18 Proliferative Diabetic Retinopathy. Neovascularization is present at the optic nerve **(1)** and along the vascular arcades **(2).** Retinal veins are engorged **(3),** and a preretinal hemorrhage **(4)** is present inferior to the fovea. This boat-shaped hemorrhage blocks the view of the retinal vessels. A more diffuse hemorrhage **(5)** is present in an arcuate pattern just inferior to the preretinal hemorrhage that represents a mild vitreous hemorrhage. A few small, hard exudates are visible in the fovea **(6).** (From Palay D, Krachmer J: *Ophthalmology,* ed 2, St Louis 2005, Mosby.)

Before the development of clinical proteinuria (more than 300 mg/day), no clinical signs or symptoms of progressive glomerulosclerosis are likely to be evident. Later, hypoproteinemia, reduction in plasma oncotic pressure, fluid overload, anasarca (generalized body edema), and hypertension may occur. In type 1 DM, about 24% of individuals have a decline in GFR without albuminuria.[183] As renal function continues to deteriorate, individuals with type 1 diabetes may experience hypoglycemia, which necessitates a decrease in insulin therapy. The hypoglycemia occurs because the kidney's ability to metabolize insulin is lost along with other renal functions. As the glomerular filtration rate drops below 10 ml/minute, uremic signs such as nausea, lethargy, acidosis, anemia, and uncontrolled hypertension occur (see Chapter 38 for a discussion of renal failure). Impaired kidney function accelerates retinopathy and cardiovascular disease. Control of hypertension and hyperglycemia delays the onset of end-stage kidney disease.

The development of more sensitive tests has permitted the detection of small amounts of urinary albumin (i.e., microalbuminuria). Earlier intervention with tight glucose control and angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers has reduced proteinuria and slowed the progression of nephropathy. Aggressive treatment of hypertension is another therapeutic intervention definitively shown to slow the progression of established renal disease.[184]

Diabetic Neuropathies. Diabetic neuropathy is the most common cause of neuropathy in the Western world and is probably the most common complication of diabetes. Nerves do not require insulin for glucose transport and are particularly vulnerable to the pathologic effects of chronic hyperglycemia. Peripheral neuropathy affects up to 50% of individuals with diabetes.[185]

The underlying pathologic mechanism includes both metabolic and vascular factors related to chronic hyperglycemia. Inflammation, ischemia, oxidative stress, advanced glycation

TABLE 22-11 FINDINGS IN DIABETIC RETINOPATHY

STAGES OF RETINOPATHY	PATHOLOGIC FINDINGS
Nonproliferative Retinopathy (Stage I)	
Venous abnormalities	Increased tortuosity, dilation with irregular constriction; frequency increases with increased severity of retinopathy
Microaneurysms	Mostly thin walled; 15-50 mcg in diameter; pathogenesis controversial
Interretinal hemorrhage	Circular and small; may take several months to resorb
Macular edema	Caused by serum leakage through incompetent vessel walls; may resorb in several weeks
Hard exudates	Characteristically "hard" exudates with pattern of exudation irregular in shape and sharply defined may appear and disappear over months to years; common with hypertension; "soft" exudates may appear and disappear more often; related to increased retinal capillary permeability
Preproliferative Diabetic Retinopathy (Stage II)	
Cotton-wool patches	Infarcts of the nerve fiber layer caused by retinal ischemia
Intraretinal microvascular shunts	Tortuous shunts between patent and occluded retinal vessels
Proliferative Diabetic Retinopathy (Stage III)	
Neovascularization	New vessels surrounded by connective tissue; five distinct groups representing different hazards to the eye
Glial proliferation	Often produced to reinforce neovascularization; may occur on optic disc and along vascular arcades
Vitreoretinal traction hemorrhage; retinal detachment	Traction occurring from the vitreous jelly; eventually causes small blood vessels to hemorrhage and retinal detachment to occur

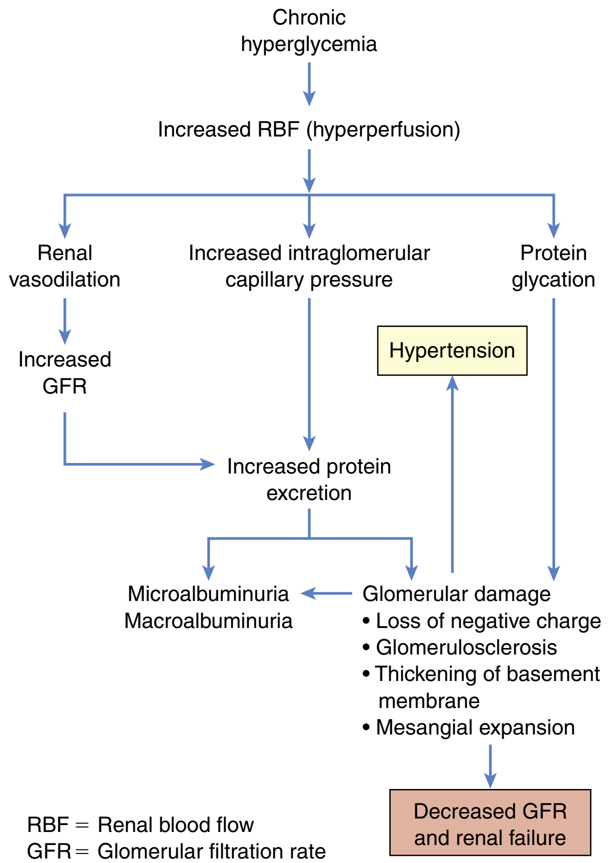

FIGURE 22-19 Diabetic Nephropathy.

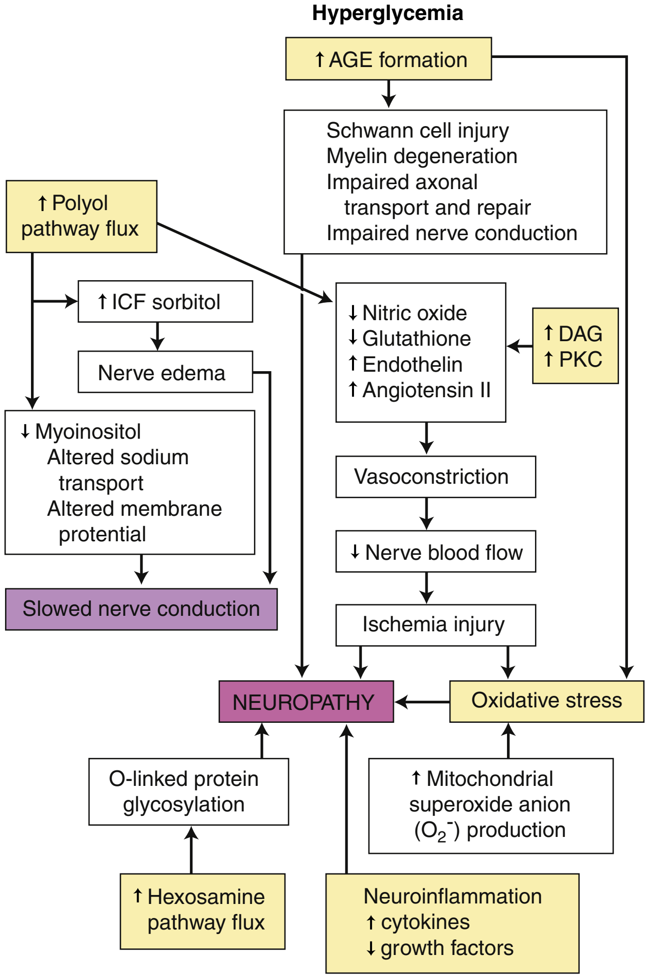

FIGURE 22-20 Multifactorial Pathogenesis of Diabetic Neuropathy. The yellow boxes represent the consequences of chronic hyperglycemia in the development of neuropathy. *AGE,* Advanced glycation end product; *DAG,* diacylglycerol; *ICF,* intracellular fluid; *PKC,* protein kinase C.

end products and increased formation of polyols contribute to demyelination, nerve degeneration, and delayed conduction (Figure 22-20).[186] Both somatic and peripheral nerve cells show diffuse or focal damage resulting in polyneuropathy. Sensory deficits generally precede motor involvement. The extremities are involved first in a "stocking and glove" pattern.

Diabetic neuropathy is a form of "dying back" neuropathy, in which the distal portions of the neurons are initially and eventually more severely affected. The earliest morphologic change is axonal degeneration that preferentially involves sensory nerve fibers, particularly the smaller polymodal unmyelinated peripheral C fibers and the larger myelinated Aδ fibers. Metabolic activity of Schwann cells is disturbed, causing segmental loss of myelin and a characteristic pattern of demyelination and remyelination observed in long-term diabetic neuropathy. The location of the pathologic condition can include the spinal cord, the posterior root ganglia, or the peripheral nerves. These changes may occur alone or in combination. Nerve degeneration begins in the periphery.

Distal symmetric polyneuropathy (sensory, autonomic, and motor nerve involvement) is the most common neuropathy with involvement of both large and small nerve fibers. Loss of small nerve fiber function includes neuropathic pain and loss of sensation, and carries high risk for development of foot ulceration with subsequent gangrene and amputation. Large nerve fiber involvement results in sensory loss of proprioception and vibration with ataxia, loss of coordination, and risk for falls and fractures. Motor involvement results in weakness and muscle atrophy, particularly in the lower legs and feet.[187]

Involvement of the autonomic nervous system can occur early. Multiple alterations can develop affecting gastrointestinal enteric nerves (nausea, bloating, gastroparesis, diarrhea, or constipation), bladder and sexual function (loss of bladder sensation, urine retention, recurrent infection, erectile dysfunction), sweating, and body temperature regulation. Cardiovascular autonomic neuropathy is a serious complication with heart rate variability, changes in baroreceptor reflexes, postural hypotension, dysrhythmias, exercise intolerance, painless myocardial infarction, and sudden death.[188] Alterations in cognitive function and increased risk for dementia may accompany long-term complications in the brain, particularly in persons with type 2 diabetes. The neurodegenerative mechanisms are not clear.[189]

There are varying manifestations of diabetic neuropathies involving both the somatic and the autonomic nerves (Table 22-12). Some of the neuropathic syndromes are progressive, but many—such as painful peripheral neuropathy, mononeuropathy (wristdrop, footdrop), diabetic amyotrophy, diabetic

TABLE 22-12 CLASSIFICATION OF DIABETIC NEUROPATHIES

TYPE OF NEUROPATHY	CHARACTERISTICS
Hyperglycemic neuropathy	Hyperesthesia, tingling and pain associated with hyperglycemia that resolves with glycemic control
Distal symmetric polyneuropathy (sensorimotor neuropathy)	Loss of large and small myelinated and unmyelinated nerve fibers Longest nerves affected first with numbness, tingling, and pain (sharp, burning, aching) in toes and feet and then ascending to hands (stocking and glove pattern); loss of vibration and proprioception (large nerve fiber); loss of sensory light touch and temperature and pain (small nerve fiber) Motor nerves affected later with weakness, depressed reflexes, and gait disturbances
Autonomic neuropathy	Cardiovascular: postural hypotension; exercise intolerance; silent myocardial infarction Gastrointestinal: decreased esophageal motility, gastroparesis and delayed gastric emptying, diabetic constipation or diarrhea Genitourinary tract: neurogenic bladder, urine retention, erectile dysfunction and retrograde ejaculation in men Sudomotor: anhidrosis, gustatory sweating Cranial nerve III: pain and ptosis and may spare the pupil
Mononeuropathies (focal neuropathies)	Compression and entrapment syndromes: carpel tunnel syndrome, radial nerve (wristdrop), peroneal nerve (footdrop), femoral nerve Cranial neuropathies: cranial nerve III, pain and ptosis and may spare the pupil Truncal mononeuropathy: abdominal or lower chest pain or hyperesthesia, abdominal muscle weakness Asymmetric lower limb neuropathy (diabetic amyotrophy; diabetic polyradiculopathy): involvement of lower thoracic and lumbar nerve roots (upper leg weakness, upper leg muscle atrophy, diminished knee and ankle tendon reflexes); may have paresthesia, hyperesthesia, pain

neuropathic cachexia, and visceral manifestations associated with autonomic neuropathy (e.g., diabetic diarrhea and orthostatic hypotension)—may spontaneously improve. *Charcot neuroarthropathy* (Charcot joint) is the progressive degeneration and structural disorganization of a joint, particularly in the feet of individuals affected by long-term diabetes. The pathogenesis is not clear but may be related to loss of sensation or neurally mediated vascular alterations with osteoclastic bone resorption, or both.[190]

Macrovascular Disease

Macrovascular disease (lesions in large and medium sized arteries) increases morbidity and mortality and increases risk for accelerated atherosclerosis and myocardial infarction, stroke, and peripheral vascular disease, particularly among individuals with type 2 diabetes mellitus. Children with poorly controlled diabetes have high risk for macrovascular disease within one or two decades.[191] Unlike microangiopathy, atherosclerotic disease is unrelated to the severity of diabetes and is often present in those with insulin resistance and impaired glucose tolerance.[192] The premature atherosclerosis of diabetes has many contributing factors, including hyperinsulinemia (insulin resistance), hyperglycemia, hypertriglyceridemia, low levels of high-density lipoprotein (HDL), high levels of low-density lipoprotein (LDL), lipoprotein oxidation, and platelet abnormalities. Advanced glycosylated end products attach to their receptor (RAGE) in the walls of blood vessels, promoting oxidative stress, inflammation, and endothelial and vascular smooth muscle dysfunction (Figure 22-21). The process tends to be more severe and accelerated with the presence of other risk factors, including hyperlipidemia, hypertension, and smoking.[193]

Coronary Artery Disease. Coronary artery disease (CAD) is the most common cause of morbidity and mortality (up to 75%) in both men and women with diabetes mellitus. In general, the prevalence of CAD increases with the duration but not the severity of diabetes. Risk factors contributing to disease include hyperglycemia and insulin resistance, high levels of LDLs and triglycerides (lipotoxicity), low levels of HDLs, increased levels of apolipoprotein B, platelet abnormalities, and endothelial cell dysfunction.[194]

Myocardial infarction (death of heart muscle as a result of coronary artery occlusion) is the cause of death in up to 75% of those with diabetes. Individuals with diabetes mellitus have a higher mortality during the acute phase of myocardial infarctions than do nondiabetic individuals because they are often asymptomatic as a result of sensory and autonomic neuropathy. Atherosclerotic CAD is accelerated in diabetes because of hyperglycemia-induced endothelial dysfunction, impaired fibrinolysis, increased platelet aggregation, plaque instability, dysfunctional arterial remodeling, and fibrotic and calcified coronary arteries.[195] In addition, the incidence of cardiomyopathy (heart failure or myocardial dysfunction in the absence of CAD and hypertension) is higher in individuals with diabetes. The reason is unclear but may be related to metabolic remodeling of the myocardium with the presence of increased amounts of collagen in the ventricular wall, which reduces the mechanical compliance of the heart during filling, inflammation, and changes in calcium management.[195a] Diastolic dysfunction is the earliest symptom.[196] Guidelines have been developed to reduce the risk and improve prevention, screening, and treatment of cardiovascular and coronary artery disease in individuals with diabetes.[136]

Stroke. Stroke is twice as common in those with diabetes (particularly type 2 diabetes) as in the nondiabetic population. Ischemic stroke is more common than hemorrhagic stroke. The survival rate for an individual with diabetes after a massive stroke is typically shorter than that for a person without

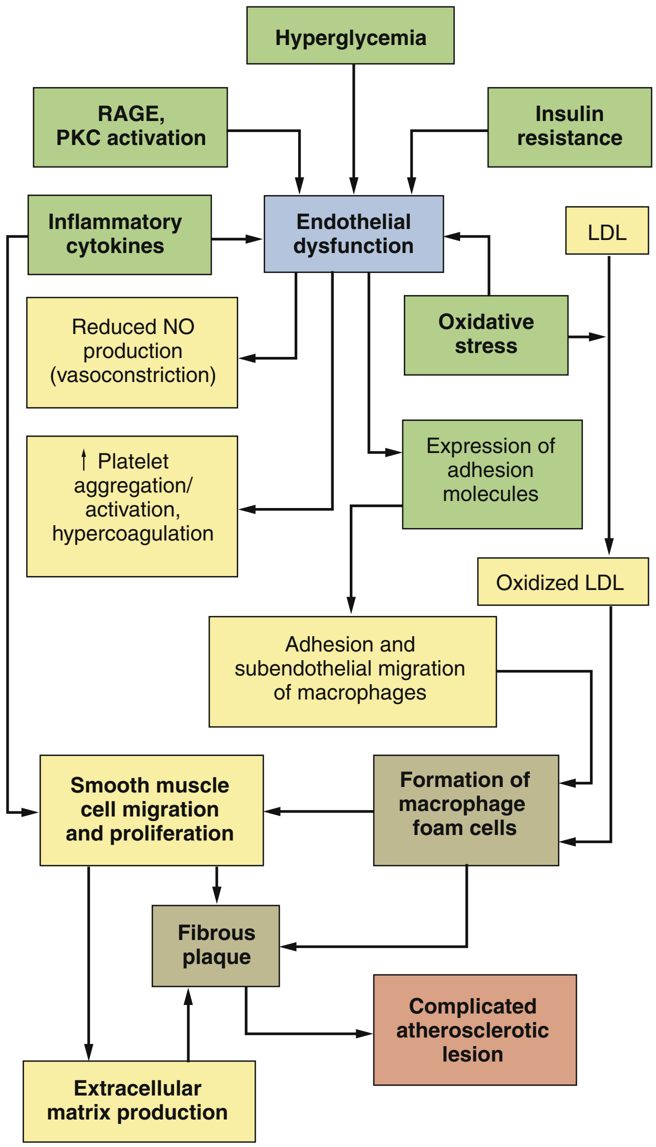

FIGURE 22-21 Diabetes Mellitus and Atherosclerosis. Diabetes with its associated hyperglycemia, relative hypoinsulinemia, oxidative stress, and proinflammatory state contributes to atherogenesis by causing arterial endothelial dysfunction (impaired vasodilation and adhesion of inflammatory cells), dyslipidemia, and smooth muscle proliferation. *LDL,* Low-density lipoprotein; *NO,* nitric oxide; *PKC,* protein kinase; *RAGE,* receptor for advanced glycation end product; *TG,* triglyceride. (Data from D'Souza A et al: *Mol Cell Biochem* 331[1-2]:89–116, 2009; Stratmann B, Tschoepe D: *Best Pract Res Clin Endocrinol Metab* 23[3]:291–303, 2009.)

diabetes. Hypertension, hyperglycemia, hyperlipidemia, and thrombosis are definite risk factors (see Chapters 17 and 32), and aggressive management of blood pressure, hyperglycemia, and lipidemia in individuals with diabetes has been shown to reduce the incidence of stroke.[197]

Peripheral Arterial Disease. There is an increased incidence of peripheral arterial disease (PAD), neuropathy, gangrene, and amputation in diabetic persons, particularly in individuals with type 2 diabetes.[198,199] The atherosclerotic process in diabetic persons is more common, appears at a younger age, and advances more rapidly than vascular changes in nondiabetic persons.[200] The prevalence of PAD is nearly equal in males and females with diabetes. Age, duration of diabetes, glycemic control, genetics, and additional risk factors influence the development of PAD.[201]

Atherosclerosis combined with peripheral neuropathy causes the occlusions, ulcers, and gangrenous changes of the lower extremities. They tend to occur in patchy areas of the feet and toes.[202] Smaller vessels often have more occlusion than larger vessels in the same individuals. Figure 22-22 illustrates how foot lesions of diabetes can lead to amputation. More than 60% of nontraumatic amputations in the United States are performed on individuals with diabetes. Referral to specialists can reduce amputation rates by 45% to 85%.[203]

Infection

Increased morbidity and mortality from infectious agents have been documented in those with diabetes.[204] The individual with diabetes is at increased risk for infection for several reasons[205,206]:

1. *The senses.* Impaired vision caused by retinal changes and impaired touch caused by sensory neuropathy lead to loss of protection with injury. Repeated trauma increases risk for infection in open wounds, soft tissue, or bones (osteomyelitis).
2. *Hypoxia.* Once skin integrity is compromised, tissues' susceptibility to infection increases as a result of vascular disease and hypoxia. In addition, the glycosylated hemoglobin in the RBCs impedes the release of oxygen to tissues.
3. *Pathogens.* Some pathogens proliferate rapidly because of increased glucose in body fluids, which provides an excellent source of energy.
4. *Blood supply.* Decreased blood supply results from vascular changes and autonomic dysfunction, which decreases the supply of white blood cells to the affected area.
5. *Suppressed immune response.* Chronic hyperglycemia impairs both the innate and the adaptive immune responses, including abnormal vasoactive responses and defective chemotaxis and phagocytosis. Clinical signs of infection may be absent.
6. *Delayed wound healing.* Slower collagen synthesis and decreased angiogenesis increase the opportunity for infection.

The risk of infection is especially high for individuals undergoing surgery and for those taking immunosuppressant medications.[207]

ALTERATIONS OF ADRENAL FUNCTION

Disorders of the Adrenal Cortex

Disorders of the adrenal cortex are related to either hyperfunction or hypofunction. Hyperfunction that causes increased levels of circulating cortisol leads to Cushing disease, or Cushing syndrome; hyperfunction that causes increased secretion of adrenal androgens and estrogens leads to virilization or feminization; and hyperfunction that causes increased levels of aldosterone leads to hyperaldosteronism, which may be primary or

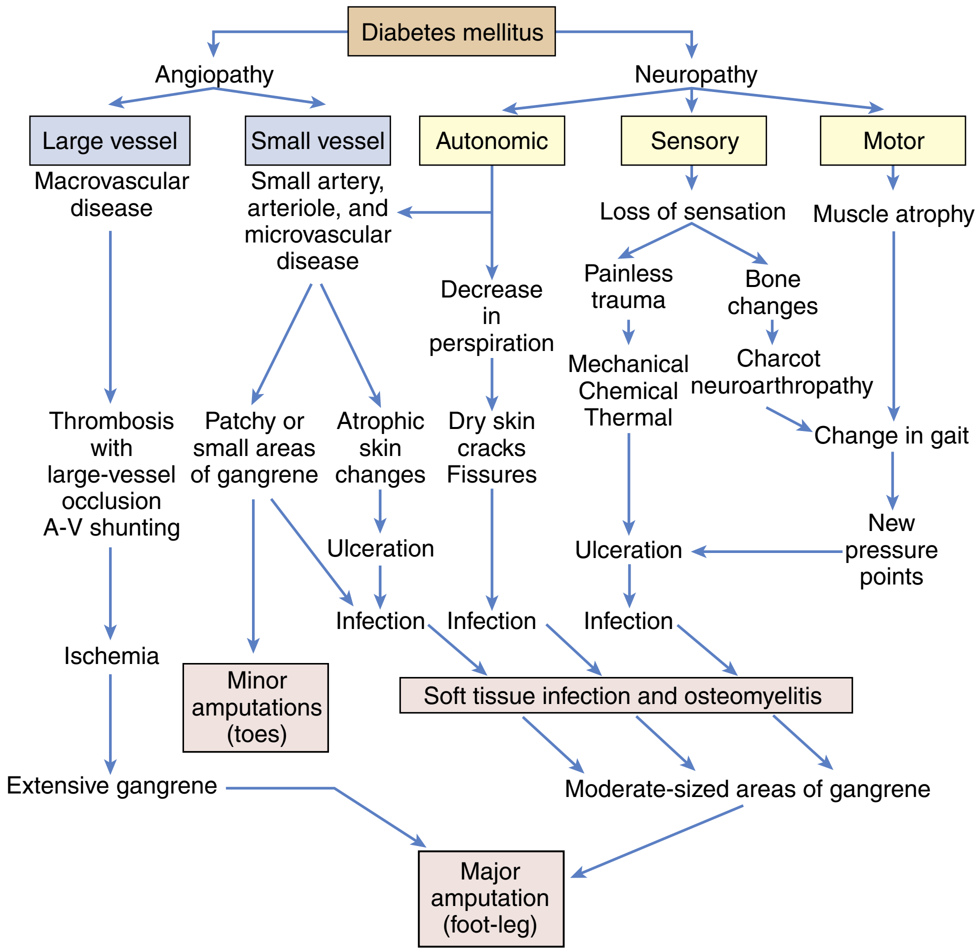

FIGURE 22-22 How Foot Lesions of Diabetes Can Lead to Amputation. (From Levin ME, O'Neal LW, Bowker JH: *The diabetic foot,* ed 5, St Louis, 1993, Mosby.)

secondary. Hypofunction of the adrenal cortex leads to Addison disease.

Adrenocortical Hyperfunction: Cushing Disease, Cushing Syndrome

Cushing syndrome refers to the complex of clinical manifestations resulting from chronic exposure to excess cortisol. **Cushing disease** is overproduction of pituitary ACTH by a pituitary adenoma (can occur at any age). Ectopic secretion of ACTH by an ectopic-secreting non–pituitary tumor (e.g., a small cell carcinoma of the lung; more common in older adults) also can cause hypercortisolism. Rarely, *ACTH-independent hypercortisolism* is caused by cortisol secretion from a benign or malignant tumor of one or both adrenal glands (more common in children). All are rare. A **Cushing-like syndrome** may develop as a result of the exogenous administration of glucocorticoids.[208]

PATHOPHYSIOLOGY. With ACTH-dependent hypercortisolism, the excess ACTH stimulates excess production of cortisol and there is loss of feedback control of ACTH secretion. Whatever the cause, two observations consistently apply to individuals with Cushing syndrome: (1) they do not have diurnal or circadian secretion patterns of ACTH and cortisol, and (2) they do not increase ACTH and cortisol secretion in response to a stressor.[209] In individuals with ACTH-dependent hypercortisolism, secretion of both cortisol and adrenal androgens is increased, and corticotropin-releasing hormone (CRH) secretion is inhibited. ACTH-independent secreting tumors of the adrenal cortex, however, generally secrete only cortisol. Elevated cortisol levels suppress CRH and ACTH secretion from the hypothalamus and anterior pituitary, respectively, which leads to low levels of ACTH. Low levels of ACTH cause atrophy of the remaining normal portions of the adrenal cortex, which over time will alter the cortisol-secreting activity of normal cells. When the secretion of cortisol by the tumor exceeds normal cortisol levels, symptoms of hypercortisolism develop.

CLINICAL MANIFESTATIONS. Weight gain is the most common feature and results from the accumulation of adipose tissue in the trunk, facial, and cervical areas. These characteristic patterns of fat deposition have been described as "truncal [central] obesity," "moon face," and "buffalo hump" (Figures 22-23 and 22-24). Transient weight gain from sodium and water retention may be present because of the mineralocorticoid effects of cortisol, exhibited when cortisol is present in high levels.

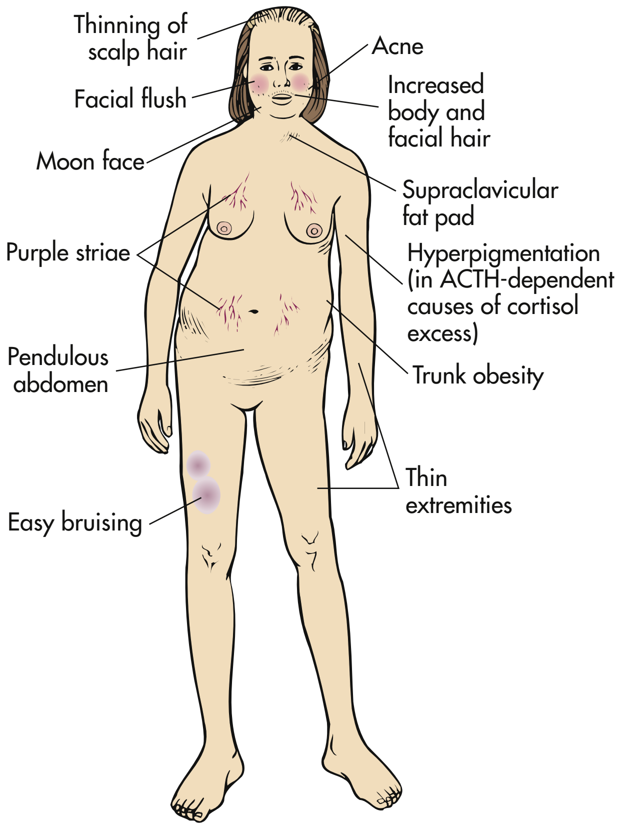

FIGURE 22-23 Symptoms of Cushing Disease. *ACTH,* Adrenocorticotropic hormone.

FIGURE 22-24 Cushing Syndrome. **A,** Patient before onset of Cushing syndrome. **B,** Patient 4 months later. Moon facies is clearly demonstrated. (From Zitelli BJ, McIntire SC, Nowalk AJ: *Zitelli and Davis' atlas of pediatric physical diagnosis,* ed 6, London, 2012, Saunders.)

Glucose intolerance occurs because of cortisol-induced insulin resistance and increased gluconeogenesis and glycogen storage by the liver. Overt diabetes mellitus develops in approximately 20% of individuals with hypercortisolism. Polyuria is a manifestation of hyperglycemia and resultant glycosuria.

Protein wasting is caused by the catabolic effects of cortisol on peripheral tissues. Muscle wasting leads to muscle weakness and is especially obvious in the muscles of the extremities with thinning of the limbs. In bone, loss of the protein matrix and increases in bone resorption lead to osteoporosis and can result in pathologic fractures, vertebral compression fractures, bone and back pain, kyphosis, and reduced height. Hypercalciuria may result in renal stones, which are experienced by approximately 20% of individuals with this disease. Loss of collagen also leads to thin, weakened integumentary tissues through which capillaries are more visible; the tissues are easily stretched by adipose deposits. Together these changes account for the characteristic purple striae most often observed in the truncal area. Loss of collagenous support around small vessels makes them susceptible to rupture, leading to easy bruising, even with minor trauma. Thin, atrophied skin is also easily damaged, leading to skin breaks and ulcerations. Bronze or brownish hyperpigmentation of the skin, mucous membranes, and hair occurs when there are very high levels of ACTH. This is caused by increased levels of melanocyte-stimulating hormones resulting from excess conversion of pro-opiomelanocortin when ACTH concentration is elevated.[210]

With elevated cortisol levels, vascular sensitivity to catecholamines is increased significantly, leading to vasoconstriction and hypertension. Metabolic syndrome with abdominal obesity, hypertension, glucose intolerance, and dyslipidemias is a common complication (see Box 22-2, p. 739). Individuals with Cushing syndrome are at increased risk for cardiovascular complications (CAD, heart failure, and stroke).[211] Chronically elevated cortisol levels also cause suppression of the immune system, increased susceptibility to infections, and poor wound healing.

Approximately 50% of individuals with Cushing syndrome experience alterations in their mental status, caused by the effects of cortisol on hippocampal neurons and the subsequent implications on learning, memory, and other neurologic functions when cortisol levels are elevated. These may range from irritability and depression to severe psychiatric disturbances such as schizophrenia.[212]

Females may experience symptoms of increased adrenal androgen levels, increased hair growth (especially facial hair), acne, and oligomenorrhea. Rarely do androgen levels become

high enough to cause changes of the voice, recession of the hairline, and clitoral hypertrophy unless an adrenal carcinoma is involved. Infertility is more common among women.[213]

EVALUATION AND TREATMENT. A variety of laboratory tests must be used to diagnose hypercortisolism and to determine the underlying disorder.[214] These include urinary free cortisol concentration higher than 50 mcg per 24 hours, abnormal dexamethasone suppressibility of either urinary or serum cortisol, and simultaneous measurement of ACTH and cortisol levels. Late evening salivary cortisol levels are used as a screening test and to document alterations in the diurnal variation of cortisol level. Routine laboratory examinations may reveal hyperglycemia, glycosuria, hypokalemia, and metabolic alkalosis. Tumors are diagnosed using imaging procedures. Guidelines are available for the diagnosis of Cushing syndrome.[215]

Treatment is specific for the cause of hypercorticoadrenalism and includes medication, radiation, and surgery. Differentiation among pituitary, ectopic, and adrenal causes is essential for effective treatment. Without treatment, approximately 50% of individuals with Cushing syndrome die within 5 years of onset as a result of overwhelming infection, suicide, complications from generalized arteriosclerosis, and hypertensive disease.[216]

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia is an autosomal recessive disorder that causes the deficiency of an enzyme that is critical in cortisol biosynthesis. Because cortisol production is low, ACTH concentration increases and causes adrenal hyperplasia, which results in the overproduction of either mineralocorticoids or androgens. The most common form is a 21-hydroxylase deficiency that involves both mineralocorticoid and cortisol synthesis. Affected female infants are virilized and infants of both genders exhibit salt wasting.[217]

Hyperaldosteronism

Hyperaldosteronism is characterized by excessive aldosterone secretion by the adrenal cortex. There are both primary and secondary forms of hyperaldosteronism.

Primary hyperaldosteronism (Conn disease, primary aldosteronism) is caused by excessive secretion of aldosterone from an abnormality of the adrenal cortex, usually a single benign aldosterone-producing adrenal adenoma. Bilateral adrenal nodular hyperplasia and adrenal carcinomas account for the remainder of cases. The incidence is estimated to be between 1% and 2% of all hypertensive individuals and is the most common cause of secondary hypertension.[218]

Secondary hyperaldosteronism (secondary aldosteronism) involves excessive aldosterone secretion from an extra-adrenal stimulus, most often angiotensin II through a renin-dependent mechanism. (Factors that affect renin and aldosterone secretion are summarized in Table 22-13). This occurs in various situations, including decreased circulating blood volume (e.g., in dehydration, shock, or hypoalbuminemia) and decreased delivery of blood to the kidneys (e.g., renal artery stenosis, heart failure, or hepatic cirrhosis). Here the activation of the renin-angiotensin system and subsequent aldosterone secretion may be seen as compensatory, although in some instances (e.g., congestive heart failure) the increased circulating volume further worsens the condition. Other causes of secondary hyperaldosteronism include renin-secreting tumors of the kidney and Bartter syndrome, an inherited renal tubular defect in tubular reabsorption of sodium and resulting elevated aldosterone levels and hypokalemia. Diuretic use is perhaps the most common cause of secondary hyperaldosteronism. (Renal disorders are discussed in Chapter 38.) Apparent mineralocorticoid excess can be seen in individuals who consume excess licorice (glycyrrhizic acid) or chewing tobacco.

TABLE 22-13 PHYSIOLOGIC FACTORS AFFECTING RENIN AND ALDOSTERONE SECRETION

FACTORS	RENIN SECRETION
Age	Highest in infants; lowest in older adults
Menstrual cycle	Highest in luteal phase (see Chapter 23)
Sodium intake	Increased by salt restriction Decreased by salt loading
Potassium status	Increased by K^+ excess
Posture	Increased with erect posture
Sympathetic nervous system	Renin increased by catecholamine stimulation
Time of sampling	Highest before noon; lowest in evening

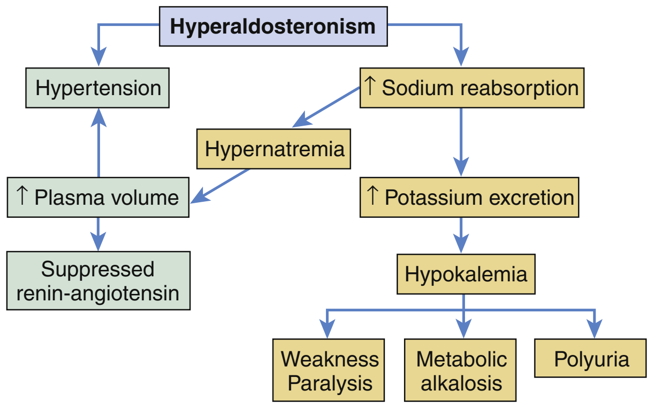

FIGURE 22-25 Pathophysiology of Primary Hyperaldosteronism. (From Bonow RO et al: *Braunwald's heart disease: a textbook of cardiovascular medicine*, ed 9, Philadelphia, 2012, Saunders.)

PATHOPHYSIOLOGY. In *primary hyperaldosteronism*, pathophysiologic alterations are caused by excessive aldosterone secretion and the fluid and electrolyte imbalances that ensue (Figure 22-25). Hyperaldosteronism promotes (1) increased renal sodium and water reabsorption with corresponding hypervolemia (see Chapter 3) and hypertension and (2) renal excretion of potassium. The extracellular fluid volume overload and suppression of normal feedback mechanisms of renin secretion are characteristic of primary disorders.

Edema usually does not occur with primary aldosteronism. Sodium loss and water loss are maintained by hypervolemia-induced atrial natriuretic factor release, pressure natriuresis, and aldosterone escape (spontaneous diuresis). The escape phenomenon changes or resets the rate of sodium excretion in the

WHAT'S NEW?

Aldosteronism and Metabolic Syndrome

Increased aldosterone production and mineralocorticoid receptor (MR) activation are associated with genomic and nongenomic actions that contribute to pancreatic fibrosis, impaired beta-cell function, and components of metabolic syndrome, including insulin resistance, hypertriglyceridemia, low levels of high-density lipoprotein, resistant hypertension, and obesity. Insulin resistance may be related to increased levels of aldosterone and decreased insulin responsiveness of GLUT4 in skeletal muscle and GLUT2 in the liver, as has been found in animal studies, or be a result of direct effects on insulin signaling and hepatic gluconeogenesis. Aldosterone increases oxidative stress and the number of proinflammatory cytokines; combined with insulin resistance, it contributes to reduced endothelial-mediated vasorelaxation, vascular injury, and atherosclerosis, causing hypertension, cardiac disease, and renal disease. High levels of aldosterone are associated with left ventricular hypertrophy, cardiac fibrosis, and diastolic dysfunction, and promote both glomerular and tubulointerstitial renal disease. MR antagonists have a significant role in the management of complications associated with metabolic syndrome although the side effects of gynecomastia and hypokalemia may limit their use.

Data from Briet M, Schiffrin EL: *Curr Hypertens Rep* 13(2):163–172, 2011; Briet M, Schiffrin EL: *J Vasc Res* 50(2):89–99, 2013; Ronconi V et al: *Curr Vasc Pharmacol* 10(2):238–246, 2012; Tirosh A, Garg R, Adler GK: *Curr Hypertens Rep* 12(4):252–257, 2010.

proximal tubules and prevents more severe sodium retention. Although this mechanism provides protection from excessive sodium reabsorption and edema, it can increase urinary losses of potassium and cause hypokalemia (see Figure 22-24). Metabolic syndrome (hypertension, obesity, dyslipidemia, insulin resistance, and hyperglycemia) is associated with primary aldosteronism (see What's New? Aldosteronism and Metabolic Syndrome). Activation of the aldosterone receptor induces insulin resistance; promotes inflammation, endothelial dysfunction, and cardiovascular remodeling; and affects adipose tissue differentiation and function.[219,220]

In *secondary hyperaldosteronism* the effect of increased extracellular volume on renin secretion may vary. If renin secretion is being stimulated by variables other than pressure-initiated cellular changes at the juxtaglomerular apparatus (see Chapter 37), increased circulating blood volume may not decrease renin secretion through feedback mechanisms. This physiologic process is normal in pregnancy and related to increased levels of plasma estrogen.

Potassium secretion also is promoted by aldosterone, so that with excessive circulating levels of aldosterone, hypokalemia occurs (see Chapter 3). In hyperaldosteronism, hypokalemic alkalosis, myocardial conduction changes, and skeletal muscle alterations may be seen, particularly with severe potassium depletion (i.e., the renal tubules may become insensitive to ADH, thus promoting excessive loss of free water). Rarely, this may result in mild hypernatremia because water is not able to follow the sodium that is reabsorbed.

CLINICAL MANIFESTATIONS. Hypertension, hypokalemia, renal potassium wasting, and neuromuscular manifestations are the hallmarks of hyperaldosteronism.[221] Hypertension is resistant to treatment and may result from increased intravascular volume or from a state of aldosterone-mediated vasoconstriction, although the latter mechanism requires very high levels of aldosterone. If hypertension is sustained, the long-term effects of elevated arterial pressure become evident, which include the development of left ventricular dilation and hypertrophy, vascular disease, and renal disease. Because of the increased arterial pressure, renin secretion is typically suppressed, although it is elevated in secondary hyperaldosteronism, which provides a means to clearly differentiate between these conditions.

Aldosterone-stimulated potassium loss can be variable. Serum potassium levels below 3.0 mEq/L result in the typical manifestations of hypokalemia. Hypokalemic alkalosis is caused by the movement of potassium from the intercellular to extracellular space in exchange for hydrogen ions as well as renal loss of hydrogen ions to facilitate sodium reabsorption (see Chapter 3).

EVALUATION AND TREATMENT. Various clinical and laboratory measurements are useful in the assessment of hyperaldosteronism and include the following[222]:

1. Blood pressure: elevated
2. Serum and urinary electrolyte levels: serum sodium level is normal or elevated; serum potassium level is normal or depressed, but urinary potassium level is elevated
3. Serum and urinary levels of aldosterone increase
4. Aldosterone suppression testing: fludrocortisone acetate (Florinef) is used
5. Plasma renin activity: suppressed
6. Plasma aldosterone concentration/plasma renin activity ratio can be high

Serum aldosterone and plasma renin activity both must be measured under controlled situations and after careful dietary regulation of sodium and potassium intake (see Table 22-13).

Imaging techniques, such as CT and nuclear magnetic resonance (NMR), may be used to localize an aldosterone-secreting adenoma. Sampling from both adrenal veins is also useful.

Treatment includes management of hypertension and hypokalemia, as well as correction of any underlying causal abnormalities. If an aldosterone-secreting adenoma is present, it is generally approached surgically. Medical management with aldosterone receptor antagonists, such as spironolactone or eplerenone (a drug without the side effects of spironolactone), is a viable option in selected cases.[222]

Hypersecretion of Adrenal Androgens and Estrogens

Hypersecretion of adrenal androgens and estrogens may be caused by adrenal tumors (either adenomas or carcinomas), Cushing syndrome, or defects in steroid synthesis. The clinical syndrome that results depends on the hormone secreted, the gender of the individual, and the ages at which the hypersecretion was initiated. Hypersecretion of estrogens causes **feminization,** the development of female sex characteristics. Hypersecretion of androgens causes **virilization,** the development of male sex characteristics (Figure 22-26).

The effects of an estrogen-secreting tumor are most evident in men and result in gynecomastia (breast enlargement) (98% of cases), testicular atrophy, and decreased libido. In female children such tumors may lead to early development of secondary

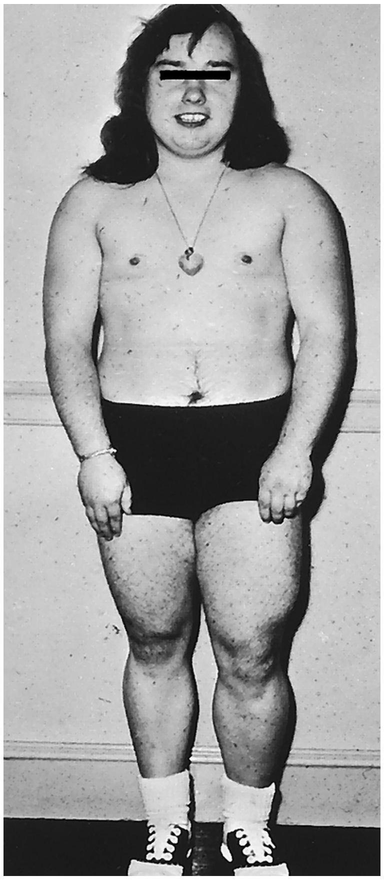

FIGURE 22-26 Virilization. Virilization of a young girl by an androgen-secreting tumor of the adrenal cortex. Masculine features include lack of breast development, increased muscle bulk, and hirsutism. (From Thibodeau GA, Patton KT: *The human body in health & disease,* ed 4, St Louis, 2010, Mosby.)

sex characteristics. An androgen-secreting tumor indicates changes more easily observed in women, including hirsutism, clitoral enlargement, deepening of the voice, amenorrhea, acne, and breast atrophy. In children, virilizing tumors promote precocious sexual development and bone aging. Treatment of androgen-secreting tumors usually involves surgical excision.

Adrenocortical Hypofunction

Hypocortisolism (low levels of cortisol secretion) develops because of either inadequate stimulation of the adrenal glands by ACTH or a primary inability of the adrenals to produce and secrete the adrenocortical hormones. In some syndromes, however, there is partial dysfunction of the adrenal cortex so that only synthesis of cortisol and aldosterone or the adrenal androgens is affected. Hypofunction of the adrenal cortex may affect glucocorticoid or mineralocorticoid secretion or a combination of both.

Addison Disease. **Primary adrenal insufficiency** is termed **Addison disease.** Addison disease is relatively rare, occurring most often in adults 30 to 60 years of age, although it may appear at any time. Addison disease, caused by autoimmune mechanisms, is more common in women.

The most common cause of Addison disease in the United States is autoimmune destruction of the adrenal cortex and it is more common in women. Other causes include infections (tuberculosis, fungal infections, human immunodeficiency virus [HIV]), infiltrative diseases (amyloidosis, metastatic carcinoma), or bilateral adrenal hemorrhage. Adrenoleukodystrophy and adrenomyeloneuropathy are two rare types of X-linked adrenal deficiency that lead to symptoms of hypocortisolism and progressive neurologic symptoms.

PATHOPHYSIOLOGY. Addison disease is characterized by inadequate corticosteroid and mineralocorticoid synthesis and elevated serum ACTH levels. Before clinical manifestations of hypocortisolism are evident, more than 90% of total adrenocortical tissue must be destroyed. Thus the adrenal glands are smaller and may be misshapen.

Idiopathic Addison disease (organ-specific autoimmune adrenalitis), which causes adrenal atrophy and hypofunction, generally is recognized as an organ-specific autoimmune disease. (Autoimmunity is discussed in Chapter 9.) 21-Hydroxylase autoantibodies and autoreactive T cells specific to adrenal cortical cells are present in 50% to 70% of individuals with idiopathic Addison disease; this percentage increases in younger persons and in those with other autoimmune diseases. Apparently, a genetic defect in immune surveillance mechanisms causes a deficiency of immune-suppressor cells. This deficiency allows the proliferation of immunocytes directed against specific antigens within the adrenocortical cells. The adrenal glands in idiopathic Addison disease are smaller than normal and may be misshapen.[223,224] Several genes have been identified.[225]

Idiopathic Addison disease often is associated with other autoimmune diseases and in such cases is known as *autoimmune polyendocrine syndrome (APS).* APSI (APS type I) is inherited as autosomal recessive with childhood onset and includes Addison disease, hypoparathyroidism, mucocutaneous candidiasis, and other less common symptoms. APSII (APS type II) is more common and involves Addison disease, immune thyroid disease, diabetes mellitus, celiac disease, and hypogonadism.[226] (Mechanisms of inheritance are described in Chapter 4.)

CLINICAL MANIFESTATIONS. The symptoms of Addison disease are primarily a result of hypocortisolism and hypoaldosteronism. With mild to moderate hypocortisolism, symptoms usually begin with weakness and easy fatigability. Skin changes, including hyperpigmentation and vitiligo, may occur. As the condition progresses, anorexia, nausea, vomiting, and diarrhea may develop. Of greatest concern is the development of hypotension that can progress to complete vascular collapse and shock.

Decreased adrenal androgen secretion is usually not clinically obvious in men because the adrenals are not a major source of male androgens. Women may experience a loss of some secondary sexual characteristics, such as pubic and axillary hair, normally maintained by the adrenal androgens.[227] Disturbances in mood and motivation are common. The symptoms of Addison disease are summarized in Table 22-14.

EVALUATION AND TREATMENT. Serum and urine levels of cortisol are depressed with primary hypocortisolism and ACTH levels are increased. Because of dehydration, blood urea nitrogen levels may increase. Serum glucose concentration is low. Eosinophil and lymphocyte counts are often elevated. Hyperkalemia is seen in Addison disease and may cause mild alkalosis (see

TABLE 22-14 CLINICAL MANIFESTATIONS AND PATHOPHYSIOLOGIC MECHANISMS OF ADDISON DISEASE

CLINICAL MANIFESTATIONS	PATHOPHYSIOLOGIC MECHANISM
Weakness and easy fatigability that worsen as the day progresses, seen especially after exposure to stressors	Not known, may be related to hypoglycemia, hypotension, decreased metabolism of proteins
Gastrointestinal disturbances: anorexia, nausea, vomiting, diarrhea, abdominal pain, weight loss	May be associated with celiac disease or electrolyte abnormalities
Hypoglycemia, manifested by fatigue, mental confusion, apathy, psychosis	Absence of cortisol leads to decreased gluconeogenesis, decreased glycogen storage by liver, decreased metabolism of proteins, increased insulin sensitivity
Hyperpigmentation	Elevations of ACTH that lead to stimulation of melanocytes
Vitiligo (white patchy areas of depigmented skin)	Autoimmune destruction of melanocytes
Addisonian crisis: severe hypotension and vascular collapse	Combined effects of hypocortisolism, hypoaldosteronism, extracellular volume depletion, and some precipitating stressor (e.g., infection, vomiting, diarrhea); decreased vasomotor tone caused by cortisol deficiency

ACTH, Adrenocorticotropic hormone.

Chapter 3). The ACTH stimulation test may be used to evaluate serum cortisol levels.

The treatment of Addison disease involves lifetime glucocorticoid and mineralocorticoid replacement therapy, together with dietary modifications and correction of any underlying disorders. In the event of acute stressors, additional cortisol must be administered to approximate the amount of cortisol that might be expected to be secreted if normal adrenal function were present (approximately 100 to 300 mg/day).[228] The individual's diet should include at least 150 mEq of sodium per day, with sodium intake increased in the event of excessive sweating or diarrhea.

Secondary Hypocortisolism. **Secondary hypocortisolism** commonly results from prolonged administration of exogenous glucocorticoids, which suppress ACTH secretion. This causes adrenal atrophy and results in inadequate corticosteroidogenesis once the exogenous glucocorticoids are withdrawn. Decreased ACTH secretion also can result from pituitary infarction, pituitary tumors that compress ACTH-secreting cells, or hypophysectomy. In all instances of low ACTH levels, adrenal atrophy occurs and endogenous adrenal steroidogenesis is depressed. Clinical manifestations of secondary hypocortisolism are similar to those of Addison disease, although hyperpigmentation usually does not occur. The renin-angiotensin system usually is normal, so aldosterone and potassium levels also tend to be normal.

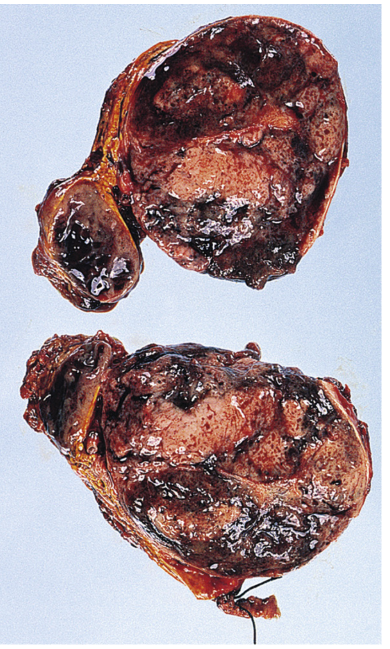

FIGURE 22-27 **Pheochromocytoma.** Gross appearance of adrenal pheochromocytoma. (From Rosai J: *Rosai and Ackerman's surgical pathology,* ed 10, Philadelphia, 2011, Mosby.)

Disorders of the Adrenal Medulla

Tumor of the Adrenal Medulla

Adrenomedullary hyperfunction is caused by **pheochromocytomas** (chromaffin cell tumors) of the adrenal medulla, which secrete catecholamines (Figure 22-27). They are rare and less than 10% of cases are malignant. Most pheochromocytomas produce norepinephrine, although large tumors secrete epinephrine and norepinephrine.

The true incidence of pheochromocytoma in the general population is not known. About one tenth of 1% of the adult hypertensive population has a pheochromocytoma. The tumors are most common in people 40 to 60 years of age, with men and women equally affected. Familial forms of the disease are associated with mutations in the *RET* proto-oncogene, the von Hippel-Lindau *(VHL)* gene, and the neurofibromatosis type 1 gene *(NF1)*. Any of the succinate dehydrogenase complex subunit genes can lead to pheochromocytoma (and paragangliomas).[229]

PATHOPHYSIOLOGY. Pheochromocytomas cause excessive production of norepinephrine, although large tumors secrete epinephrine and norepinephrine because of autonomous functioning of the tumor. Approximately 5% of people with pheochromocytomas have no symptoms because the tumor appears to be nonfunctioning; however, these tumors can release catecholamines in response to stressors, such as abdominal surgery.

CLINICAL MANIFESTATIONS. The clinical manifestations of a pheochromocytoma are related to the chronic effects of catecholamine secretion. Hypertension is the most common sign and it may be sustained or paroxysmal. Other symptoms include diaphoresis, tachycardia, palpitations, and severe headache.[230] Hypertension is a result of increased peripheral vascular

resistance. Headaches appear because of sudden changes in catecholamine levels in the blood, affecting cerebral blood flow. Hypermetabolism and sweating are related to chronic activation of sympathetic receptors in adipocytes, hepatocytes, and other tissues. Glucose intolerance may occur because of catecholamine-induced inhibition of insulin release by the pancreas. Complaints of warmth, heat intolerance, weight loss, and constipation are common despite a normal or an increased appetite.

An acute episode of hypertension related to hypersecretion of catecholamines may follow specific events. Exercise, excessive ingestion of tyrosine-containing foods (e.g., aged cheese, red wine, beer, yogurt), ingestion of caffeine-containing foods, external pressure on the tumor, and induction of anesthesia all can increase secretion of catecholamines by the tumor.

These tumors tend to be extremely vascular and can rupture. Such an event can cause massive and potentially fatal hemorrhage. Rupture of a pheochromocytoma is characterized by a sudden, unexplained decrease in blood pressure; sudden, severe abdominal pain; and a rigid abdomen.

EVALUATION AND TREATMENT. A diagnosis of pheochromocytoma is made when increased catecholamine production is demonstrated in the blood or urine. Individuals with this disorder can have total urine catecholamine levels greater than 250 mg/day. After elevation of urinary or plasma catecholamine levels is documented, the site of the tumor is determined using MRI. Because of the possibility of metastasis, whole-body scanning may be done.

Management of catecholamine excess is essential to prevent hypertensive emergencies and requires the use of α- and β-adrenergic blockers. The usual treatment of pheochromocytoma is laparoscopic surgical excision of the tumor with adjunctive radiopharmaceuticals or chemotherapy. Medical therapy is continued to stabilize blood pressure before surgery. Drugs used include α-adrenergic blocking agents and, possibly later, β-adrenergic blocking agents. Open resection is completed for large tumors or when metastasis is suspected. Malignant pheochromocytoma is rarely curable and is usually managed by a combination of surgical debulking of the tumor combined with chemotherapy.[231]

SUMMARY REVIEW

Mechanisms of Hormonal Alterations

1. Abnormalities in endocrine function may be caused by hypersecretion or hyposecretion of hormones, causing alterations in normal hormone levels.
2. Endocrine abnormalities also may be caused by alterations in receptor function through a variety of mechanisms: (a) a decrease in the number of receptors, (b) receptor insensitivity to the hormone, (c) antibodies against specific receptors, and (d) defects in second-messenger generation or postreceptor defects.
3. Abnormally high levels of circulating hormones sometimes are caused by hormone release from tissues outside the endocrine system (ectopic foci) that may not respond to normal feedback mechanisms, in which case they are said to function autonomously.

Alterations of the Hypothalamic-Pituitary System

1. Dysfunction in the release of hypothalamic hormones probably is related to interruption of the connection between the hypothalamus and pituitary—namely, the pituitary stalk.
2. Disorders of the posterior pituitary include SIADH secretion and DI. SIADH secretion is characterized by abnormally high ADH secretion; DI is characterized by abnormally low ADH secretion.
3. In SIADH, high ADH levels interfere with renal free water clearance, leading to hyponatremia and hypoosmolality. SIADH secretion is associated with certain forms of cancer, apparently because of ectopic secretion of ADH by tumor cells.
4. DI may be neurogenic, caused by insufficient amounts of ADH, or nephrogenic, caused by an inadequate response to ADH. Its principal clinical features are failure to concentrate urine with polyuria and polydipsia. Dipsogenic DI occurs when excessive fluid intake lowers the plasma osmolarity to the point that it falls below the threshold for ADH secretion.
5. Hypopituitarism is dysfunction of the anterior pituitary that causes failure of hormonal functions. Symptoms may be mild to severe.
6. Causes of hypopituitarism include pituitary infarction, space-occupying lesions such as tumor or aneurysm, surgical removal, or infections. Symptoms are variable depending on which hormones are deficient (e.g., TSH, ACTH, or GH).
7. Hyperpituitarism is caused by pituitary adenomas. These are usually benign slow-growing tumors that arise from cells of the anterior pituitary.
8. Expansion of a pituitary adenoma causes neurologic and secretory effects. Pressure from the expanding tumor causes hyposecretion of cells, dysfunction of the optic chiasm (leading to visual disturbances), and dysfunction of the hypothalamus and some cranial nerves.
9. Hypersecretion of GH causes acromegaly in adults and giantism in children. Pituitary adenoma is the most common cause of acromegaly.
10. Prolonged, abnormally high levels of GH lead to proliferation of body and connective tissues. Renal, thyroid, cardiovascular, and reproductive dysfunctions develop slowly, together with a change in bony proportions and insulin resistance.
11. GH deficiency in children results in growth failure and fasting hypoglycemia. Adult GH deficiency results in fatigue, osteoporosis, and increased mortality.
12. Pituitary prolactinomas, renal failure, and medications can result in increased levels of prolactin and affect reproductive organs and function in both men and women.

SUMMARY REVIEW—cont'd

Alterations of Thyroid Function

1. Thyrotoxicosis is a general condition in which TH levels are elevated and produce an exaggerated physiologic response in tissues. The condition can be primary, secondary, or subclinical.
2. In general, hyperthyroidism has a range of endocrine, reproductive, gastrointestinal, integumentary, and ocular manifestations. These are caused by increased circulating levels of TH and by stimulation of the sympathetic division of the autonomic nervous system.
3. Graves disease, the most common form of hyperthyroidism, is caused by thyroid-stimulating immunoglobulins that stimulate thyroid TSH receptors, resulting in thyroid hyperplasia and increased synthesis of TH.
4. Manifestations of Graves disease can include symptoms of hyperthyroidism, diffuse thyroid enlargement, disorders of the skin, and enlargement of extraocular muscles.
5. The cutaneous manifestation of Graves disease is pretibial myxedema, a condition characterized by subcutaneous swelling of the legs and, occasionally, the hands.
6. Ocular manifestations of Graves disease are caused by hyperactivity of the sympathetic division of the autonomic nervous system and by immune-induced infiltration of extraocular muscles, orbital fat accumulation, and edema (exophthalmos).
7. Toxic multinodular goiter and solitary toxic adenoma occur when some hyperplastic, hyperfunctioning thyroid nodules autonomously secrete TH, causing hyperthyroidism and producing symptoms similar to those of Graves disease.
8. Toxic multinodular goiters result from multiple functioning adenomas.
9. Thyrotoxic crisis (thyroid storm) is a severe form of hyperthyroidism that often is associated with physiologic stress. Without treatment, death occurs quickly.
10. Hypothyroidism is caused by deficient production of TH by the thyroid gland. The condition may be primary, secondary, or subclinical.
11. Causes of primary hypothyroidism include iodine deficiency, autoimmune thyroiditis, subacute or painless thyroiditis, silent or subacute lymphocytic thyroiditis, iatrogenic hypothyroidism, and postpartum thyroiditis.
12. Autoimmune thyroiditis (Hashimoto disease) is associated with lymphocyte infiltration, antibody activation of natural killer cells, induction of apoptosis with gradual loss of thyroid function, and hypothyroidism.
13. Subacute thyroiditis, a form of hypothyroidism, is a self-limited nonbacterial inflammation of the thyroid gland. The inflammatory process damages follicular cells, causing leakage of triiodothyronine (T_3) and thyroxine (T_4). Hyperthyroidism then is followed by transient hypothyroidism, which is corrected by cellular repair and a return to normal levels in the thyroid.
14. Secondary hypothyroidism is caused by hypothalamic-pituitary dysfunction in which TRH and TSH are not produced in sufficient amounts.
15. Thyroid carcinoma is a relatively rare cancer. The most consistent causal risk factor associated with thyroid carcinoma is exposure to ionizing radiation, especially in childhood.
16. Hypothyroidism affects all body systems. Symptoms depend on the degree of TH deficiency. Common manifestations include decreased energy metabolism and loss of heat production.
17. Myxedema is the characteristic sign of hypothyroidism. Myxedema is caused by alterations in connective tissue with water-binding proteins. The excess water leads to thickened mucous membranes and edema, particularly around the eyes and in the hands and feet.
18. Myxedema coma is a severe form of hypothyroidism, which may be life threatening without emergency medical treatment.
19. Congenital hypothyroidism is TH deficiency at birth; it occurs with thyroid agenesis and results in hypothyroidism, growth failure, and mental retardation from absence of thyroxine.
20. Papillary and follicular thyroid carcinomas are the most common thyroid malignancies probably caused by exposure to ionizing radiation, particularly during childhood. Thyroid nodules are present with normal thyroxine levels.

Alterations of Parathyroid Function

1. Hyperparathyroidism may be primary, secondary, or tertiary and is characterized by greater than normal secretion of PTH.
2. Primary hyperparathyroidism is usually caused by a parathyroid adenoma with interruption of the normal mechanisms that regulate calcium and PTH levels. Manifestations include chronic hypercalcemia, increased bone resorption, and hypercalciuria.
3. Secondary hyperparathyroidism is a compensatory response to hypocalcemia and often occurs with chronic renal failure or chronic vitamin D deficiency.
4. Tertiary hyperparathyroidism is excessive secretion of PTH and hypercalcemia that occurs after long-standing secondary hyperparathyroidism.
5. Pseudohypoparathyroidism and familial hypocalciuric hypercalcemia are inherited conditions. In pseudohypoparathyroidism there is resistance to PTH action and familial hypocalciuric hypercalcemia mimics hyperparathyroidism with failure of calcium sensing by the parathyroid gland.
6. Hypoparathyroidism, defined by abnormally low PTH levels, is caused by thyroid surgery, autoimmunity, or genetic mechanisms.
7. The lack of circulating PTH in hypoparathyroidism causes depressed serum calcium levels, increased serum phosphate levels, decreased bone resorption, and eventual hypocalciuria.

SUMMARY REVIEW—cont'd

Dysfunction of the Endocrine Pancreas: Diabetes Mellitus

1. Diabetes mellitus is a group of diseases characterized by hyperglycemia resulting from defects in insulin secretion or insulin action, or both. The two most common types of diabetes mellitus are type 1 and type 2.
2. A diagnosis of diabetes mellitus is based on glycosylated hemoglobin (HbA_{1c}) levels, fasting plasma glucose (FPG) levels, and 2-hour plasma glucose levels during oral glucose tolerance testing (OGTT).
3. Type 1 diabetes mellitus includes an autoimmune (most common) and a nonimmune type. The immune type (type 1A) is associated with genetic susceptibility, environmental factors, and autoantibody, T-cell, and macrophage destruction of pancreatic beta cells with loss of insulin production and a relative excess of glucagon. Antibodies also can be formed against glutamic acid decarboxylase and insulin. Nonimmune type diabetes (type 1B) occurs secondary to other disease.
4. A diagnosis of diabetes mellitus is based on elevated plasma glucose concentrations and classic signs and symptoms.
5. Type 2 diabetes mellitus is caused by genetic susceptibility that is triggered by environmental factors. The most compelling environmental risk factor is obesity. Insulin production continues but the weight and number of beta cells decrease.
6. Several mechanisms of insulin resistance (hyperinsulinemia) cause reduced glucose uptake and metabolism in type 2 diabetes. These mechanisms include alteration in the production of adipokines by adipose tissue (i.e., leptin resistance), elevated levels of serum free fatty acids and intracellular lipid deposits, release of inflammatory cytokines from adipose tissue, reduced insulin-stimulated mitochondrial activity, and obesity-associated insulin resistance.
7. In type 2 diabetes amylin deficiency results in increased glucagon secretion and hyperglycemia. Deposition of amyloid in the pancreas contributes to beta-cell loss.
8. Decreased ghrelin levels have been associated with insulin resistance and hyperleptinemia in type 2 diabetes.
9. Other specific types of diabetes mellitus include MODY associated with autosomal dominant gene mutations and gestational diabetes associated with onset of glucose intolerance during pregnancy.
10. Acute complications of diabetes mellitus include hypoglycemia, DKA, HHNKS, the Somogyi effect, and the dawn phenomenon.
11. Hypoglycemia is a lowered blood glucose level that may be related to exogenous (i.e., insulin shock or insulin reaction), endogenous, or functional causes.
12. Symptoms of hypoglycemia are divided into adrenergic, caused by activation of the sympathetic nervous system; and neuroglycopenic, reflecting defective central nervous system metabolism resulting from impaired energy generation.
13. DKA develops when there is an absolute or relative deficiency of insulin and an increase in the amounts of insulin counterregulatory hormones of catecholamines, cortisol, glucagon, and GH; increased lipolysis; and accelerated gluconeogenesis and ketogenesis. It is most common in type 1 diabetes, but also occurs in type 2.
14. HHNKS is pathophysiologically similar to DKA, although levels of FFAs are lower in HHNKS and lack of ketosis indicates that some level of insulin is present. The hyperosmolar state can cause osmotic diuresis and profound dehydration, causing coma.
15. The Somogyi effect is a combination of hypoglycemia with rebound hyperglycemia caused by effects of counterregulatory hormones. It is most common in persons with type 1 diabetes mellitus and in children.
16. The dawn phenomenon is an early morning rise in glucose levels caused by nocturnal elevations of GH concentration.
17. Chronic complications of diabetes mellitus are related to chronic hyperglycemia and include microvascular disease (e.g., retinopathy, nephropathy, and neuropathy), macrovascular disease (e.g., CAD, stroke, and peripheral vascular disease), and infection. Metabolic changes contributing to complications include oxidative stress, shunting of glucose to the polyol pathway, activation of protein kinase C, formation of AGEs, and accumulation of hexosamines.
18. Microvascular complications are associated with vascular alterations in the endothelium and the basement membrane as well as thrombosis.
19. Diabetic retinopathy is caused by several mechanisms including microvascular changes and thrombosis that lead to microvascular occlusion, retinal ischemia, increased vascular permeability, microaneurysm formation, hemorrhages, and neovascularization with loss of vision.
20. Diabetic nephropathy is related to hyperglycemia, hyperperfusion, oxidative stress, and inflammation with glomerular enlargement and glomerular basement membrane thickening, diffuse intercapillary glomerulosclerosis, expansion of the mesangial matrix, and progressive renal failure.
21. Diabetic neuropathies may be caused by vascular and metabolic mechanisms, or by a combination of both, with axonal and Schwann cell degeneration and abnormalities in sensory and motor nerve conduction velocity, and involvement of the autonomic nervous system.
22. Macrovascular disease associated with diabetes mellitus is associated with hyperglycemia, hyperlipidemia, inflammation, and altered endothelial function.
23. The incidence of coronary heart disease, peripheral vascular disease, and stroke is greater in persons with diabetes than in nondiabetic individuals.
24. CAD and stroke in diabetes are a consequence of accelerated atherosclerosis, hypertension, and increased risk for thrombus formation.
25. Peripheral vascular disease is a consequence of neuropathy and occlusion of large and small arteries with an increased risk of ischemia, necrosis, and amputation.

SUMMARY REVIEW—cont'd

26. Individuals with diabetes are at risk for a variety of infections related to sensory impairment, vascular complications, impaired white blood cells and suppressed immunity, rapid proliferation of pathogens, and delayed wound healing.

Alterations of Adrenal Function

1. Disorders of the adrenal cortex are related to hyperfunction or hypofunction. No known disorders are associated with hypofunction of the adrenal medulla, but medullary hyperfunction causes clinically defined syndromes.
2. Hypercortisolism is divided into ACTH-dependent (Cushing disease or ectopic ACTH syndrome) and ACTH-independent (adrenal adenoma or adenocarcinoma) mechanisms.
3. Cushing disease is excessive anterior pituitary ACTH production most commonly by an ACTH-secreting pituitary microadenoma.
4. Cushing syndrome occurs whenever there is an excessive level of cortisol regardless of cause. Exogenous forms result from exogenous administration of glucocorticoids. Endogenous forms are either corticotropin dependent (most common and caused by an ACTH-secreting pituitary tumor) or corticotropin independent (usually caused by an adrenal cortical tumor).
5. Individuals with Cushing disease lose diurnal and circadian patterns of ACTH and cortisol secretion, and they lack the ability to increase secretion of these hormones in response to a stressor. Individuals experience weight gain, glucose intolerance, protein wasting, bone disease, hyperpigmentation, and immunosuppression.
6. Congenital adrenal hyperplasia is an autosomal recessive disorder with inadequate synthesis of cortisol and increased levels of ACTH that cause adrenal hyperplasia and overproduction of mineralocorticoids or androgens.
7. Primary hyperaldosteronism is a disorder of excessive aldosterone secretion usually caused by an adrenal cortical adenoma or bilateral nodular hyperplasia. The condition is characterized by hypertension, hypokalemia, renal potassium wasting, and neuromuscular manifestations.
8. Secondary hyperaldosterone secretion is related to a variety of conditions associated with elevated renin release and activation of angiotensin II. These include decreased circulating blood volume, decreased renal blood supply, elevated estrogen levels, Bartter syndrome, and renin-secreting tumors.
9. Adrenal tumors, either adenomas or carcinomas, can autonomously secrete androgens or estrogens.
10. Hypofunction of the adrenal cortex can affect glucocorticoid or mineralocorticoid secretion or both. Hypofunction can be caused by a deficiency of ACTH or by a primary deficiency in the gland itself.
11. Hypocortisolism (low levels of cortisol) is caused by inadequate adrenal stimulation by ACTH or by primary cortisol hyposecretion. Primary adrenal insufficiency is termed Addison disease.
12. Addison disease is characterized by elevated ACTH levels with inadequate corticosteroid synthesis and output. Causes include idiopathic autoimmune disease, tuberculosis of the adrenal gland, familial adrenal insufficiency, amyloidosis, metastatic destruction of the adrenal glands, and adrenal hemorrhage.
13. Manifestations of Addison disease are related to hypocortisolism and hypoaldosteronism. Symptoms include weakness, fatigability, hypoglycemia and related metabolic problems, lowered response to stressors, vitiligo, hyperpigmentation, and manifestations of hypovolemia and hyperkalemia.
14. Secondary hypercortisolism is characterized by low to absent ACTH levels, leading to inadequate adrenal stimulation, adrenal atrophy, and decreased corticosteroidogenesis. The most common cause is withdrawal of exogenous administration of glucocorticoids. Manifestations are similar to those of Addison disease only without hyperpigmentation.
15. Hyperfunction of the adrenal medulla is caused by a pheochromocytoma, which is a catecholamine-producing tumor. Symptoms of catecholamine excess are related to their sympathetic nervous system effects and include hypertension, palpitations, tachycardia, glucose intolerance, excessive sweating, and constipation.

- Review Questions and Answers

CHAPTER OUTLINE

The male and female reproductive systems have several anatomic and physiologic features in common. Most obvious is their major function, reproduction, through which a 23-chromosome female gamete, the **ovum,** and a 23-chromosome male gamete, the **spermatozoon (sperm cell),** unite to form a 46-chromosome zygote that is capable of developing into a new individual. The male reproductive system produces sperm and delivers them to the female reproductive tract. The female reproductive system produces the ovum and, if it is fertilized, can nurture and protect it (at that point called the **embryo** and **developing fetus**) and expel it at birth. These functions are determined not only by anatomic structures but also by complex hormonal, neurologic, and psychogenic factors.[1]

*Angela Deneris contributed to the previous edition.

DEVELOPMENT OF THE REPRODUCTIVE SYSTEMS

The structure and function of male and female reproductive systems depend on steroid hormones called **sex hormones** and their precursors. Hormonal effects on the reproductive systems begin well before birth and continue for life.

Sexual Differentiation and Hormone Production In Utero

Initially in embryonic development, the reproductive structures of male and female embryos are homologous (the same) and consist of one pair of primary sex organs, or **gonads,** and two pairs of ducts, the mesonephric ducts (wolffian ducts) and the paramesonephric ducts (müllerian ducts) (Figure 23-1). Both pairs of ducts empty into an opening called the *urogenital sinus.*

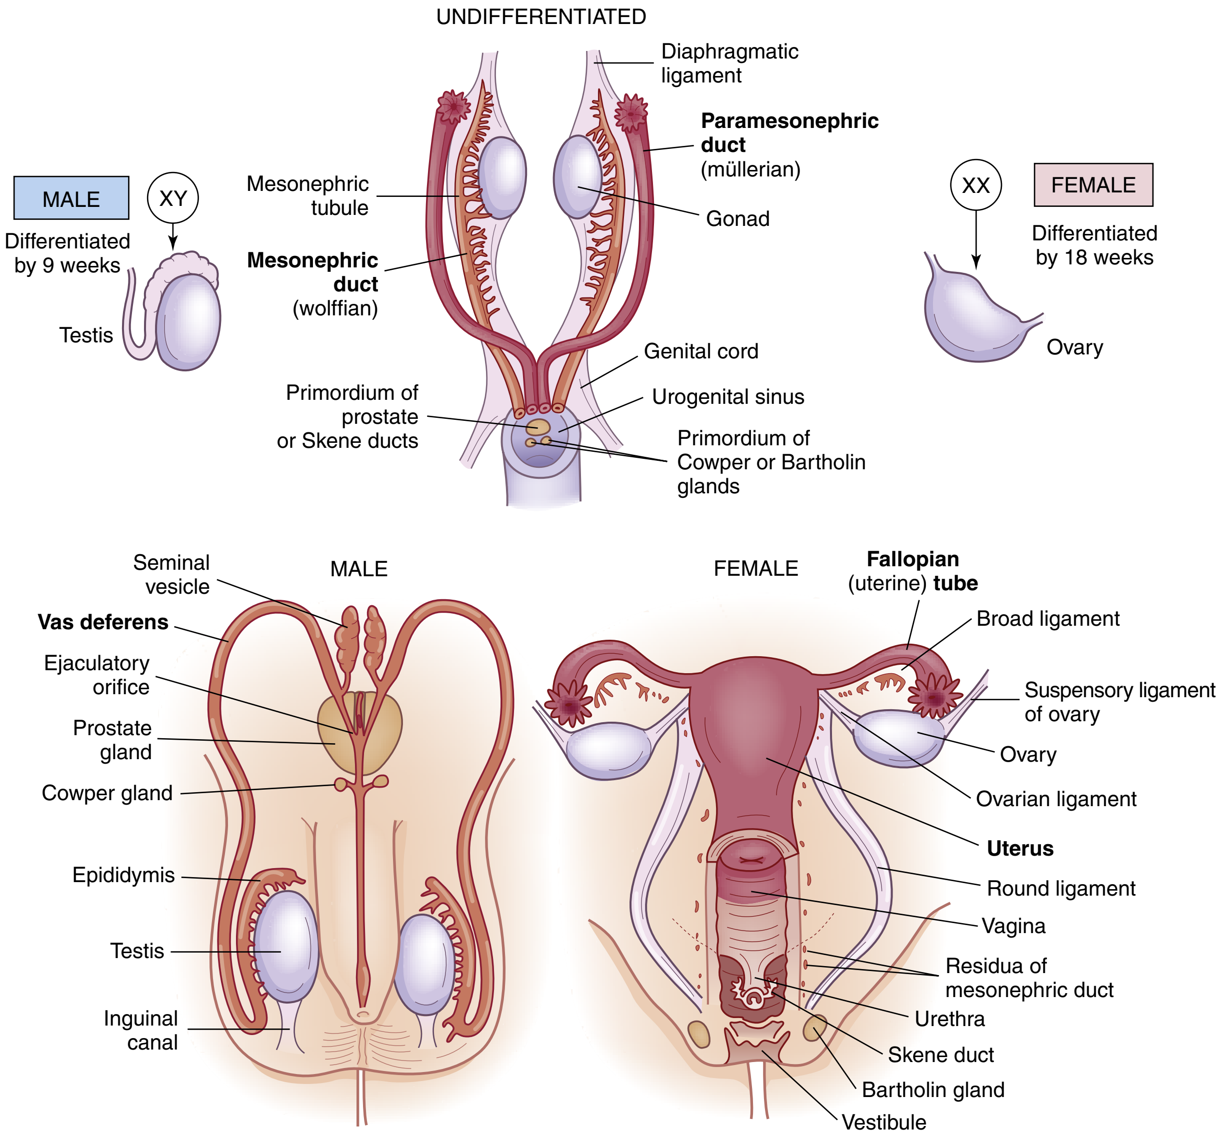

FIGURE 23-1 Internal Genitalia Development. Embryonic and fetal development of the internal genitalia.

Between 6 and 7 weeks of gestation, the male embryo will differentiate under the influence of testes-determining factor (TDF), a protein expressed by a gene in the sex-determining region on the Y chromosome (SRY). When the *SRY* gene is expressed, male gonadal development prevails. TDF stimulates the male gonads to develop into the two testes and by 8 weeks of gestation testosterone secretion begins. By 9 months' gestation, the male gonads (testes) have descended into the scrotum. The testes produce sperm after puberty.

Female gonadal development occurs in the absence of *SRY* expression and with the expression of other genes.[2] The presence of *estrogen* and the absence of *testosterone* cause regression of the wolffian system and, at 6 to 8 weeks' gestation, the two female gonads develop into ovaries, which will produce ova. By the tenth week, the loss of wolffian ducts allows the müllerian ducts to join and become the uterus, fallopian tubes, cervix, and upper two thirds of the vagina. The fallopian tubes carry ova from the ovaries to the uterus during a woman's reproductive years.

Like the internal reproductive structures, the external structures develop from homologous embryonic tissues. During the first 7 to 8 weeks of gestation, both male and female embryos develop an elevated structure called the *genital tubercle* (Figure 23-2). **Testosterone** is necessary for the genital tubercle to differentiate into male genitalia; otherwise, female genitalia develop, which may occur even in the absence of ovaries possibly because of the presence of placental estrogens.

Anterior pituitary gland development starts between the 4th and 6th weeks of fetal life, and the vascular connection between the hypothalamus and the pituitary is established by the 12th week. **Gonadotropin-releasing hormone (GnRH)** is produced in the hypothalamus by 10 weeks' gestation and controls the production of two gonadotropins by the anterior pituitary gland, **luteinizing hormone (LH)** and **follicle-stimulating hormone (FSH).** In the female fetus, high levels of FSH and LH are excreted. FSH and LH stimulate the production of estrogen and progesterone by the ovary. The production of FSH and LH rises until about 28 weeks' gestation, until the production of

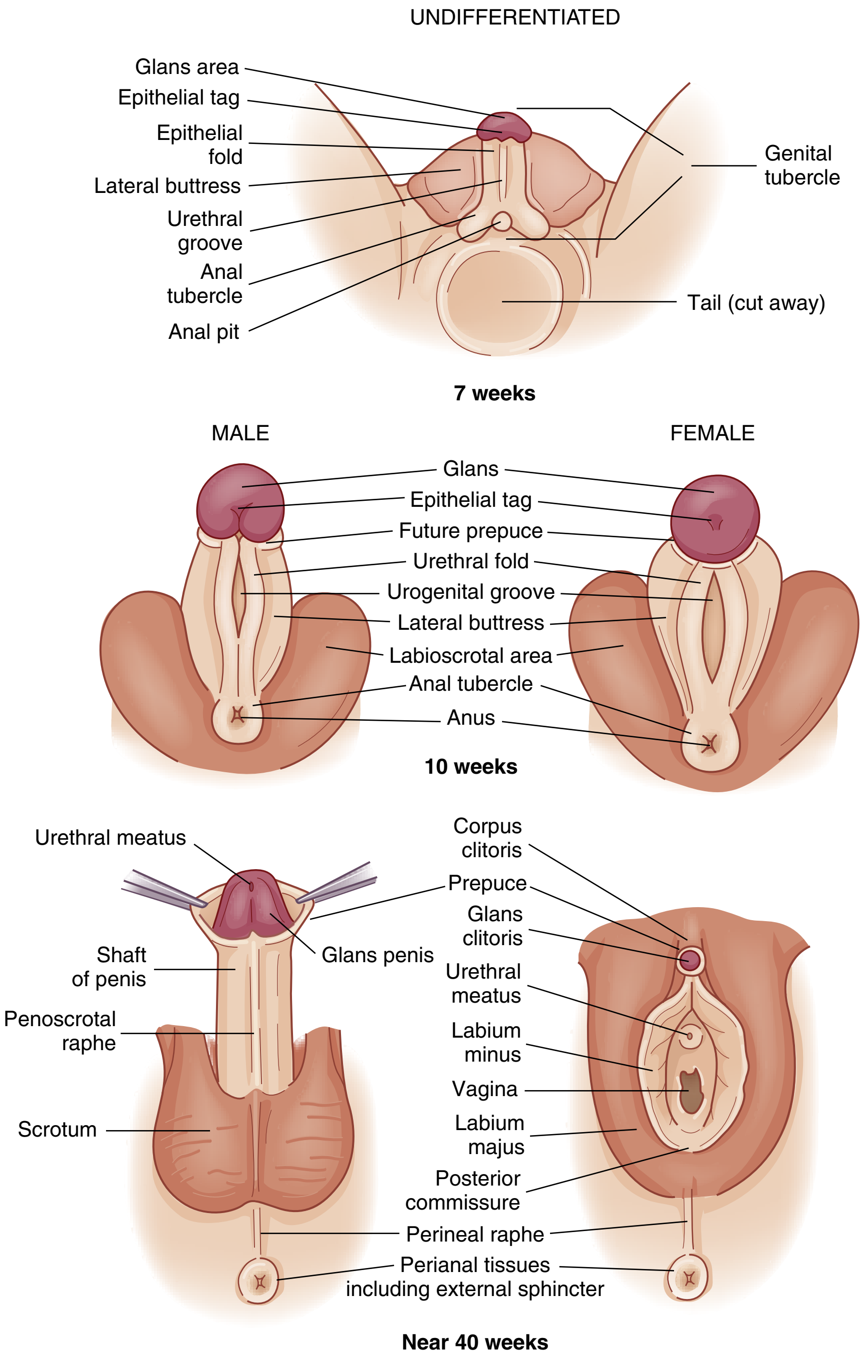

FIGURE 23-2 **External Genitalia Development.** Embryonic and fetal development of the external genitalia.

estrogen and progesterone by the ovaries and placenta is high enough to result in the decline of gonadotropin production.[1] Production of primitive female gametes (ova) occurs solely during fetal life. From puberty to menopause, one female gamete matures per menstrual cycle. Production of the male gametes (sperm) begins at puberty; after that millions are produced daily, usually for life.

By the end of pregnancy a sensitive negative-feedback system, which includes the **gonadostat** (also known as the **gonadotropin-releasing hormone pulse generator**), is operative in the human fetus. The gonadostat responds to high placental estrogens by releasing low levels of GnRH. Soon after birth steroid hormones levels drop because of withdrawal of maternal placental hormones. Hypothalamic pulsatile GnRH is secreted and gonadotropins LH and FSH are released and peak at 3 to 6 months for boys and 12 to 18 months for girls, and then fall steadily. The gonadotropins will be suppressed until the onset of puberty.

Puberty and Reproductive Maturation

Puberty is the onset of sexual maturation and differs from adolescence. Adolescence is the stage of human development

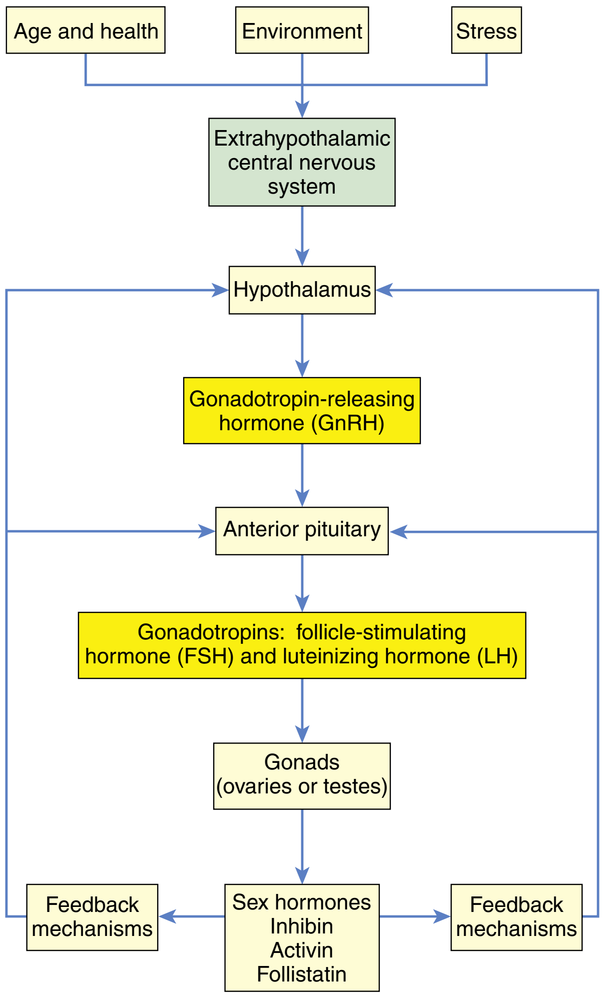

FIGURE 23-3 Hormonal Stimulation of the Gonads. The hypothalamic-pituitary-gonadal axis.

between childhood and adulthood and includes social, psychologic, and biologic changes. In girls, puberty begins at about ages 8 to 9 years with thelarche (breast development). In boys, it begins later—at about age 11 years. Genetics, environment, ethnicity, general health, and nutrition can influence the timing of puberty. Girls who are obese mature earlier, perhaps from higher estrogen levels related to leptin and gonadotropin secretion,[3] and girls who have low body fat, reduced body weight, and intense exercise may experience delayed maturation.[4] Although leptin is not the trigger for puberty onset, it plays an important permissive role.

Reproductive maturation involves the hypothalamic-pituitary-gonadal (HPG) axis, the central nervous system, and the endocrine system (Figure 23-3). A sequential series of hormonal events promotes sexual maturation as puberty approaches. About 1 year before puberty in girls, there is an increase in frequency and amplitude of nocturnal pulses of gonadotropin secretion, LH, and FSH and an increased response in the pituitary to GnRH. This, in turn, stimulates gonadal maturation **(gonadarche)** with estradiol secretion in girls and testosterone secretion in boys. Estradiol causes breast development **(thelarche),** maturation of the reproductive organs (vagina, uterus, ovaries), and fat deposit in hips in girls. Estrogen and increased production of growth factors cause rapid skeletal growth in both boys and girls. Testosterone causes growth of the testes, scrotum, and penis. A positive feedback loop is created with gonadotropins stimulating the gonads to produce more sex hormones. The most important hormonal effects occur in the gonads. In males the testes begin to produce mature sperm that are capable of fertilizing an ovum. Male puberty is complete with the first ejaculation that contains mature sperm. In females, the ovaries begin to release mature ova. Female puberty is complete with the first ovulatory menstrual period; however, this can take up to 1 to 2 years after menarche. **Adrenarche** is the increased production of adrenal androgens (dehydroepiandrosterone and androstenedione, which is converted to testosterone and estrogen) prior to puberty, which occurs in both sexes, and is exhibited by axillary and pubic hair growth and body odor. Puberty is complete when an individual is capable of reproduction.

THE FEMALE REPRODUCTIVE SYSTEM

The function of the reproductive system is to produce mature ova and, when they are fertilized, protect and nourish them through embryonic and fetal life and expel them at birth. In females the most important internal reproductive organs in females are the ovaries, fallopian tubes, uterus, and vagina. The external genitalia protect body openings and play an important role in sexual functioning.[1,5,6]

External Genitalia

Figure 23-4 shows the external female genitalia, which are known collectively as the **vulva,** or pudendum. The major structures are as follows:

- **Mons pubis** (*mons veneris*). A fatty layer of tissue over the pubic symphysis (joint of the pubic bones). During puberty the mons pubis becomes covered with pubic hair, and sebaceous and sweat glands become more active. Estrogen causes fat to be deposited under the skin, giving the mons pubis a moundlike shape. This cushion of tissue protects the pubic symphysis during sexual intercourse.
- **Labia majora** (*singular,* **labium majus**). Two folds of skin that arise at the mons pubis and extend back to the fourchette, forming a cleft. Like the mons pubis, the labia majora undergo changes at puberty: the amount of fatty tissue increases, pubic hair grows on the lateral surfaces, and sebaceous glands on the hairless medial surfaces begin to secrete lubricants. Because of an extensive network of nerve endings, the labia majora are highly sensitive to temperature, touch, pressure, and pain and are homologous to the male scrotum (see Figures 23-2 and 23-15). The principal function of the labia majora is to protect the inner structures of the vulva.
- **Labia minora** (*singular,* **labium minus**). Two smaller, thinner folds of skin lie within the labia majora. Anteriorly they form the clitoral hood, or prepuce, and frenulum then split to enclose the vestibule and converge near the anus, forming the fourchette. The labia minora are hairless, pink, and

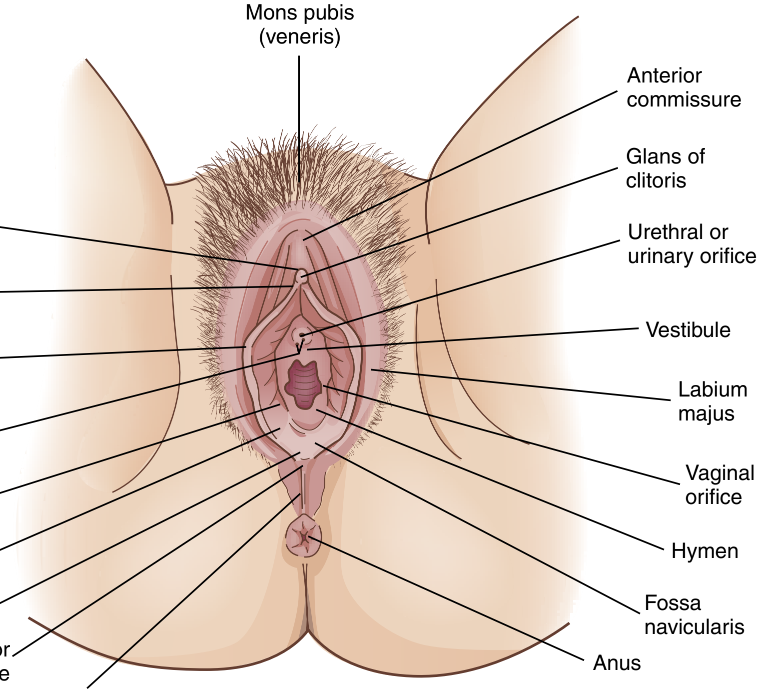

FIGURE 23-4 External Female Genitalia.

moist and are well supplied with nerves, blood vessels, and sebaceous glands. These glands secrete a bactericidal fluid that has a distinctive odor and lubricates and waterproofs the vulvar skin. During sexual arousal the labia minora become swollen with blood.

- **Clitoris.** A richly innervated, erectile organ that lies anterior between the labia minora. It is a small, cylindric structure having a glans that is visible and a shaft that lies beneath the skin (see Figure 23-4). The clitoris is homologous to the male penis. Like the penis the clitoris is a major site of sexual stimulation and orgasm. With sexual arousal erectile tissues in the clitoris fill with blood, causing it to enlarge somewhat. Similar to other vulvar glands, the clitoris secretes a fluid, called *smegma,* which has a unique odor and may be erotically stimulating to the male.
- **Vestibule.** An area protected by the labia minora and contains the external opening of the vagina, called the **introitus,** or vaginal orifice. A thin, perforated membrane called the **hymen** may cover the introitus. The vestibule also contains the opening of the urethra, or **urinary meatus** (orifice). These structures are lubricated by two pairs of glands: Skene glands and Bartholin glands. The ducts of **Skene glands** (also called the **lesser vestibular** or **paraurethral glands**) open on both sides of the urinary meatus. The ducts of **Bartholin glands** (**greater vestibular** or **vulvovaginal glands**) open on either side of the introitus. In response to sexual stimulation, Bartholin glands secrete mucus that lubricates the inner labial surfaces, as well as enhances the viability and motility of sperm. Skene glands help lubricate the urinary meatus and the vestibule. Secretions from both sets of glands facilitate coitus. Also, in response to sexual excitement, the highly vascular tissue just beneath the vestibule fills with blood and becomes engorged.
- **Perineum.** An area with less hair, skin, and the subcutaneous tissue lying between the vaginal orifice and anus. Unlike the rest of the vulva, this area has little subcutaneous fat so that the skin is close to the underlying muscles. The perineum covers the muscular **perineal body,** a fibrous structure that comprises elastic fiber, connective tissue, and the common attachment of the **bulbocavernosus,** the external anal sphincter, and the levator ani muscles (see Figure 23-4). The perineum varies in length from 2 to 5 cm or more and stretches remarkably. The length of the perineum and the elasticity of the perineal body influence tissue resistance and injury during childbirth.

Internal Genitalia

Vagina

The **vagina** is an elastic fibromuscular canal, 9 to 10 cm long in a reproductive-aged female, which extends up and back from the introitus to the lower portion of the uterus. As Figure 23-5 shows, it lies between the urethra (and part of the bladder) and the rectum. Mucosal secretions from the upper genital organs, menstrual fluids, and products of conception leave the body through the vagina, which also receives the penis during coitus. During sexual excitement the vagina lengthens and widens and the lower third becomes congested with blood.

The vaginal wall is composed of four layers:

1. Its lining is a mucous membrane of squamous epithelial cells. (Types of epithelium are described and illustrated in Chapter 1, Table 1-7.) This layer thickens and thins in response to hormones, particularly estrogen. The

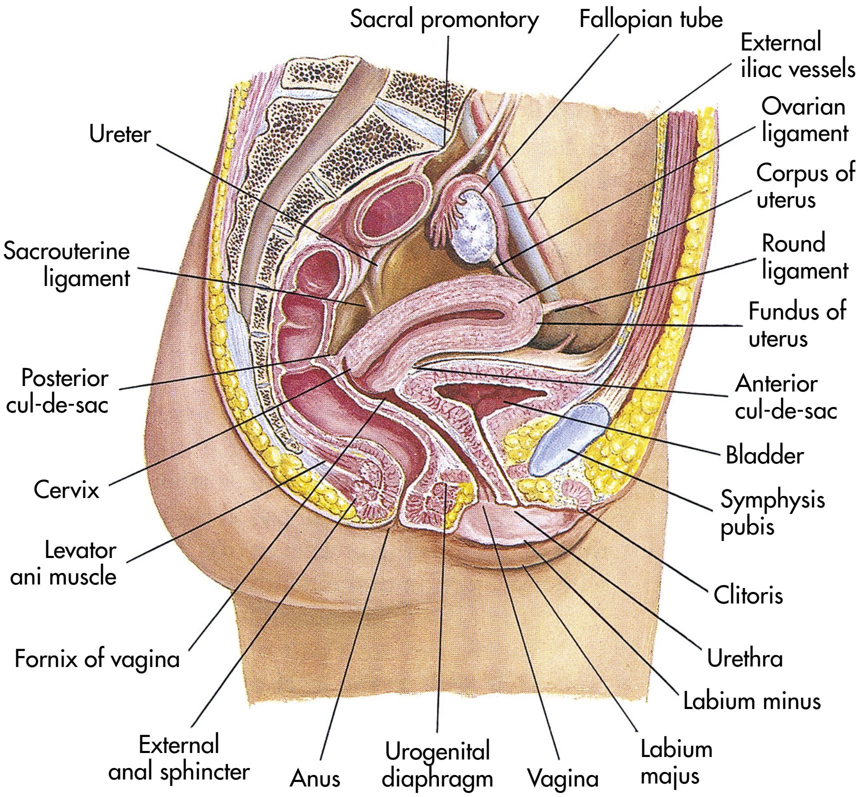

FIGURE 23-5 Internal Female Genitalia and Other Pelvic Organs. Midsagittal view. (Modified from Seidel HM et al: *Mosby's guide to physical examination,* ed 7, St Louis, 2011, Mosby.)

squamous epithelial membrane is continuous with the membrane that covers the lower part of the uterus. In women of reproductive age, the mucosal layer is arranged in transverse wrinkles, or folds, called **rugae** (*singular,* **ruga**) that permit stretching during coitus and childbirth.

2. Fibrous connective tissue containing numerous blood and lymphatic vessels
3. Smooth muscle
4. Connective tissue and a rich network of blood vessels.

The upper part of the vagina surrounds the cervix, the lower end of the uterus (see Figure 23-5). The recessed space around the cervix is called the **fornix** of the vagina. The posterior fornix is "deeper" than the anterior fornix because of the angle at which the cervix meets the vaginal canal. In most women this angle is about 90 degrees. A pouch called the **cul-de-sac** separates the posterior fornix and the rectum.

Its elasticity and relatively sparse nerve supply enhance the vagina's function as the birth canal. During sexual arousal the vaginal wall becomes engorged with blood, like the labia minora and clitoris. Engorgement pushes some fluid to the surface of the mucosa, enhancing lubrication. The vaginal wall does not contain mucus-secreting glands; rather, secretions drain into the vagina from the endocervical glands or enter from the vestibule, from the Bartholin and Skene glands.

Two factors help maintain the self-cleansing action of the vagina and defend it from infection, particularly during the reproductive years: (1) an acid-base balance that discourages the proliferation of most pathogenic bacteria and (2) the thickness of the vaginal epithelium. Before puberty, vaginal pH is about 7 (neutral) and the vaginal epithelium is thin. At puberty the pH becomes more acidic (4 to 5) and the squamous epithelial lining thickens. These changes are maintained until menopause (cessation of menstruation), at which time the pH rises again to more alkaline levels and the epithelium thins out. Therefore, protection from infection is greatest during the years when a woman is most likely to be sexually active. Between puberty and menopause, vulnerability to infection varies somewhat with cyclic changes in pH and epithelial thickness. Both defenses are greatest when estrogen levels are high and the vagina contains a normal population of *Lactobacillus acidophilus,* a harmless resident bacterium that helps maintain pH at acidic levels. Any condition that causes vaginal pH to rise, such as douching or use of vaginal sprays or deodorants, low estrogen levels, or destruction of *L. acidophilus* by antibiotics, lowers vaginal defenses against infection.

Uterus

The **uterus** is a hollow pear-shaped organ whose lower end opens into the vagina. The functions of the uterus are to anchor and protect a fertilized ovum, provide an optimal environment while it develops, and push the fetus out at birth. In addition, the uterus plays an important role in sexual response and conception. During sexual excitement the opening of the uterus (the cervix) dilates slightly. At the same time, the uterus increases in size and moves upward and backward, creating a tenting effect in the midvagina that results in the cervix "sitting" in a pool of

semen. During orgasm, rhythmic contractions facilitate movement of sperm through the cervical os while also enhancing physical pleasure.

At puberty the uterus attains its adult size and proportions and descends from the abdomen to the lower pelvis, between the bladder and the rectum (see Figure 23-5). The uterus of a mature, nonpregnant female is approximately 7 to 9 cm long and 6.5 cm wide, with muscular walls 3.5 cm thick. It is held loosely in position by ligaments, peritoneal tissue folds, and pressure of adjacent organs, especially the urinary bladder, sigmoid colon, and rectum. In most women the uterus is anteverted; that is, it is tipped forward so that it rests on the urinary bladder. However, it may be retroverted, or tipped backward. Various degrees of flexion are normal (Figure 23-6).

Figure 23-7 shows a cross section of the uterus. The uterus has two major parts: the body, or **corpus,** and the cervix. The top of the corpus, above the insertion of the fallopian tubes, is called the **fundus.** The diameter of the uterine cavity is widest at

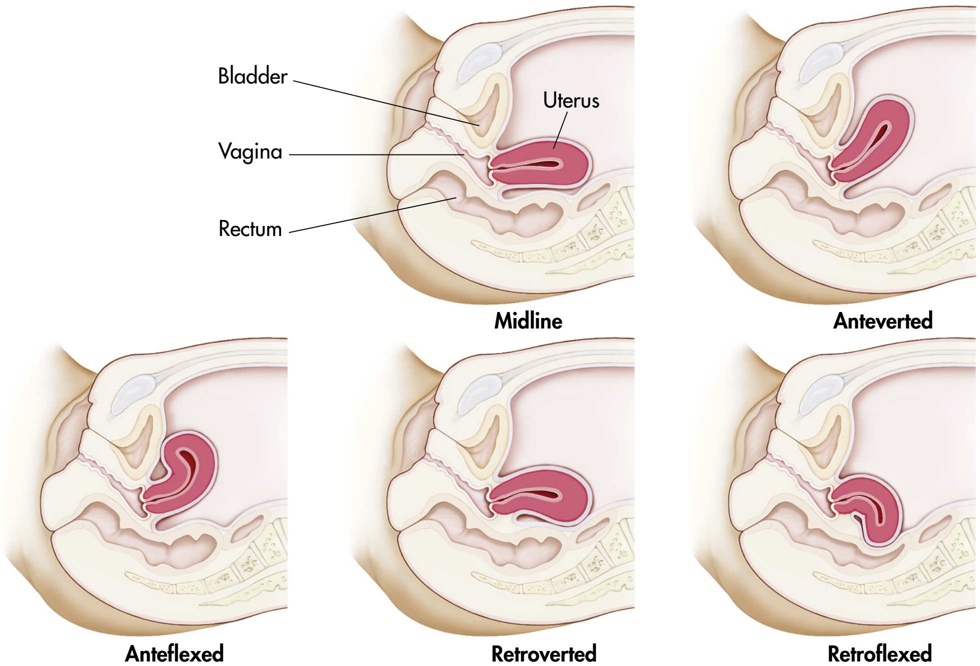

FIGURE 23-6 Variations in Uterine Position.

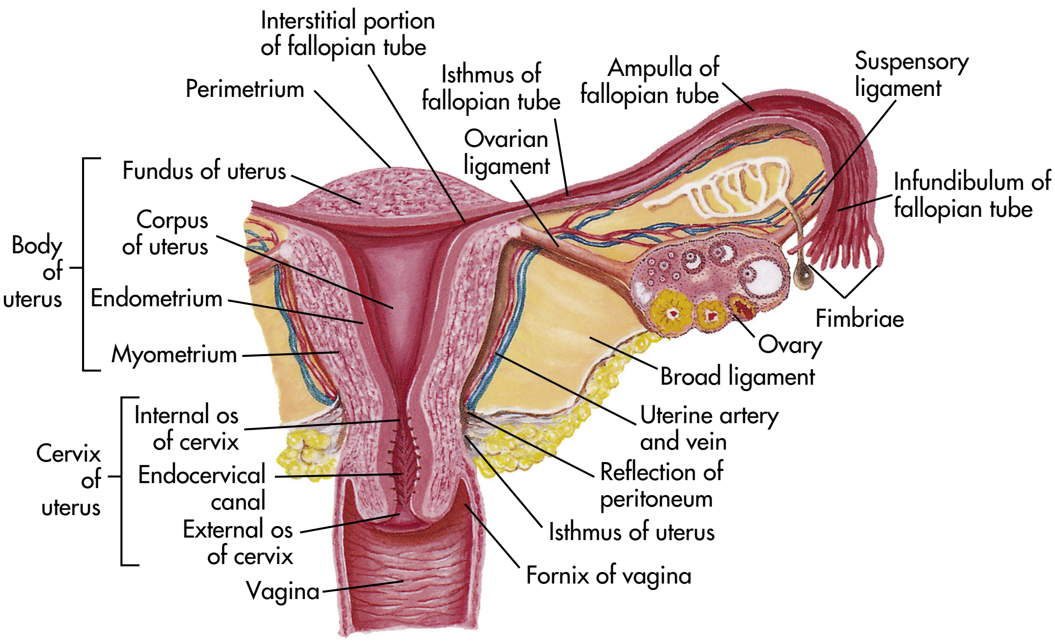

FIGURE 23-7 Cross Section of Uterus, Fallopian Tube, and Ovary. (From Seidel HM et al: *Mosby's guide to physical examination,* ed 7, St Louis, 2011, Mosby.)

the fundus and narrowest at the **isthmus,** which is the narrowed part of the corpus just above the cervix. The **cervix,** or neck of the uterus, extends from the isthmus to the vagina. The passageway between the cervix's upper opening (the internal os) and its lower opening (the external os) is called the **endocervical canal.** The entire uterus, like the upper vagina, is innervated exclusively by motor and sensory fibers of the autonomic nervous system.

The uterine wall is composed of three layers: the perimetrium, the myometrium, and the endometrium (see Figure 23-7). The **perimetrium (parietal peritoneum)** is the outer serous membrane that covers the uterus. The **myometrium** is the thick muscular middle layer. The myometrium is thickest at the fundus, apparently to facilitate birth. The **endometrium,** or uterine lining, is composed of a functional layer (superficial compact layer and spongy middle layer) and a basal layer. The functional layer of the endometrium is responsive to sex hormones. Between puberty and menopause this layer proliferates and sloughs off monthly. The basal layer, which is attached to the myometrium, regenerates the functional layer after it sloughs (menstruation).

The endocervical canal does not have an endometrial layer. Rather, it is lined with columnar epithelial cells (see Table 1-7). The endocervical lining is continuous with that of the outer cervix and vagina, but it is not made up of the same type of epithelial cells. The point at which the columnar epithelium of the cervix meets the squamous epithelium of the vagina is called the *transformation zone,* or the **squamous-columnar junction.** The transformation zone is especially susceptible to the oncogenic human papillomavirus (HPV), especially HPV types 16 and 18, which can lead to cervical dysplasia and, ultimately, cervical cancer (see What's New? Human Papillomavirus (HPV) Vaccine and Cancer Prevention in Women and Men); these are the cells sampled during the Papanicolaou test (Pap test).[7]

The cervix acts as a mechanical barrier to infectious microorganisms that may be present in the vagina. The external cervical os is a very small opening that contains thick, sticky mucus (the *mucous plug*) during the luteal phase of the menstrual cycle and all of pregnancy. During ovulation the mucus changes under the influence of estrogen and forms watery strands, or spinnbarkeit mucus, to facilitate the transport of sperm into the uterus. In addition, the downward flow of cervical secretions moves microorganisms away from the cervix and uterus. In women of reproductive age, the pH of these secretions is inhospitable to most bacteria. Furthermore, mucosal secretions contain enzymes and antibodies (mostly immunoglobulin A) of the secretory (humoral) immune system (see Chapter 8). These defenses do not always prevent infection, even if they are intact. Besides infection, uterine pathophysiology includes displacement of the uterus within the pelvis, benign growths (fibroids) of the uterine wall, hyperplasia of the endometrium, endometriosis, and cancer.

Fallopian Tubes

The two **fallopian tubes (oviducts, uterine tubes)** enter the uterus bilaterally just beneath the fundus (see Figure 23-7). Their function is to conduct the ova from the spaces around the ovaries to the uterus. From the uterus the fallopian tubes curve up and over the two ovaries. Each tube is 8 to 12 cm long and about 1 cm in diameter, except at its ovarian end, which flares out like the bell of a trumpet. This widened end, called the **infundibulum,** is fringed or fimbriated. The **fimbriae** (*singular,* **fimbria**) (fringes) move, creating a current that draws the ovum into the infundibulum. Once the ovum has entered the fallopian tube, cilia and peristalsis (muscle contractions) keep it moving toward the uterus.

The ampulla, or distal third, of the fallopian tube is the usual site of fertilization (see Figure 23-7). Sperm released into the vagina travel upward through the endocervical canal and uterine cavity and enter the fallopian tubes. If an ovum is present in either tube, fertilization can occur. Whether or not the ovum encounters sperm, it continues to travel through the fallopian tube to the uterus. If fertilized, the ovum (then called a *blastocyst*) implants itself in the endometrial layer of the uterine wall. If not fertilized, the ovum breaks down within 12 to 24 hours.

WHAT'S NEW?

Human Papillomavirus (HPV) Vaccine and Cancer Prevention in Women and Men

Two HPV vaccines are approved in the United States: the quadrivalent HPV recombinant vaccine in males and females (HPV 6, 11, 16, and 18); and the bivalent HPV recombinant vaccine (HPV 16 and 18) in females. HPV types 16 and 18 are oncogenic and can cause cervical dysplasia, cervical cancer, anal cancer, penile cancer, and cancer of the head and neck. Types 6 and 11 cause genital warts. HPV is responsible for 99.7% of cervical cancer cases, 40% of penile cancers, and an estimated 5% of all cancers worldwide. Symptoms of infection are often silent, and approximately 50% of women are estimated to be infected, usually during adolescence. Men who have sex with men are at high risk. The incidence of genital warts and cancer is reduced in those receiving the vaccine. The vaccine is administered by intramuscular injection and the recommended schedule is a three-dose series with the second and third doses administered 2 and 6 months after the first dose. The recommended age for vaccination of females is 11 to 12 years. The vaccine can be administered as young as age 9 years. Catch-up vaccination is recommended for females ages 13 to 26 years who have not been previously vaccinated. The vaccine is not disease treatment, and disease may develop related to non–vaccine-related HPV infection. Pap smear screening for cervical cancer should be continued. Efforts are in progress to make the vaccine affordable in less-developed countries, with the hope of eradicating cervical cancer.

Vaccination programs target women to prevent cervical cancer. The quadrivalent vaccine has been approved for males 9 to 26 years of age to prevent genital warts. Rates of vaccination among men and low income minority women are low, and education and financing efforts need to be expanded for these groups. Cost effectiveness of vaccinating men is controversial. There are no antiviral therapies for this disease.

Data from Alexander KA, Giuliano AR: *Am J Med* 125(7):S1, 2012; Fontenot HB, Morelock N: *Nurs Womens Health* 16(1):57–65, 2012; Laz TH, Rahman M, Berenson AB: *Cancer* 119(7):1386–1392, 2013; Low GM et al: *Viral Immunol* 25(3):174–186, 2012; Stanley MA: *J Gen Virol* 93(Pt 4):681–691, 2012; Stupiansky NW, Alexander AB, Zimet GD: *Curr Opin Infect Dis* 25(1):86–91, 2012.

Disorders that affect the fallopian tubes (e.g., congenital malformations, infection, and inflammation) can block the path of sperm and ovum and cause infertility or ectopic (tubal) pregnancy.

Ovaries

The **ovaries,** the female gonads, are the primary female reproductive organs. Their two main functions are secretion of female sex hormones and development and release of female gametes, or ova.

The almond-shaped ovaries are located on both sides of the uterus and are suspended and supported by the mesovarian portions of the broad ligament, ovarian ligaments, and suspensory ligaments (see Figure 23-7). The ovaries are smaller than their male homologs, the testes. In women of reproductive age, each ovary is 3 to 5 cm long, 2.5 cm wide, and 2 cm thick and weighs 4 to 8 g. Size and weight vary somewhat from phase to phase of the menstrual cycle (see p. 778).

Figure 23-8, *A* shows a cross section of an ovary. The central part, or medulla, is composed of connective tissue and contains many small arteries, veins, and lymphatics that enter at the hilum. Surrounding the medulla is the cortex. At birth the cortex of each ovary contains approximately 2 million ova within primordial (immature) **ovarian follicles.** Follicles grow and undergo atresia continuously and irrevocably throughout a woman's life. By puberty the number ranges between 300,000 and 500,000 ova. Between puberty and menopause the ovarian cortex always contains follicles and ova in various stages of development, including the primary and secondary follicles (see Figure 23-8, *A*). Once every menstrual cycle (about every 28 days), usually only one of the follicles reaches maturation (see Figure 23-8, *B* and *C*) and discharges its ovum through the ovary's outer covering, the germinal epithelium. During the reproductive years, 400 to 500 ovarian follicles mature completely and release an ovum **(ovulation).** The rest either fail to develop at all or degenerate without maturing completely and are known as atretic follicles[1] (see Figure 23-8).

After release of the mature ovum (ovulation), the follicle develops into another structure, the **corpus luteum** (see Figure 23-8). The immediate fate of the corpus luteum depends on whether the ejected ovum is fertilized. If fertilization occurs, the corpus luteum enlarges and begins to secrete hormones that maintain and support pregnancy. If fertilization does not occur, the corpus luteum secretes these hormones for approximately 14 days and then degenerates, which triggers the maturation of another follicle. The **ovarian cycle**—the process of follicular maturation, ovulation, corpus luteum development, and corpus luteum degeneration—is continuous from puberty to menopause, except during pregnancy or hormonal contraceptive use. At menopause this process ceases and the ovaries atrophy to the point that they cannot be felt during pelvic examination.

Sex hormones are secreted by cells within the ovarian cortex including two types of cells in the ovarian follicle (**theca cells** and **granulosa cells**) and cells of the corpus luteum (see Figure 23-8). These cells all contain receptors for the gonadotropins (LH, FSH) or for the sex hormones, which are discussed in the next section.

Female Sex Hormones

The sex hormones are all steroid hormones and are synthesized from cholesterol (see Chapter 21). Male and female sex hormones are present in all adults. However, the female body contains low levels of testosterone and other androgens, and the male body contains low levels of estrogen. Individual effects of sex hormones depend on their amount and concentration in the blood.

The dominant female sex hormones, estrogen and progesterone, are produced primarily by the ovaries. During fetal development, infancy, and childhood, sex hormone production is low. At puberty hormone production surges, triggering sexual maturation and development of secondary sex characteristics. From puberty to menopause, the sex hormones control the menstrual cycle and are produced cyclically, that is, production surges and diminishes monthly, creating the ovarian and uterine changes associated with the menstrual cycle. These hormones also are produced in higher levels during pregnancy by the placenta, inhibiting ovulation. Androgens are produced in small amounts by the ovaries and the adrenals and have important functions in women.

Estrogens and Androgens

Estrogen is a generic term for three similar hormones: estradiol, estrone, and estriol. **Estradiol (E_2)** is the most potent and plentiful of the three and is principally produced (95%) by the ovaries (ovarian follicle and corpus luteum). Androgens are converted to estrone in the ovary and peripheral adipose tissue. Estriol is the peripheral metabolite of estrone and estradiol.

Estrogen has numerous biologic effects, many of which involve interactions with other hormones, and is needed for maturation of reproductive organs, development of secondary sex characteristics (differentiating male and female physical characteristics that are not directly related to reproduction), closure of long bones after the pubertal growth spurt, regulation of the menstrual cycle, and endometrial regeneration after menstruation. Estrogen also has metabolic effects on the bones, liver, blood vessels, brain and central nervous system, kidneys, and skin. After menopause ovarian production of estradiol and estrone is markedly diminished (see Menopause, p. 791). At this time the majority of estrogen is derived from extraovarian and extraglandular production of estrones.[1]

Like other steroid hormones, estrogens are derived from cholesterol in a complex, enzyme-mediated series of reactions. (Mechanisms of hormone synthesis and action are described in Chapter 21.) The hypothalamus secretes GnRH in a pulsatile manner that stimulates gonadotropin (LH and FSH) release from the anterior pituitary. Gonadotropins trigger ovarian production of estrogen. The primary function of LH is to stimulate theca cells of the ovarian follicle to produce androgens, mainly androstenedione. (Androgens are discussed further on p. 789 and in the section on male reproductive function.) Some of these androgens are converted to estrogen by the theca cells themselves, and others diffuse into the granulosa cells. Within the granulosa layer, FSH induces conversion (aromatization) of androgens to estrogens. Estrogens are then released into the bloodstream. Estrogen and FSH together increase FSH

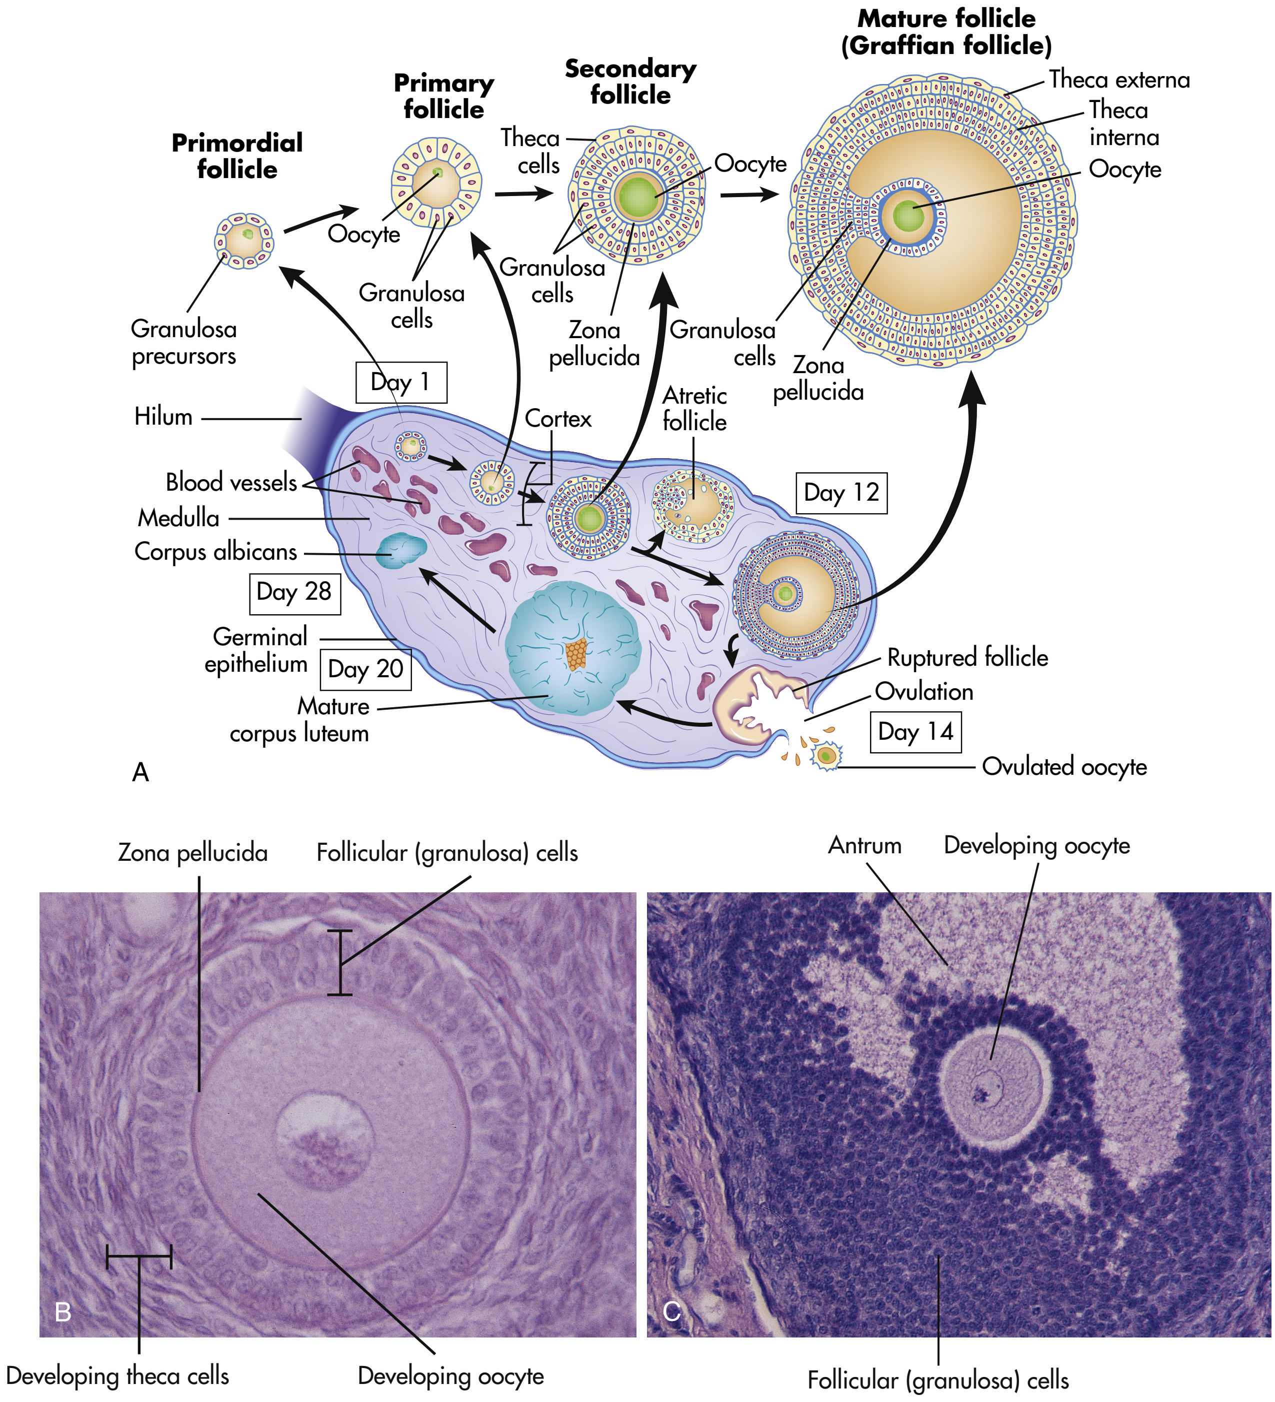

FIGURE 23-8 Cross Section of Ovary and Development of an Ovarian Follicle. **A,** Schematic representation (not to scale) of the structure of the ovary, showing the various stages in the development of the follicle and its successor structure, the corpus luteum. **B,** A developing oocyte surrounded by hormone-secreting follicular (granulosa) cells. **C,** A more mature ovarian follicle has a fluid-filled cavity called the *antrum*. (**A** adapted from Berne RM, Levy MN, editors: *Physiology,* ed 5, St Louis, 2003, Mosby. **B** and **C** from Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

receptors in the follicle, stimulating additional granulosa cells until a dominant follicle is determined.

Disturbances of estrogen production can be caused by abnormalities that affect (1) secretion of GnRH by the hypothalamus, (2) secretion of LH or FSH by the anterior pituitary, (3) hormonal feedback mechanisms, or (4) structural integrity of the ovaries. Estrogen's role in the menstrual cycle is described on page 781.

Although **androgens** are primarily male sex hormones produced by the testes, small amounts are produced in the adrenal cortex in both men and women and in the ovaries. Some androgens (dehydroepiandrosterone and its metabolite androstenedione) are precursors of estrogens (estrone, estradiol). At puberty, androgens contribute to the skeletal growth spurt and cause growth of pubic and axillary hair. The androgens also

TABLE 23-1 COMPLEMENTARY AND OPPOSING EFFECTS OF ESTROGEN AND PROGESTERONE

STRUCTURE	EFFECT OF ESTROGEN	EFFECT OF PROGESTERONE
Vaginal mucosa	Proliferation of squamous epithelium; increase in glycogen content of cells; layering (cornification) of cells	Thinning of squamous epithelium; decornification
Cervical mucosa	Production of abundant fluid secretions that favor survival and enhance motility of sperm	Production of thick, sticky secretions that tend to "plug" the cervical os
Fallopian tube	Increase of motility and ciliary action	Decrease of motility and ciliary action
Uterine muscle	Increase of blood flow; increase of contractile proteins and uterine muscle and myometrial excitability and action potential; increase of sensitization to oxytocin	Relaxation of myometrium; decrease of sensitization to oxytocin
Endometrium	Stimulation of growth; increase in number of progesterone receptors	Activation of glands and blood vessels; accumulation of glycogen and enzymes; decrease in number of estrogen receptors
Breasts	Growth of ducts; promotion of prolactin effects	Growth of lobules and alveoli; inhibition of prolactin effects

activate sebaceous glands, accounting for some cases of acne during puberty, and play a role in libido.

Progesterone

Luteinizing hormone (LH) from the anterior pituitary stimulates the corpus luteum to secrete **progesterone,** the second major female sex hormone. LH surge occurs when there is a peak level of estrogen, about 24 to 36 hours before ovulation. LH promotes luteinization of the granulosa in the dominant follicle and results in progesterone production and the development of blood vessels and connective tissue. A rising level of progesterone can be detected from the preovulatory follicle as early as day 10 of the menstrual cycle. Small amounts of progesterone also are secreted steadily by the adrenal cortex. Before ovulation the ovary and the adrenal glands each contribute approximately 50% of total progesterone production. Conversely, large amounts are secreted from the ovary while the corpus luteum is active for about 9 to 13 days after ovulation. Progesterone secreted by the corpus luteum stimulates the thickened endometrium to become more complex in preparation for implantation of a blastocyst. If conception and implantation do occur, the corpus luteum persists and secretes progesterone (and estrogen) until the placenta is well established at approximately 8 to 10 weeks' gestation. Together, estrogen and progesterone control the menstrual cycle. The opposing and complementary effects of progesterone and estrogen are listed in Table 23-1.

Progesterone is sometimes called the *hormone of pregnancy*. Progesterone's effects in pregnancy include: (1) maintaining the thickened endometrium; (2) relaxing smooth muscle in the myometrium, which prevents premature contractions and helps the uterus expand; (3) thickening (hypertrophy) of the myometrium, which prepares it for the muscular work of labor; (4) promoting growth of lobules and alveoli in the breast in preparation for lactation but prevents lactation until the fetus is born; (5) preventing additional maturation of ova by way of suppressing FSH and LH, thereby stopping the menstrual cycle; (6) providing immune modulation allowing tolerance against fetal antigens (the mother's immune system does not attack the fetus); and preventing preterm birth.[8-10]

The Menstrual (Ovarian) Cycle

In addition to pregnancy the obvious manifestation of female reproductive functioning is menstrual bleeding (the menses), which starts with **menarche** (first menstruation) and ends with **menopause** (cessation of menstrual flow for 1 year). In the United States the average age of first menstruation is 12 years in black females, 12.5 years in Hispanic females, and 12.6 years in white females, with a range from 9 to 17 years.[11] Menarche appears to be related to body weight, especially percentage of body fat (ratio of fat to lean tissue), which may trigger a change in the metabolic rate and lead to hormonal changes associated with early menarche.[12] There is an increased sensitivity to **leptin** (a regulatory hormone of appetite and energy metabolism) during puberty and, in theory, the adolescent consumes more calories to meet caloric needs of the pubertal growth spurt.[13] The percent of body fat and leptin levels in girls continue to increase, whereas muscle mass increases in boys.[14]

At first, cycles are anovulatory and may vary in length from 10 to 60 days or more. As adolescence proceeds into adulthood, regular patterns of menstruation and ovulation are established at intervals ranging from 25 to 35 days. The length of the menstrual cycle varies considerably among women. The commonly accepted cycle average is 28 (27 to 30) days, with rhythmic intervals of 21 to 35 days considered normal. Approximately 2 to 8 years before menopause, cycles begin to lengthen again. Menstrual cyclicity and regular ovulation are dependent on (1) the activity of the gonadostat (GnRH pulse generator); (2) the initial pituitary secretion of the gonadotropin FSH; and (3) estrogen (estradiol) positive feedback for the preovulatory FSH and LH surge, oocyte maturation, and corpus luteum formation and production of progesterone.[15]

Phases of the Menstrual Cycle

The menstrual (ovarian) cycle (Figure 23-9) consists of ovulation, which occurs in two phases: the follicular/proliferative and the luteal/secretory phase and each lasts about 14 days. Ovulation occurs between the follicular and luteal phases. If implantation of the blastocyst does not occur in the late luteal phase, **menstruation (menses)** occurs, also known as the ischemic/menstrual phase.[16]

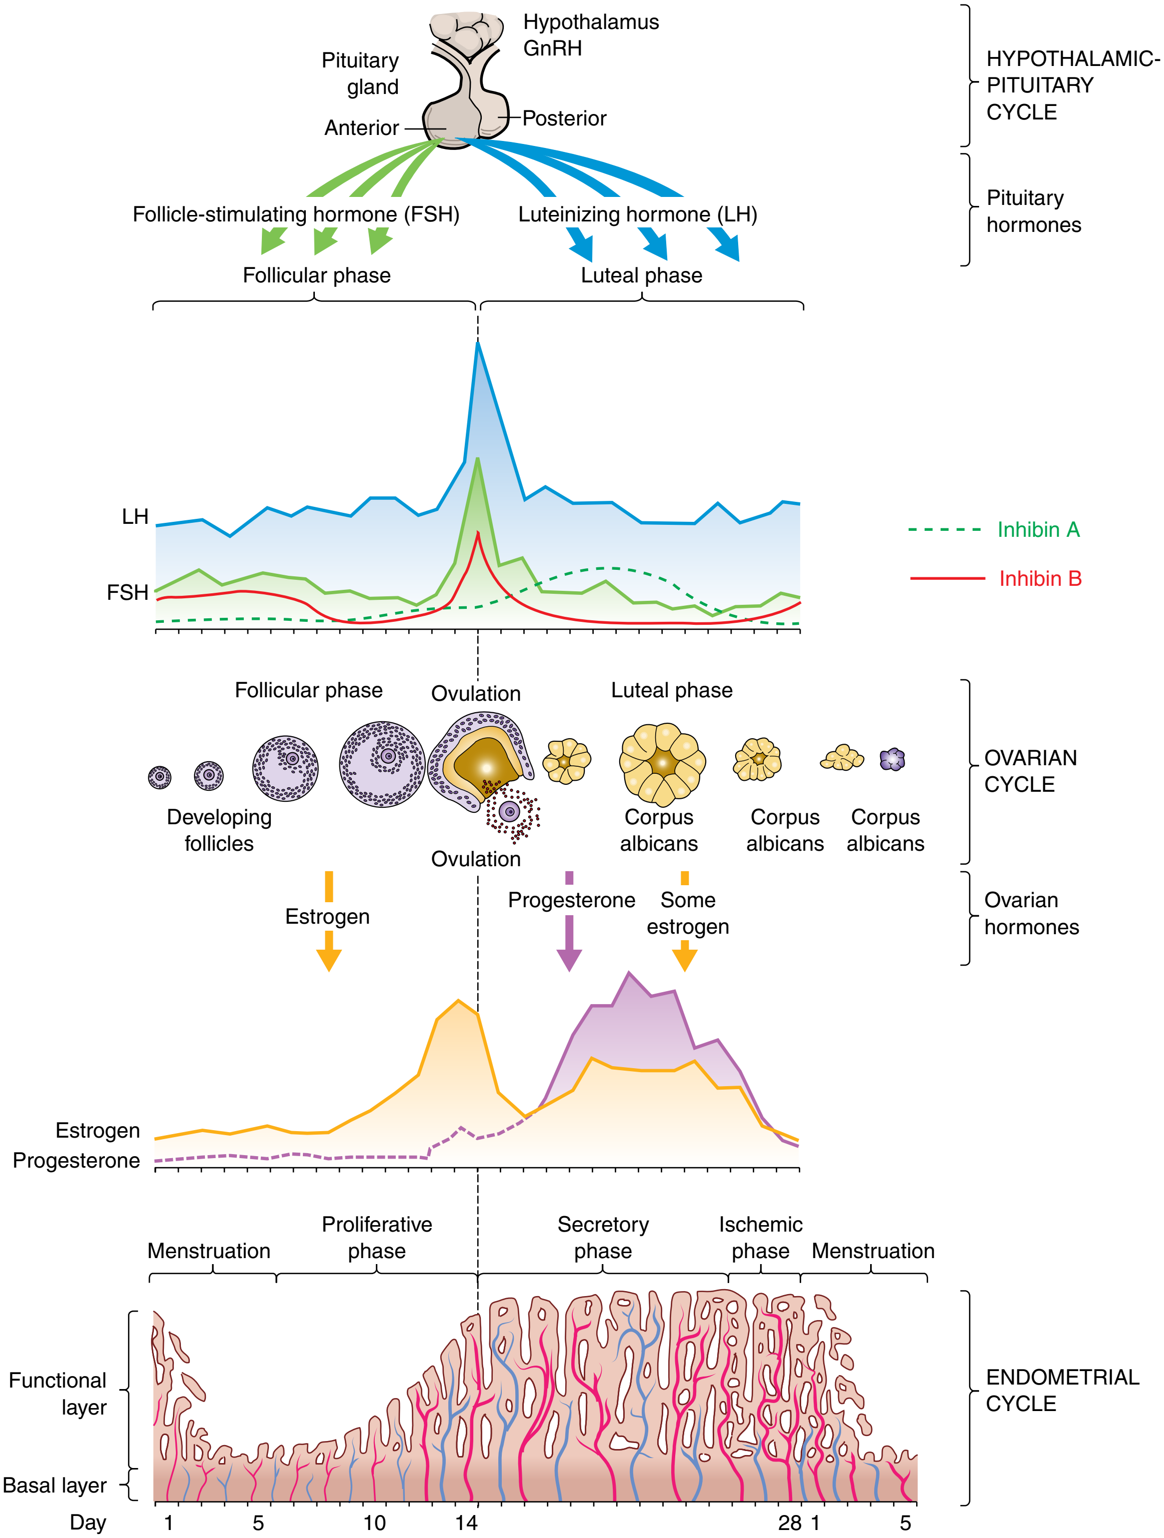

FIGURE 23-9 The Menstrual Cycle. *GnRh,* Gonadotropin-replacing hormone. (Adapted from Lowdermilk DL et al: *Maternity and women's health care*, ed 10, St Louis, 2012, Mosby.)

TABLE 23-2 HORMONAL FEEDBACK MECHANISM IN THE MENSTRUAL CYCLE

PHASE OF CYCLE AND OVARIAN HORMONE LEVELS	FEEDBACK TO HYPOTHALAMUS AND ANTERIOR PITUITARY	RESULTANT GnRH, FSH, AND LH LEVELS	OVARIAN AND MENSTRUAL EVENTS
Early follicular phase: estrogen levels low; minute amount of progesterone secreted	Negative and inhibitory	All low	Ovarian follicle develops; endometrium proliferates
Late follicular (preovulatory) phase: estrogen levels high; progesterone increases with small surge before ovulation	Positive and stimulatory	All surge; LH dominates	Process of ovulation begins; endometrial proliferation complete
Ovulatory phase: estrogen levels dip; progesterone levels begin to rise	Negative and inhibitory	All fall sharply	Corpus luteum begins to develop; endometrium enters secretory phase
Early luteal phase: estrogen and progesterone levels high; progesterone dominates	Negative and inhibitory	All continue to decline, but gradually	Corpus luteum fully developed; endometrium ready for implantation
Late luteal phase: estrogen and progesterone levels fall sharply	Negative and inhibitory; feedback lessens slightly	All rise slightly	Corpus luteum regresses; endometrium breaks down; menstruation begins
Menstrual phase: estrogens levels low; minute amount of progesterone secreted	Negative and inhibitory	All low	More ovarian follicles begin to develop; functional layer of endometrium is shed

FSH, Follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *LH,* luteinizing hormone.

During the **follicular/proliferative phase** GnRH and a balance between activin and inhibin from the granulosa cells contribute to the rise of FSH, which stimulates a number of follicles. The pulsatile secretion of FSH from the anterior pituitary gland rescues a dominant ovarian follicle from apoptosis by day 5 to 7 of the cycle. Together estrogen and FSH increase FSH receptors in the granulosa cells of the primary follicle, making them more sensitive to FSH. FSH and estrogen combine to induce production of LH receptors on the granulosa cells, thus promoting LH stimulation to combine with FSH stimulation, causing a more rapid secretion of follicular estrogen. As estrogen increases, FSH levels drop because of an increase in inhibin-B secreted by the granulosa cells in the dominant follicle. This drop in FSH decreases the growth of less-developed follicles (see Figure 23-9). Estrogen causes cells of the endometrium to proliferate and stimulates production of LH. A surge in both FSH and LH are required for final follicular growth and ovulation.

Increase in stromal tissue in the late follicular phase is associated with a rise in androgen levels. Androgen production enhances the process of follicle atresia and may stimulate libido at the point of ovulation.[1]

Ovulation marks the beginning of the **luteal/secretory phase** of the menstrual cycle. The ovarian follicle begins its transformation into a corpus luteum (see Figure 23-8, *A*), hence the name *luteal phase*. Pulsatile secretion of LH from the anterior pituitary stimulates the corpus luteum to secrete progesterone, which in turn initiates the secretory phase of endometrial development. Glands and blood vessels in the endometrium branch and curl throughout the functional layer, and the glands begin to secrete a thin glycogen-containing fluid, the *secretory phase.* If conception occurs, the nutrient-laden endometrium is ready for implantation. Human chorionic gonadotropin (HCG) is secreted 3 days after fertilization by the blastocytes and maintains the corpus luteum once implantation occurs at about day 6 or 7. HCG can be detected in maternal blood and urine 8 to 10 days after ovulation. The production of estrogen and progesterone continues until the placenta can adequately maintain hormonal production. If conception and implantation do not occur, the corpus luteum degenerates and ceases production of progesterone and estrogen. Without progesterone or estrogen to maintain it, the endometrium becomes ischemic (blood-starved) and disintegrates. Menstruation then occurs—the **ischemic/menstrual phase—**marking the beginning of another cycle.

Ovarian cycles appear to have a minimum length of 24 to 26.5 days: the primary ovarian follicle requires 10 to 12.5 days to develop, and the luteal phase appears relatively fixed at 14 days (±3 days). Menstrual blood flow usually lasts 3 to 7 days, but it may last as long as 8 days or stop after 1 to 2 days and still be considered within normal limits. Bleeding is consistently scant to heavy and varies from 30 to 80 ml, with most blood loss occurring during the first 3 days of menses. Menstrual discharge consists of blood, mucus, and desquamated endometrial tissue and does not clot under normal circumstances. It is usually dark and produces a characteristic musty odor on oxidation. Environmental factors such as severe emotional stress, illness, malnutrition, obesity, and seasonal variation may affect the length of the menstrual cycle.[1,17-19]

Hormonal Controls

Hormonal control of the menstrual cycle depends on complex interactions among the hypothalamus, the anterior pituitary, and the ovaries (or hypothalamic-pituitary-ovarian [HPO] axis)[20] (Table 23-2). Hormonal control is dependent on negative and positive ovarian feedback mechanisms. GnRH controls the gonadotropin production of FSH and LH, and the constant and pulsatile release of GnRH is critical to the timing of the menstrual cycle. GnRH is secreted by the hypothalamus into the hypophyseal portal system and travels to the anterior pituitary, where it stimulates the secretion of LH and FSH. FSH and LH are released from the anterior pituitary in pulses that correspond to the pulsatile secretion of GnRH.

During the early follicular phase, estrogen levels rise steadily and, through negative feedback, suppress FSH and positively increase the production of LH. During the late follicular phase, the preovulatory rise in progesterone facilitates the positive feedback of estrogen; estrogen levels begin to increase, stimulating a surge of LH secretion from the anterior pituitary. The midcycle surge of LH and FSH induces ovulation. A nonsteroidal ovarian factor, gonadotropin surge-attenuating factor (GnSAF), may antagonize the effect of estrogen on the pituitary and regulate the surge of LH at midcycle.[21] Rising estrogen and progesterone levels during the luteal phase may inhibit the anterior pituitary, and thus reduce LH and FSH secretion. Just before the onset of menstruation, FSH and LH levels begin to increase slightly, probably because of declining estrogen and progesterone levels (see Figure 23-9).

A variety of growth factors and autocrine/paracrine peptides influence hormonal control and follicular response.[1] During the early follicular stage, FSH stimulates FSH and LH receptors, insulin-like growth factor 1, and production of inhibin and activin in the ovary. **Activin** from granulosa cells stimulates the secretion of FSH and increases the pituitary response to GnRH, and increases FSH-binding in the granulosa cells in the dominant follicle. FSH stimulates **inhibin** secretion from granulosa cells and it in turn suppresses FSH synthesis. Inhibin B is primarily secreted in the follicular phase of the cycle but sharply spikes when ovulation occurs. Inhibin A is secreted in the luteal phase and further suppresses FSH. Inhibin also restrains prolactin and growth hormone release, interferes with GnRH receptors, and promotes breakdown of intracellular gonadotropins. In summary, the balance between activin and inhibin regulates FSH secretion, and **follistatin** inhibits activin and boosts inhibin activity. Inhibin and activin also regulate LH stimulation of androgen synthesis in theca cells.[22,23] Figure 23-9 depicts fluctuating estrogen, progesterone, gonadotropin, and inhibin levels. Research continues to advance understanding of the function and structural complexity of these polypeptides and their interaction with GnRH, gonadotropins, and sex hormones.[24]

Ovarian Cycle

By stimulating follicles, gonadotropins initiate their growth and maturation. The most important hormonal event is a rise in FSH. The decline in the late luteal phase of estrogen, progesterone, and inhibin secretion allows FSH to rise; concurrently there is a slight increase in LH levels (see Figure 23-9). FSH stimulates granulosa cell growth and initiates estrogen production in these cells in the next cycle. At this time a group of ovarian follicles is recruited and begins to mature; the exact number depends on the remaining pool of inactive follicles. As the follicles mature, granulosa cells multiply, increasing estradiol secretion. Within a few days of the cycle, one follicle becomes dominant and the others atrophy. The mechanism for follicular recruitment or dominance is unknown.[25] The dominant follicle begins to secrete progressively larger amounts of estrogen (estradiol), which exerts an increase in GnRH receptor concentration and an increase in pituitary sensitivity to GnRH, creating a positive-feedback effect causing an FSH and LH surge. Ovulation generally occurs 1 to 2 hours before the final progesterone surge, or about 12 to 36 hours after the onset of the FSH and LH surge. Progesterone, proteolytic enzymes, and prostaglandins (E and F series) trigger mechanisms controlling follicular rupture and release of the ovum.[1] Possible mechanisms include thinning, stretching, degradation, and digestion of the follicular wall and contraction of smooth muscle cells of the follicle. The role of prostaglandins is essential to ovulation, and infertility patients should be advised to avoid the use of drugs that inhibit prostaglandin synthesis.[26]

The FSH and LH surge also transforms the granulosa cells of the ovulatory follicle into the corpus luteum. The corpus luteum secretes estrogen and progesterone in amounts that depend in part on adequate development of the follicle before ovulation. Progesterone acts centrally and locally within the ovary to suppress new follicular growth during the early and midluteal phases. If pregnancy does not occur, the corpus luteum persists for 11 to 14 days, then regresses and eventually disappears. An increase in pulse frequency of GnRH from a low level of estrogen and progesterone reactivates hormonal control of the menstrual cycle and FSH secretion increases.

Uterine Phases

Uterine phases of the menstrual cycle—proliferative, secretory, and ischemic/menstrual phases—involve cyclic endometrial changes controlled by estrogen and progesterone. Hormonal effects are influenced by the presence of receptors and numerous growth factors, peptides, and enzymes that act as intermediaries between the sex steroids and the endometrium.[27] During the midfollicular phase, increasing levels of estrogen contribute to endometrial repair and proliferation, increasing endometrial thickness. Once ovulation occurs and serum progesterone levels increase, the endometrial tissue develops secretory characteristics. If implantation of a fertilized ovum does not take place, endometrial tissue begins to break down approximately 11 days after ovulation. The period of breakdown is sometimes called the *ischemic phase* (see Figure 23-9). Sloughing of tissue (menstrual bleeding) begins about 14 days after ovulation.

Cervical mucus also undergoes cyclic changes. During the proliferative phase the cervical mucus is thin and watery. Peak estrogen levels occur just before ovulation and maximally stimulate the cervical glands to produce mucus. Cervical mucus becomes abundant and more elastic (spinnbarkeit). In the presence of estrogen, tiny channels develop in the mucus, which allows sperm access to the interior of the uterus. Changes in the consistency of cervical mucus can be used to identify fertile intervals.

Vaginal Response

Vaginal endothelium also responds to cyclic hormonal changes. Under the influence of estrogen, epithelial cells of the vagina grow maximally during the follicular/proliferative phase. After ovulation, layers of keratinized cells overgrow the basal epithelium, a process known as **cornification.** Near the end of the luteal phase, leukocytes invade vaginal epithelium, removing the outer layers in a process termed **decornification.**

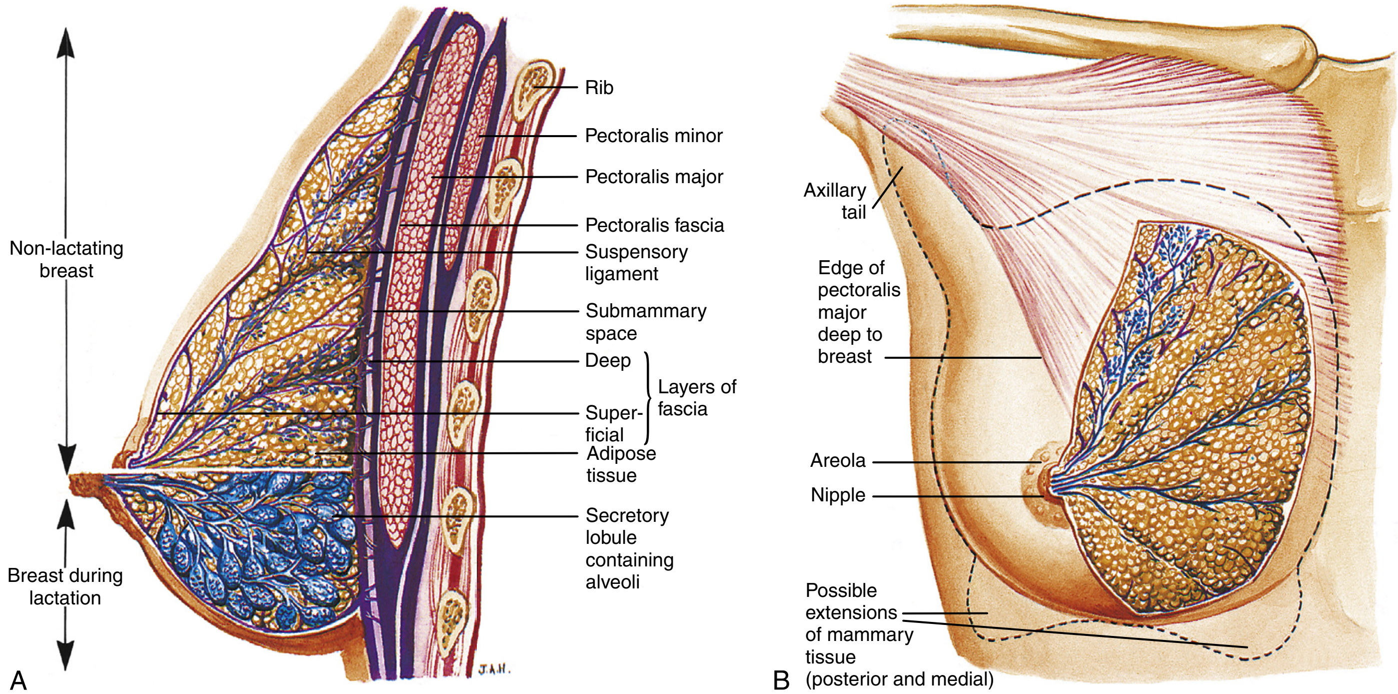

FIGURE 23-10 Schematic Diagram of Breast. **A,** Lactating breast. **B,** Structures of the breast. (From Shah P: Breast. In Standring S, editor: *Gray's anatomy*, ed 39, London, 2005, Elsevier Churchill Livingstone.)

Body Temperature

Basal body temperature (BBT) undergoes characteristic biphasic changes during menstrual cycles in which ovulation occurs. During the follicular phase the BBT fluctuates around 37° C (98° F). After the LH surge, the average temperature increases by 0.2° to 0.5° C (0.4° to 1° F). At the end of the luteal phase, 1 to 3 days before the onset of menstruation, BBT declines to follicular-phase levels. The shift in temperature is related to ovulation, corpus luteum formation, and increased serum progesterone levels. Progesterone probably acts on the thermoregulatory center of the hypothalamus to increase body temperature. Changes in BBT are used to document ovulatory cycles but when used alone are not the best method to predict the exact timing of ovulation.

STRUCTURE AND FUNCTION OF THE BREAST

The adult **breast** lies on the ventral surface of the thorax, within the superficial fascia of the chest wall, extending vertically from the second rib to the sixth or seventh intercostal space and laterally from the side of the sternum to the midaxillary line. Breast tissue also may extend into the axilla; this tissue is known as the *tail of Spence.*

The Female Breast

The female breast is composed of 15 to 20 pyramid-shaped lobes that are separated and supported by suspensory (Cooper) ligaments (Figure 23-10). Each lobe contains 20 to 40 lobules that are subdivided into glandular alveoli. The lobes and lobules are surrounded and separated by muscle strands and fatty connective tissue. The amount of fatty connective tissue varies from individual to individual, depending on weight and genetic and endocrine factors, and contributes to the diversity of breast size and shape and function of the mammary epithelium. During pregnancy the alveoli further develop, becoming composed of secretory acini that synthesize milk (lactation) (see Figure 23-10). Given this function, it is only during a pregnancy/lactation cycle and subsequent hormonal changes that the gland remodels into a milk-secreting organ and reaches its ultimate mature development stage.[28] The breast has the capacity to regress to a resting state after cessation of lactation and then undergo the same cycle of expansion and regression in subsequent pregnancies, a process possibly maintained by stem cells.[28,29] This remarkable plasticity of the breast suggests tight hormonal control and dramatic tissue-stromal restructuring. Investigators are focusing on the anatomy as a tool to advance knowledge on normal and aberrant breast development and to understand the origin of breast cancer.[30-32] After pregnancy, the milk is continuously secreted into the alveolar lumen and is stored there until the myoepithelial cells are stimulated by oxytocin to contract, which triggers the let-down reflex.[33] The alveoli empty into a network of lactiferous ducts. These ducts reach the skin through 9 or 10 openings (pores) in the nipple. The lobes and lobules are surrounded and separated by muscle strands and fatty connective tissue.

An extensive capillary network surrounds the alveoli and is supplied by perforating branches of the internal mammary, the thoracoacromial, the internal and lateral thoracic, and the intercostal arteries. Venous return follows arterial supply, with relatively rapid emptying into the superior vena cava. The breasts receive sensory innervation from branches of the second through sixth intercostal nerves and the cervical plexus. This accounts for the fact that breast pain may be referred to the

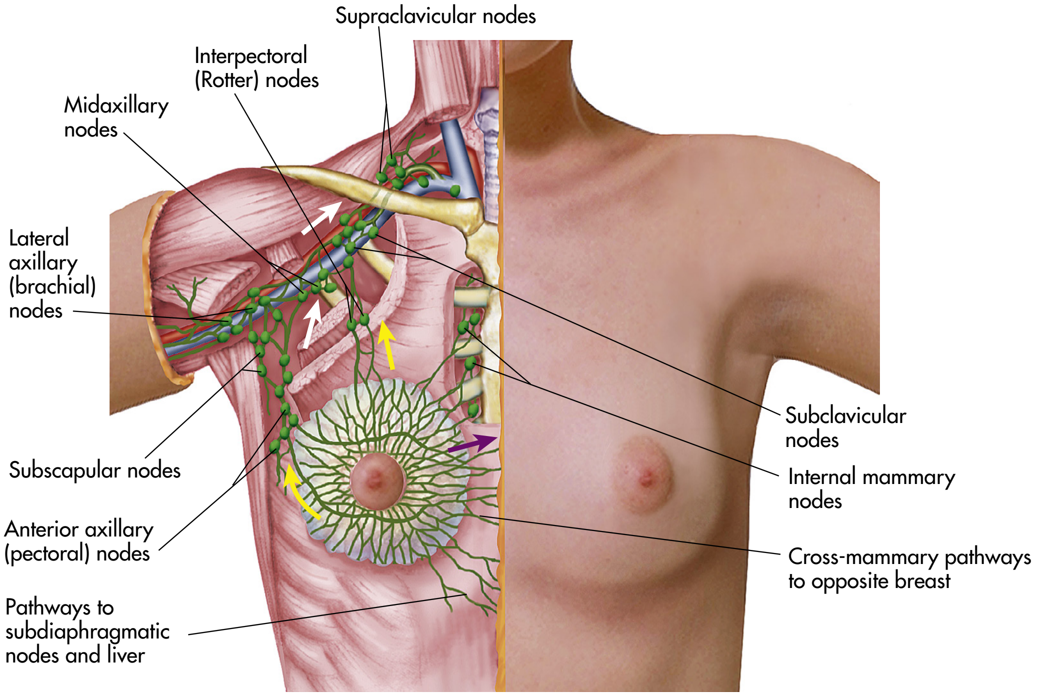

FIGURE 23-11 **Lymphatic Drainage of the Female Breast.** Arrows indicate the direction of lymphatic drainage. (From Seidel HM et al: *Mosby's guide to physical examination,* ed 7, St Louis, 2011, Mosby.)

chest, back, scapula, medial arm, and neck. Lymphatic drainage of the breast occurs largely through axillary nodes with minor drainage through the superficial mammary routes (Figure 23-11). There may be asymmetry between the breasts.[34,35]

The **nipple** is a pigmented, cylindric structure that is located within the central area of the areola. It measures 0.5 to 1.3 cm in diameter and is approximately 10 to 12 mm in height when erect. On its surface lie multiple openings, one from each lobe. The **areola** is the pigmented circular area in the center of the breast surrounding the nipple. It may be 15 to 60 mm in diameter. A number of sebaceous glands, the **glands of Montgomery,** are located within the areola and aid in lubrication of the nipple during lactation. The nipple and areola contain smooth muscles that receive motor innervation from the sympathetic nervous system. Breast-feeding, sexual stimulation, and exposure to cold cause the nipple to become erect.

Fetal and early postnatal breast tissue development occurs independently from the sex hormones, but the fetal breast tissue becomes progressively responsive to hormonal stimulation at birth. The neonatal breasts are rudimentary, containing 10 to 12 branching ducts. During childhood, breast, nipple, and areola growth is slow, keeping pace with other body tissues. (Male breast development normally does not progress any further.) At the onset of puberty in the female, estrogen secretion stimulates mammary growth. Breast development, or **thelarche,** is usually the first sign of puberty in the female. Full differentiation and maturation of breast tissue occur over approximately 4 years and are mediated by a variety of hormones, including estrogen, progesterone, prolactin, growth hormone, thyroxine, insulin, and cortisol. Estrogen promotes the increase in size of the breast by the formation of a mass of tissue under the areola, increases the size and pigmentation of the areola, and promotes development of the lobular ducts. The breast cells of parous women are different than those of women who never become pregnant. During menopause the lobules of the parous breast regress to prepregnancy composition and become identical to the nulliparous breast. Variations in breast development are listed in Box 23-1.

BOX 23-1 VARIATIONS IN BREAST DEVELOPMENT

- Ectopic breast development may occur in males and females with tissue in the axilla, abdomen, labia in females, or back and buttocks (less common). The breast tissue develops from the milk line, an embryonic mammary ridge of ectoderm.
- Accessory nipples (polythelia) or mammary glands (polymastia) are caused by cellular migration along the milk line; polythelia occurs in approximately 1% of the population and is slightly more common in men.
- Inverted nipples usually revert to normal during the first month; persistence into adulthood may cause concerns with lactation.
- Failed development of the nipple (athelia) or entire mammary gland (amastia) is rare and may include a complete lack of development, unilateral failure, or extreme asymmetry. This is caused by complete involution of the mammary ridge in the milk lines.
- Symmetric or asymmetric hyperplasia occurs in approximately 1% to 4% of all females.

Data from DeSilva NK, Merritt DF: Chapter 545, Breast concerns. In Kliegman RM et al, editors: *Nelson textbook of pediatrics,* ed 19, p 834, Philadelphia, 2011, Saunders; Greydanus DE, Matytsina L, Gains M: *Prim Care* 33(2):455–502, 2006.

During the reproductive years the breast undergoes cyclic changes in response to changes in the levels of estrogen and progesterone associated with the menstrual cycle. During the follicular/proliferative phase of the menstrual cycle, high estradiol levels increase the vascularity of breast tissue and stimulate proliferation of ductal and alveolar tissue. This effect is sustained into the luteal/secretory phase of the cycle. During this phase progesterone levels influence the growth of the alveoli and increase and contribute to the breast changes induced by estradiol. Specific effects of estrogen and progesterone include dilation of the ducts and conversion of the alveolar cells into secretory cells, as well as fluid secretion, mitotic activity, and deoxyribonucleic acid (DNA) production of nonglandular tissue and glandular epithelium.[1] Most women experience some degree of premenstrual breast fullness, tenderness, and increased nodularity. Breast volume may increase as much as 10 to 30 ml. Because the length of the menstrual cycle does not allow for complete regression of new cell growth, breast growth continues at a slow rate until approximately 35 years of age. Because of the cyclic changes that occur in breast tissue, clinical breast examination is recommended at the conclusion of or a few days after menses, when hormonal effects are minimal and breasts are at their smallest and least tender.

During pregnancy the breast reaches its maximum development. With increased levels of estrogen the lobules further differentiate. Progesterone stimulates development of cells lining the alveoli to produce milk. Lactation (milk production) occurs after childbirth in response to increased levels of prolactin. Prolactin secretion, in turn, increases by continued breast-feeding. Oxytocin, another hormone released during and after delivery, controls milk ejection from alveolar cells. Milk is continuously secreted into the alveolar lumen and is stored there until the myoepithelial cells are stimulated by suckling stimulation of oxytocin, which triggers the let-down reflex.[33] The alveoli empty into a network of lactiferous ducts. These ducts reach the skin through 9 or 10 openings (pores) in the nipple.

The function of the female breast is primarily to provide a source of nourishment for the newborn. Physiologically, breast milk is the most appropriate nourishment for newborns. Not only does its composition change over time to meet the changing digestive capabilities and nutritional requirements of the infant but it also contains immune cells, specific immunoglobulins, especially immunoglobulin A (IgA), and nonspecific antimicrobial factors, such as lysozymes and lactoferrin, that protect the infant against infection, allergies, and asthma. Evidence suggests breast-feeding decreases future incidence in the infant of adult obesity, lowers atherosclerotic disease, and lowers the incidence of types 1 and 2 diabetes.[36] During lactation high prolactin levels interfere with hypothalamic-pituitary hormones that stimulate ovulation. Lactation usually suppresses the menstrual cycle (lactational amenorrhea) and prevents ovulation for the first 6 months postpartum.[37] In many parts of the world breast-feeding is the major means of contraception. Breasts are also a source of pleasurable sexual sensation and in Western cultures have become a sexual symbol.

The Male Breast

Until puberty, development of the male breast is similar to that of the female breast. In the absence of sufficiently high levels of estrogen and progesterone, the male breast does not develop any further. The normal male breast consists of a small underdeveloped nipple, some fatty and fibrous tissue, and a few ductlike structures in the subareolar area. The male breast may appear enlarged in obese men because of accumulation of fatty tissue. Physiologic gynecomastia is a condition in which the breasts temporarily enlarge as a result of hormonal fluctuations and is common in newborns, adolescents, and older men. Of men 50 to 80 years of age, 30% to 60% may have palpable breast tissue related to circulating or local production of estrogen from elevated aromatase activity, particularly in adipose tissue.[38,39]

THE MALE REPRODUCTIVE SYSTEM

In men the external genitalia perform the major functions of reproduction, which are to produce sperm and deliver them to the female reproductive tract. Sperm, are produced in the male gonads, the testes, and delivered to the female vagina by the penis. The internal male genitalia have a more accessory function. They consist of conducting tubes and fluid-producing glands, all of which aid in the transport of sperm from the testes to the urethral opening of the penis. The male reproductive and urinary structures are shown in Figure 23-12.

External Genitalia

Testes

In men the **testes** (*singular,* testis) are the essential organs of reproduction. Like the ovaries, the testes have two functions: (1) production of gametes (in this case, sperm), and (2) production of sex hormones (in this case, androgens and testosterone). The testes are suspended outside the pelvic cavity because sperm production requires an environment that is 1° or 2° C (1.6° to 3.6° F) cooler than body temperature.

During embryonic and fetal life, the testes develop within the abdomen (see Figure 23-1). About 3 months before birth, the testes start to descend toward the developing scrotum. About 1 month before birth they enter twin passageways called **inguinal canals.** The inguinal canals are vaginal processes created by outpouchings of the peritoneum (lining of the abdominal cavity). The descent of a testis is shown in Figure 23-13. Each testis moves down outside the peritoneum until it is suspended in the scrotal sac by its supply lines: the ducts, blood vessels, lymphatic vessels, and nerves of the **spermatic cord.** When descent is complete, the abdominal end of each vaginal process closes up and the inguinal canal disappears. If peritoneal closure at the site of the inguinal canal is incomplete or weak, an inguinal hernia may occur later in life. The scrotal end of each vaginal process becomes the outer covering of the testis, the **tunica vaginalis.**

Figure 23-14 shows a sagittal section of a mature testis. The adult testis is ovoid and varies considerably in length (3 to 6 cm), width (2 to 3.5 cm), depth (3 to 4 cm), and weight (10 to 40 g). The testis is almost entirely surrounded by an outer covering, the tunica vaginalis, which separates the testis from the scrotal wall, and an inner covering, the **tunica albuginea.** Inward extensions

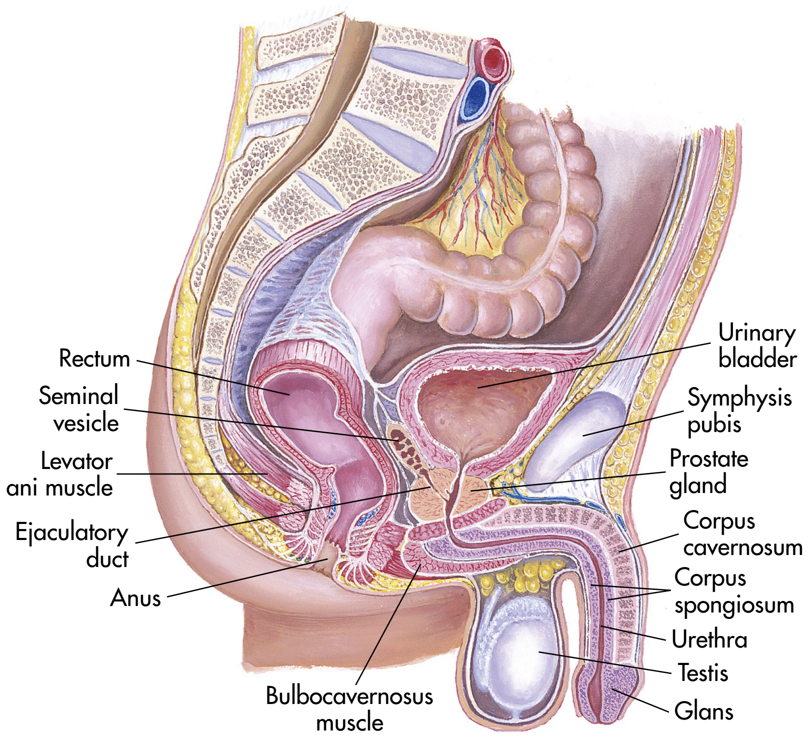

FIGURE 23-12 Structure of the Male Reproductive Organs. (From Seidel HM et al: *Mosby's guide to physical examination,* ed 7, St Louis, 2011, Mosby.)

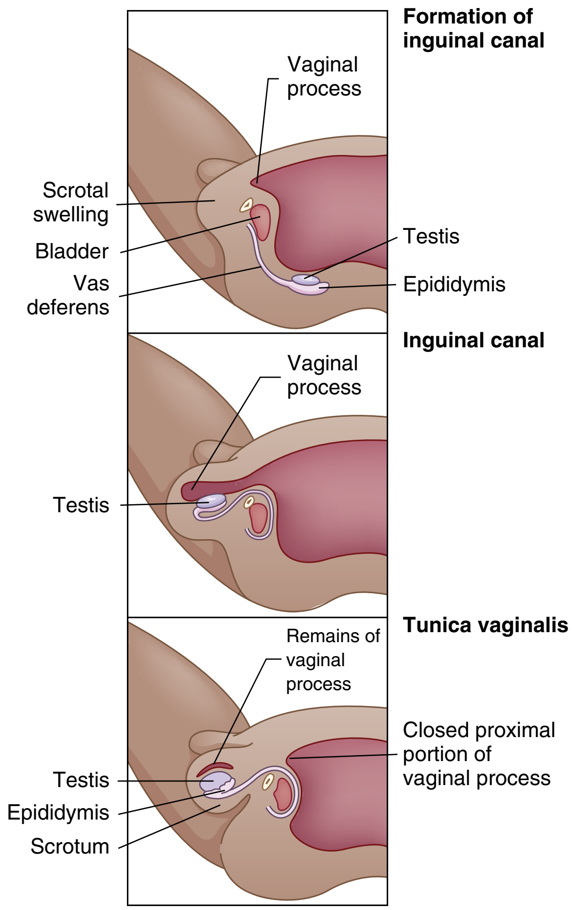

FIGURE 23-13 Descent of a Testis. The testes descend from the abdominal cavity to the scrotum during the last 3 months of fetal development.

of the tunica albuginea form septa that separate the testis into about 250 compartments, or lobules, each of which contains several tortuously coiled ducts called **seminiferous tubules.** The seminiferous tubules constitute the bulk (80%) of testicular volume and are the site of sperm production. (Sperm production, termed **spermatogenesis,** is described on p. 789.) Tissue surrounding these ducts contains blood and lymphatic vessels, fibroblastic support cells, macrophages, mast cells, and Leydig cells. **Leydig cells,** which occur in clusters and account for about 1% to 5% of testicular volume, produce androgens, chiefly testosterone.

The two ends of each seminiferous tubule join and leave the lobule through a short, straight section called the **tubulus rectus.** Sperm travel from the seminiferous tubules into these straight sections, which lead to the central portion of the testis, the **rete testis.** From the rete testis, sperm move through the **efferent tubules,** or vasa efferentia, to the epididymis, where they mature.

The testes are innervated by adrenergic fibers, whose sole function apparently is to regulate blood flow to the Leydig cells. The testes receive arterial blood from the internal spermatic and differential arteries. Arterial blood flows over the surface of the testes before entering the parenchyma (functional tissues). Surface flow cools the blood to temperatures that promote spermatogenesis, approximately 1° to 2° C (34° to 36° F) below body core temperature.[40] Additionally, the testes are suspended outside the pelvic cavity to facilitate cooling.

Epididymis

The **epididymis** (*plural,* epididymides) is a comma-shaped structure that curves over the posterior portion of each testis

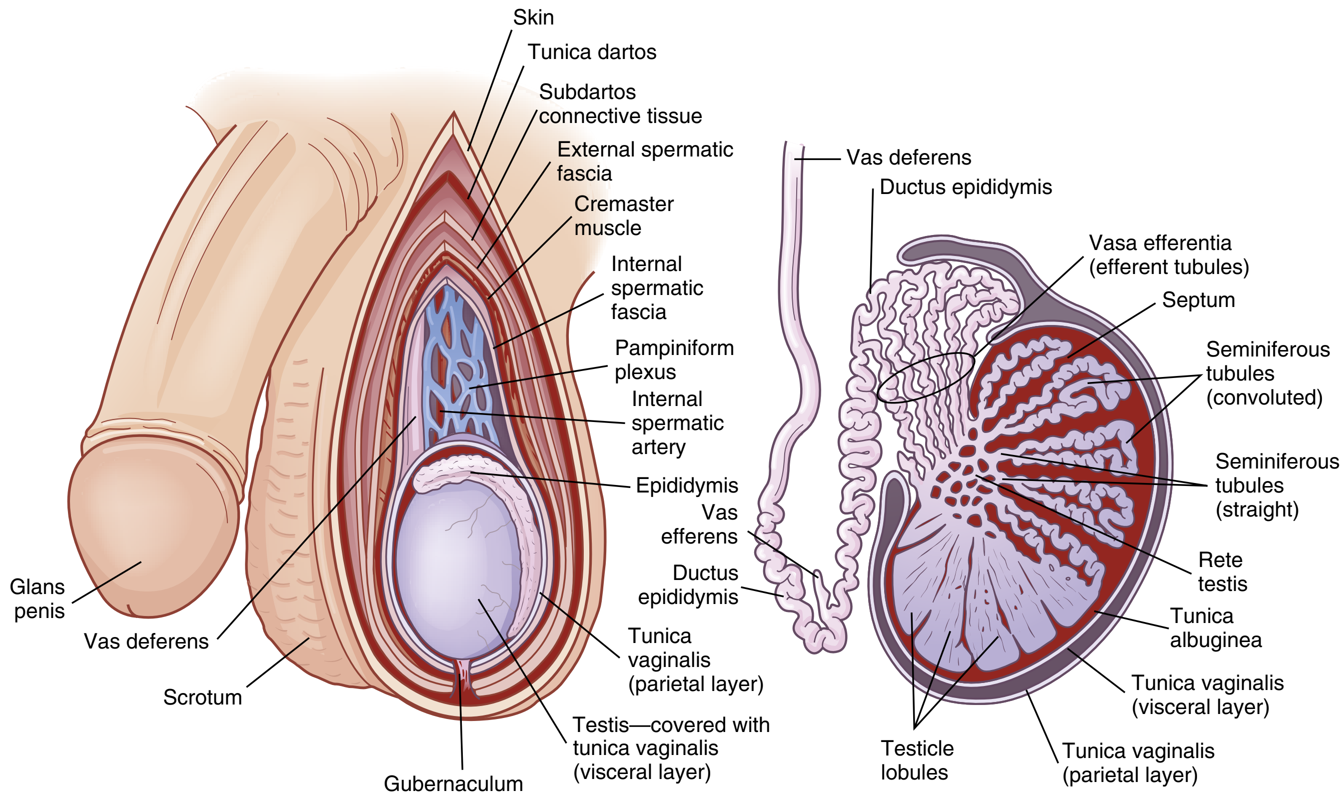

FIGURE 23-14 The Testes. External and sagittal views showing interior anatomy. (From Seidel HM et al: *Mosby's guide to physical examination,* ed 6, St Louis, 2006, Mosby.)

(see Figure 23-14). It consists of a single highly packed and markedly coiled (about 6 meters when uncoiled) duct measuring 5 cm long, whose structural function is to conduct sperm from the efferent tubules to the vas deferens. The duct can become inflamed from infection by microorganisms that ascend the urethra or from the prostate, causing epididymitis. The epididymis has physiologic functions as well. When sperm enter the head of the epididymis, they are not fully mature or motile, nor are they capable of fertilizing an ovum. During the 12 days (or more) sperm take to travel the length of the epididymis, they receive nutrients and testosterone from the epididymal epithelium, and some biochemical or physiologic mechanism enhances their capacity for fertilization.[41]

The tail of the epididymis is continuous with the **vas deferens (ductus deferens),** a duct with muscular layers capable of powerful peristalsis that transports sperm toward the urethra. After traveling the length of the epididymis, sperm are stored in the epididymal tail and vas deferens. The vas deferens enters the pelvic cavity through the spermatic cord.

Scrotum

The testes, epididymides, and spermatic cord are enclosed and protected by the scrotum. The **scrotum** is a skin-covered fibromuscular sac that is homologous to the female labia majora (see Figure 23-2). The skin of the scrotum is thin and has rugae (wrinkles or folds) that enable it to enlarge or relax away from the body. At puberty the scrotal skin darkens, develops active sebaceous glands, and becomes sparsely covered with hair. Just under the skin lies a layer of connective tissue (fascia) and smooth muscle, the tunica dartos (see Figure 23-14). The **tunica dartos** also forms a septum that separates the two testes. Exposure to cold temperatures causes the tunica dartos to contract, pulling the testes close to the warm body. In warm temperatures the tunica dartos relaxes, suspending the testes away from body heat. These mechanisms promote optimal temperatures for spermatogenesis. In addition, scrotal sensitivity to touch, pressure, temperature, and pain protects the testes against potential harm. During sexual excitement the scrotal skin and tunica thicken, the scrotum tightens and lifts, and the spermatic cords shorten, partially elevating the testes toward the body. As excitement plateaus, the engorged testes increase 50% in size, rotate anteriorly, and flatten against the body, signaling impending ejaculation.

Penis

The **penis** has two main functions: delivery of sperm to the female vagina and elimination of urine. (Urine formation and excretion are the subjects of Chapter 37.) Embryonically, the penis is homologous to the female clitoris (see Figure 23-2).

Figure 23-12 shows a sagittal section of the adult penis and its anatomic relation to other urogenital structures. Externally the penis consists of a shaft with a tip, the **glans,** which contains the opening of the urethra. For protection, the skin of the glans folds over the tip of the penis, forming the prepuce, or **foreskin.** At birth, the foreskin is adhered to the glans. Penile erections, which commonly occur, cause the adhesions to break so that

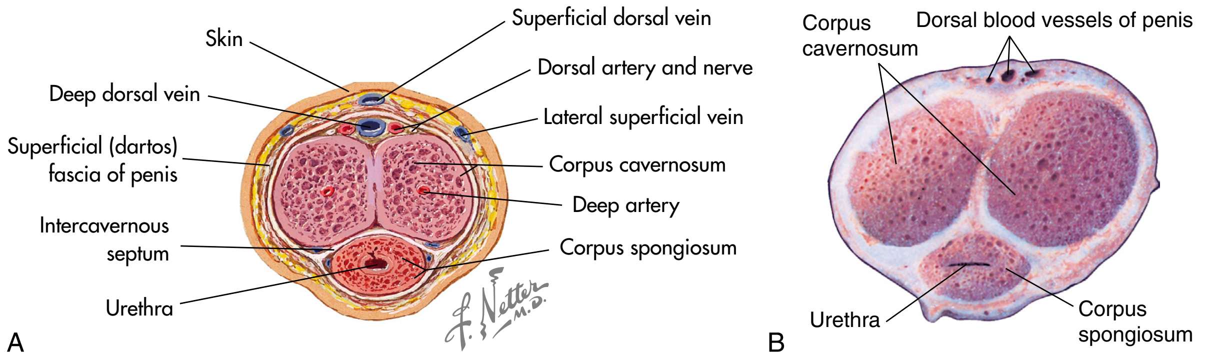

FIGURE 23-15 The Penis. **A,** Cross section of the penis. **B,** Cross section of the shaft of the penis showing three columns of erectile, or cavernous, tissue. (**A** Netter illustration from www.netterimages.com. Copyright © Elsevier Inc. All rights reserved. **B** from Vidic B, Suarez RF: *Photographic atlas of the human body,* St. Louis, 1984, Mosby.)

by age 3 years the foreskin becomes completely retractable. The skin of the penis is continuous with that of the groin, scrotum, and inner thighs. It is hairless, movable, and darker than surrounding skin.

Internally the penis consists of the urethra and three compartments: two **corpora cavernosa** (*singular,* corpus cavernosum) and the **corpus spongiosum** (Figure 23-15). The three compartments are separated by Buck fascia and, like the testes, are enclosed by a tunica albuginea. The **urethra** passes through the corpus spongiosum and ends at a sagittal slit in the glans. If the urethra is not completely surrounded by the corpus spongiosum, the meatus may open on the ventral surface of the penile shaft (hypospadias) or on the dorsal surface (epispadias).

Penetration of the female vagina is made possible by the **erectile reflex,** a process in which erectile tissues within the corpora cavernosa and corpus spongiosum become engorged with blood, generally 20 to 50 ml. The erectile tissues consist of vascular spaces, or chambers, that are supplied with blood by arterioles (small arteries). Most of the time the arterioles are constricted through tonic noradrenaline release from sympathetic nerves so that not much blood flows through the erectile tissues. Sexual stimulation, however, causes the arterioles to dilate through release of nitric oxide and fill with blood.[42] Their rapid expansion fills the erectile tissues, causing an erection. Erection apparently is maintained by compression or constriction of veins that drain the corpora cavernosa and corpus spongiosum. When sexual stimulation ceases or orgasm and ejaculation occur, these veins open up, blood flows out of the arterioles, and the penis becomes flaccid (soft and pendulous).

Erection is under the control of the autonomic nervous system but can be stimulated or inhibited by central nervous system input. Stimulation of mechanoreceptors of the penis, particularly of the glans, causes parasympathetic nerves of the autonomic nervous system to relax smooth muscle in the walls of penile arterioles. At the same time, the effects of sympathetic nerves, which normally cause arteriolar smooth muscle to constrict, are inhibited.

Erections begin in utero and continue throughout life, but ejaculation does not occur until sperm production begins at puberty. Growth of the penis and scrotal contents continues well past puberty, however, and may not be complete until the late teens or early 20s. Penis size, when flaccid, varies considerably; with an erection, differences in penis size diminish. Sexual excitement causes the corpora cavernosa to increase in length and width and become rigid; the penis becomes erect. Stimulation of the glans, which is endowed with copious sensitive nerve endings, provides maximum erotic sensation. With sexual arousal, skin color deepens, the glans doubles in size, and the urethral meatus dilates. Ejaculation occurs with frequent, strong contractions of the vas deferens, epididymis, seminal vesicles, prostate, urethra, and penis. Erection and ejaculation can occur independently of each other.[43]

Internal Genitalia

Figure 23-13 shows the anatomy of the internal genitalia and their relation to other pelvic organs. The internal genitalia consist of ducts and glands. The ducts—the two vasa deferentia, the ejaculatory duct, and the urethra—conduct sperm and glandular secretions from the testes to the urethral opening of the penis. The glands—the prostate gland, two seminal vesicles, and two Cowper (or bulbourethral) glands—secrete fluids that serve as a vehicle for sperm transport and create an alkaline, nutritious medium that promotes sperm motility and survival. Together the sperm and the glandular fluids comprise **semen.**

Sperm leave the epididymides and travel rapidly through the internal ducts in a process called **emission.** Emission occurs just seconds before ejaculation, at the moment when sexual arousal peaks. Emission always leads to ejaculation.

Emission occurs as smooth muscle in the walls of the epididymides and vasa deferentia begins to contract rhythmically, pushing sperm and epididymal secretions through the vasa deferentia. Each vas deferens is a firm, elastic fibromuscular tube that begins at the tail of the epididymis, enters the pelvic cavity within the spermatic cord, loops up and over the bladder, and ends in the prostate gland (Figure 23-16; see also Figure 23-12). Sperm are moved along by peristaltic contractions of smooth muscle in the walls of the vas deferens.

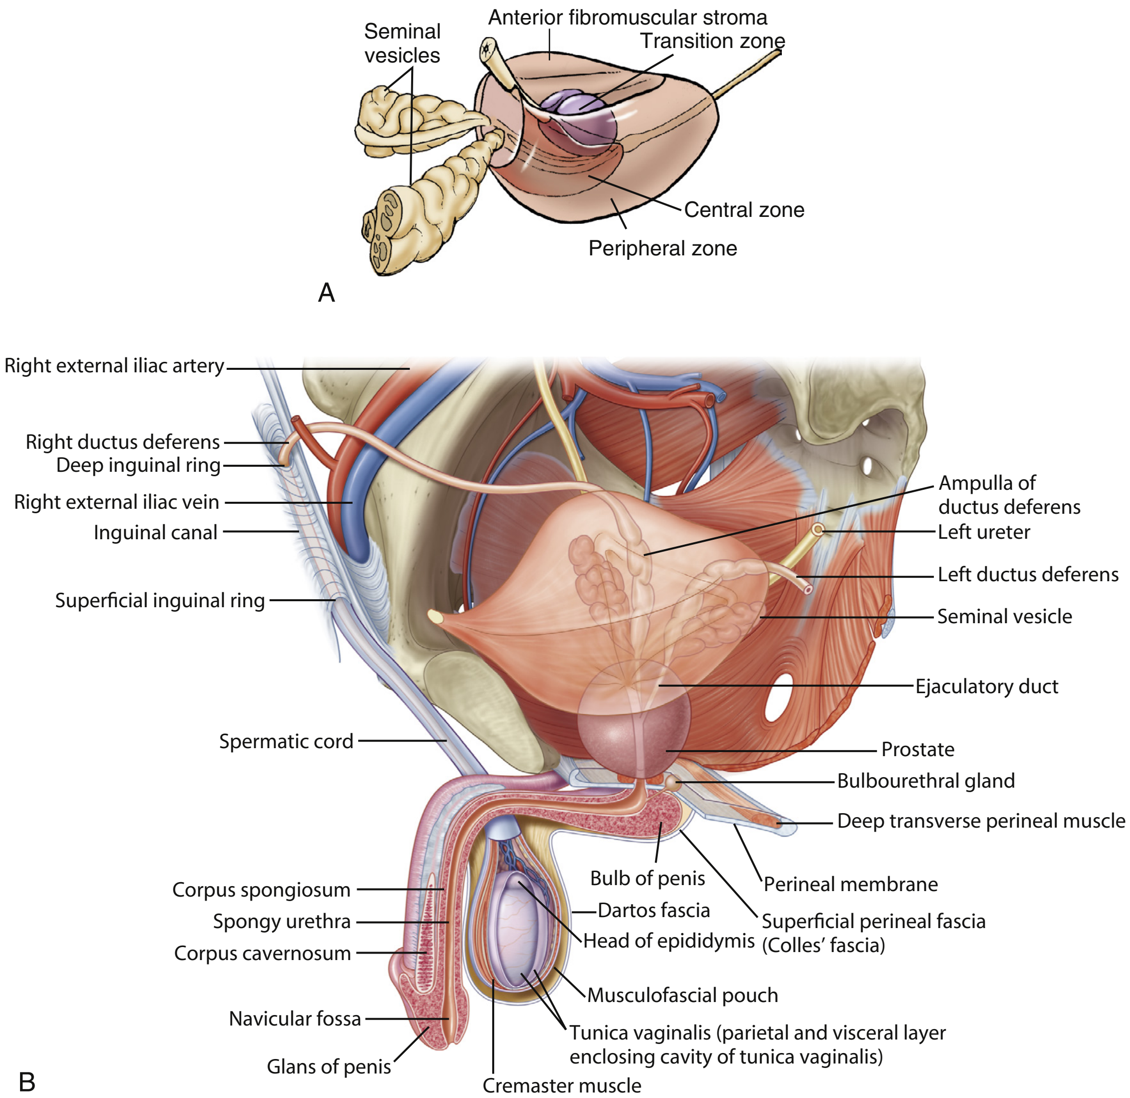

FIGURE 23-16 **Zones of the Prostate Gland and Seminal Vesicles. A,** Zones of the prostate. The peripheral zone, accounting for 70% of the prostate gland, is the site of origin of ≤70% of prostate cancers; the central zone, approximately 25% of the prostate gland, gives rise to only 1% to 5% of prostate cancers; and the transition zone, ≈5% to 10% of the prostate gland, gives rise to 20% of prostate cancers and is the site of origin of benign prostatic hyperplasia (BPH). **B,** Prostate gland within the male reproductive system. (**A** copyright Baylor College of Medicine, Houston, TX. **B** from Drake et al: *Gray's atlas of anatomy*, Philadelphia, 2008, Churchill Livingstone.)

As sperm leave the ampulla (wide portion) of the vas deferens, the seminal vesicles secrete a nutritive glucose-rich fluid into the ejaculate (semen). The **seminal vesicles** are a pair of glands, each about 4 to 6 cm long, that lie behind the urinary bladder and in front of the rectum. The seminal vesicles provide fructose as a source of energy for ejaculated sperm, and secrete prostaglandins that promote smooth muscle contraction assisting with sperm transport. The ducts of the seminal vesicles join the ampulla of the vas deferens to become the **ejaculatory duct,** which contracts rhythmically during emission and ejaculation. As can be seen in Figures 23-12 and 23-16, the ejaculatory duct joins the urethra, where both pass through the prostate gland. During emission and ejaculation a sphincter (muscle surrounding a duct) closes, preventing urine from entering the prostatic urethra.[44]

The **prostate gland** is about the size of a walnut, has three zones, and surrounds the urethra (see Figure 23-16). It is composed of glandular alveoli and ducts embedded in fibromuscular tissue. Prostate growth, development, and function are regulated by androgens and the androgen receptor. Without them the prostate is at risk for hyperplastic and malignant growth[45] (see Chapter 25). Nerves required for penile erection travel along the posterolateral surface of the prostate. Included in prostate epithelial secretions are prostate-specific antigen (PSA), cytokeratins, prostate-specific membrane antigen (PSMA), and prostate-specific acid phosphatase. Prostate secretions contribute to the ejaculate. While semen moves through the prostatic portion of the urethra, the prostate gland contracts rhythmically and secretes prostatic fluid into

the mixture. Prostatic fluid is a thin, milky substance with an alkaline pH that helps sperm survive in the acid environment of the female reproductive tract. In addition, clotting enzymes and fibrinolysin in prostatic fluids help mobilize sperm after ejaculation.

Cowper glands (bulbourethral glands), whose ducts secrete mucus into the urethra near the base of the penis, are the last pair of glands to add fluid to the ejaculate. Ejaculation occurs as semen reaches the base of the penis and muscles there begin the rhythmic contractions that push semen out. Normally a man ejaculates between 2 and 6 ml of semen, containing 75 million to 400 million sperm. About 98% of the ejaculate consists of glandular fluids; 60% to 70% of volume comes from the seminal vesicles and 20% from the prostate. Therefore, the ejaculate of a man who has undergone vasectomy (a surgical procedure that prevents sperm from entering the vas deferens) is not reduced by much: about 2%. During vasectomy, the vas deferens are severed and then tied in order to prevent sperm from entering the ejaculate; this procedure is used for permanent male birth control.

Spermatogenesis

Spermatogenesis begins at puberty and continues for life. In this respect, spermatogenesis differs markedly from oogenesis (production of primordial ova), which occurs during fetal life only.

Spermatogenesis takes place within the seminiferous tubules of the testes (see Figure 23-14). The basement membrane of each seminiferous tubule is lined with diploid (46-chromosome) germ cells called **spermatogonia** (*singular,* spermatogonium). These cells undergo continuous mitotic division. (Mitotic division, in which a cell divides into two identical cells, is described in Chapter 1.) Some of the spermatogonia move away from the basement membrane and mature, becoming **primary spermatocytes** (Figure 23-17). The primary spermatocytes undergo meiosis, a type of cell division that results in two haploid (23-chromosome) cells called **secondary spermatocytes.** (Meiosis is described and illustrated in Chapter 4.) The two secondary spermatocytes then undergo meiosis, resulting in four **spermatids.** It is the spermatids that differentiate into spermatozoa, or sperm, each of which contains 23 chromosomes (Figure 23-18).

The development of spermatids into sperm depends on the presence of **Sertoli cells (nondividing support cells)** within the seminiferous tubules. The spermatids attach themselves to Sertoli cells, from which they receive the nutrients and the hormonal signals (i.e., testosterone) they need to develop into sperm.[46] The process of spermatogenesis, from mitotic division of a spermatogonium to maturation of the spermatids, takes about 70 to 80 days. Mature sperm migrate from the seminiferous tubules to the epididymis, where their capacity for fertilization continues to develop. Although they are completely mature by the time they are ejaculated, the sperm do not become motile (capable of movement) until they are activated by biochemicals in semen and in the female reproductive tract.

Male Sex Hormones

The male sex hormones are androgens and **testosterone** is the primary male sex hormone. Leydig cells of the testes and, to a lesser degree, the adrenal glands produce testosterone and other androgens. In men, sex hormone production is relatively constant with some diurnal variation.

The androgens have a number of physiologic actions related to growth and development of male tissues and organs. They are responsible for fetal differentiation and development of the male urogenital system and have some effects on the fetal brain. After birth, the Leydig cells become quiescent until activated by the gonadotropins during puberty. At puberty, androgens cause the sex organs to grow and secondary sex characteristics to develop.

Testosterone affects nervous and skeletal tissues, bone marrow, skin and hair, and sex organs. It has an anabolic effect on skeletal muscle tissue, thereby contributing to the difference in body weight and composition between men and women. Testosterone also stimulates growth of the musculature and cartilage of the larynx, causing a permanent deepening of the voice. Testosterone directly stimulates the bone marrow and indirectly stimulates renal erythropoietin production to achieve increased hemoglobin and hematocrit levels. Because sebaceous gland activity is stimulated by testosterone, acne may develop. In the presence of testosterone, hair becomes coarser in texture, and facial hair, axillary hair, and pubic hair grow in male patterns. Later in life, testosterone causes baldness in genetically susceptible individuals. Testosterone is required for spermatogenesis and for secretion of fluid by the prostate gland, seminal vesicles, and Cowper glands. Testosterone is also associated with an increase in **libido** (sex drive). Other, less-understood, effects of testosterone include alterations in fatty acid and cholesterol metabolism.

The regulation of androgen production and spermatogenesis is achieved by a complex feedback system involving the extrahypothalamic central nervous system, the hypothalamus, the anterior pituitary, the testes, and the androgen-sensitive end organs. These relationships, which are essentially the same in women, are summarized in Figure 23-3. Extrahypothalamic influences include such variables as physiologic and psychologic stress, which may inhibit or augment hypothalamic activity. In the hypothalamus, neurotransmitters regulate GnRH synthesis and pulsatile release (about every 3 hours) into the hypophyseal portal veins. Norepinephrine stimulates GnRH secretion, and serotonin and dopamine inhibit GnRH secretion. GnRH is transported by portal flow to the median eminence of the pituitary gland, where it binds to receptors and stimulates the synthesis and secretion of gonadotropins, LH, and FSH. LH and FSH, which are named for their effects in the female reproductive system, have important effects on the male system as well. LH acts on the Leydig cells to regulate testosterone secretion. FSH acts on the seminiferous tubule Sertoli cells to promote spermatogenesis. FSH secretion is inhibited by inhibin secreted by the Sertoli cells. Similar to their action in the female gonad, inhibin functions as an autocrine/paracrine regulator in the male gonad. Inhibin inhibits proliferation of spermatogonia by

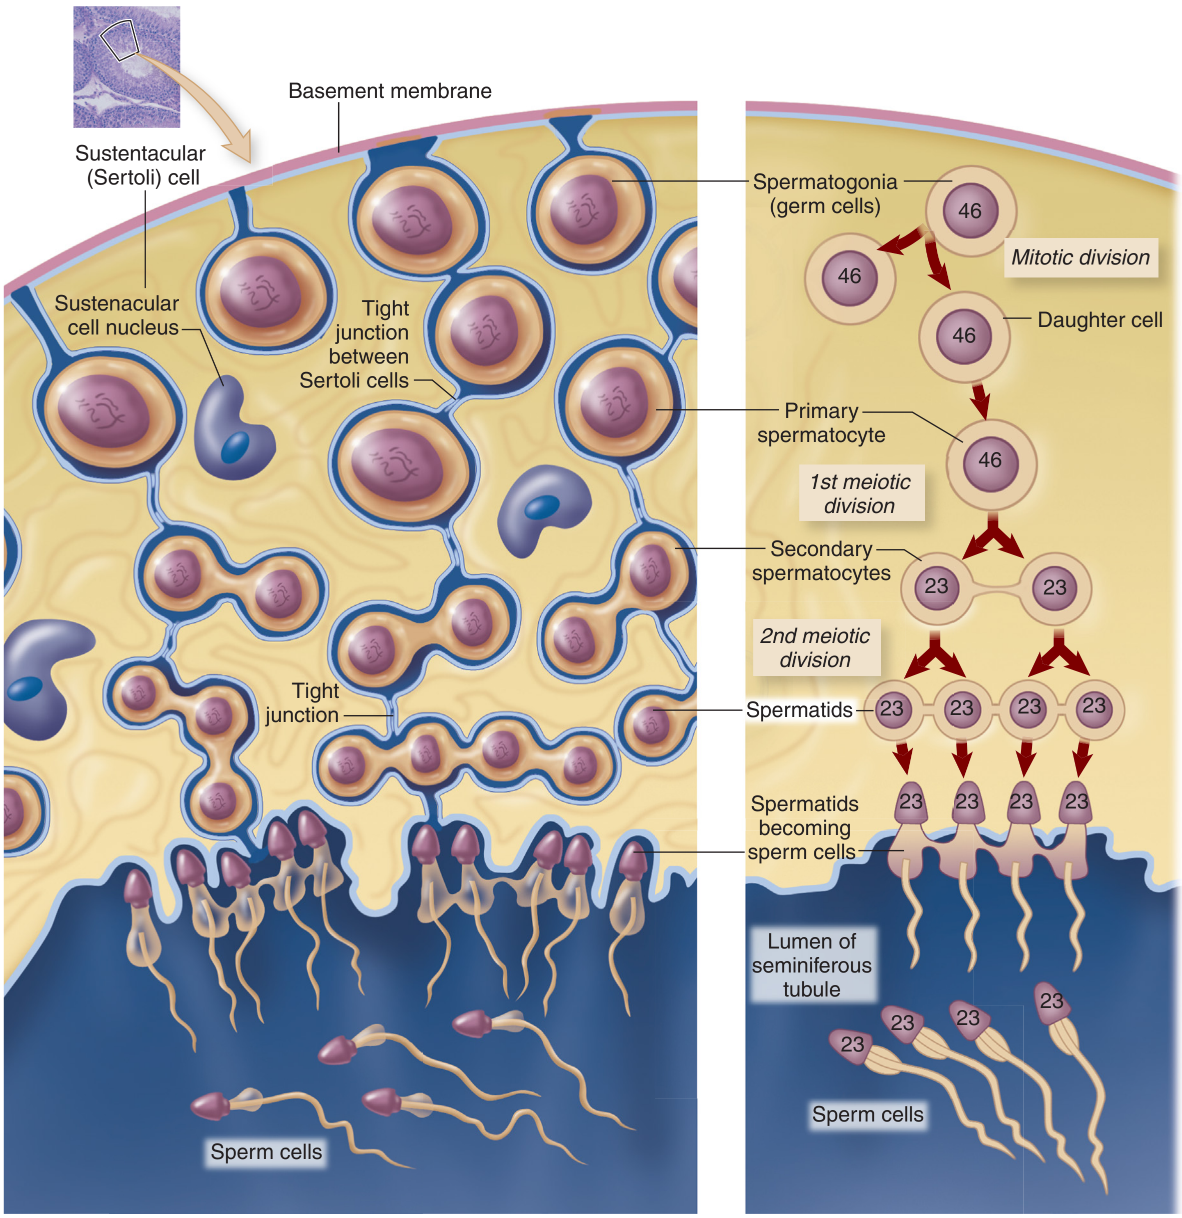

FIGURE 23-17 **Seminiferous Tubule.** Section shows process of meiosis and sperm cell formation. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

regulating pituitary FSH levels. In addition, inhibin facilitates LH stimulation of androgen biosynthesis in Leydig cells.

Ninety-eight percent of testosterone, the major steroid hormone produced by the testes, binds to either **sex hormone–binding globulin (SHBG)** (40%) or albumin (48%). The remaining 2% remains unbound in the plasma and is free to enter cells and wield its metabolic effects. Changes in the amount of available SHBG affect the amount of testosterone within tissues. The testes secrete only 25% of circulating estrogen (estradiol). The majority is produced by peripheral conversion of testosterone and androstenedione. Estrogens help regulate GnRH and LH secretion. Peripheral conversion of testosterone by 5-alpha-reductase also produces **dihydrotestosterone (DHT),** another potent androgen. DHT is necessary for external virilization during embryogenesis and androgen activity beginning at puberty and continuing throughout adulthood. **Prolactin,** a polypeptide synthesized and secreted from the pituitary, helps maintain biosynthesis of testosterone. However, elevated prolactin levels may suppress biosynthesis.[47]

In summary, hormones secreted at each level of the hypothalamic-pituitary-testicular (HPT) axis control and coordinate testicular function (Figure 23-19). This control is exerted through positive and negative feedback signals by (1) sex steroids that inhibit hypothalamic GnRH secretion and pituitary LH responsiveness to GnRH; and (2) testicular inhibin that inhibits pituitary FSH and, possibly, circulating estrogens (E_2). Any disruption along the HPT axis may lead to hypogonadism or infertility.

TESTS OF REPRODUCTIVE FUNCTION

Diagnostic tests of the male and female reproductive systems are performed to determine the cause of infertility, to detect the presence of cancerous lesions, or to identify the presence of sexually transmitted infections. (Alterations of the female reproductive system including carcinoma are discussed in Chapter 24. Alterations of the male reproductive system including carcinoma are discussed in Chapter 25. Sexually transmitted infections are discussed in Chapter 26.)

Tests of reproductive function are performed most commonly when infertility exists. Both partners are examined, and several diagnostic evaluations may be completed. The types of tests and their normal values are summarized in Tables 23-3 and 23-4. The man is evaluated for number, amount, structure, and motility of sperm and obstruction along the reproductive tract. Tests for women determine whether (1) the reproductive tract (cervix, uterus, fallopian tubes) is adequately patent to allow for passage of ovum and sperm, (2) ovulation occurs normally, (3) the endometrium is responding normally to hormones, and (4) reproductive tissues are free of tumors or infections. Hormonal assays evaluate the adequacy of pituitary function and target organ response. The position and size of organs or the presence of tumors can be detected by direct observation procedures using a laparoscope or by radiographic studies, such as plain films, computerized scans, or tomography.[48]

AGING AND REPRODUCTIVE FUNCTION

Aging and the Female Reproductive System

Natural **menopause** is a normal developmental event marking the end of reproduction. It is universally experienced by midlife women at the average age of 50.5 to 51.4 years in North America with variability between 40 and 60 years.[49,50] A number of factors are thought to influence the age of menopause, including genetics, socioeconomic status, race, parity, oral contraceptive use, and lifestyle, such as smoking or weight.[51] It can occur 2 years sooner on average for smokers; thinner women also tend to experience menopause at a slightly younger age. However, it is genetically predetermined and has been documented by family history. Menopause is the cessation of ovulation due to loss of ovarian follicles resulting in reduced ovarian production of estradiol, increased FSH and LH, and decreased inhibin (inhibits release of FSH). The primary changes of menopause are as follows:[52]

- *Perimenopause:* This is the transitional period between reproductive and nonreproductive years, a transition lasting

TABLE 23-3 TESTS AND NORMAL VALUES OF REPRODUCTIVE FUNCTION/FERTILITY

TEST	DESCRIPTION	NORMAL VALUE
Basic Assessment		
Semen analysis (two samples at least 2 weeks apart)	Determines number, motility, and structure of sperm cells	Volume = 2-6 ml Number = >20 million/ml Motility = >50% with forward progression
White blood cells	Determines presence of bacteria/leukocytes	Morphology = >50% normal shape
Immunologic tests	Detects antibody to sperm	Immunobead test = <20% with adherent particles Sperm MAR test (mixed antiglobulin reaction) = <10% with adherent particles $<10^6$ WBC/ml No sperm agglutinins present
Other Assessments		
Basal body temperature	Determines whether ovulation has occurred	Decrease in basal body temperature before ovulation followed by a rise in temperature at the time of ovulation
FSH level	Day 3 of cycle	Lab specific results
Estradiol	Days 3 of cycle	Low FSH in conjunction with low estradiol—lab specific results
Progesterone	Midluteal phase – one week before menses	Lab specific results—low level associated with decreased or absent ovulation.
Prolactin	Day 3 of cycle	Lab specific results—high levels can interfere with ovulation
TSH level	Day 3 of cycle	Lab specific results—elevated value associated with hypothyroidism
Cervical mucus	Evaluates presence of ovulation from estrogenic effects at ovulation; mucus also may be examined for pH, glucose, or proteins or cultured for presence of infection	Fern pattern appears when cervical mucus dries on a clean slide; mucus is clear, watery, and elastic (spinnbarkeit ≥8-10 cm) with no inflammatory cells
Postcoital cervical mucus (Sims-Huhner test)	Tests ability of sperm to penetrate and maintain motility in cervical mucus 2-4 hours after coitus approximately 1 day before ovulation	≥10 motile sperm in each high-power field; motility in one direction; previous sperm analysis normal
Zona binding test or hamster penetration test	Nonliving oocytes are surgically removed and bisected; sperm added to the hemi-oocyte to test fertilizing capability	Bonding <30% predicted failed fertilization 70% of the time Bonding >30% predicted successful fertilization 85% of the time Results may vary with lab
Ultrasound vaginal scanning	Provides superior quality resolution of the uterine, fallopian, and ovarian structures; also can be used to study folliculogenesis, ovulation, and luteogenesis to detect abnormalities	Normal structures visualized
More Specialized Tests		
Endometrial biopsy	Determines whether ovulation has occurred by obtaining endometrial tissue on day 26 of 28-day menstrual cycle (or postovulatory day 12)	Finding is “secretory-type” endometrium if ovulation has occurred; read in conjunction with day of cycle and serum progesterone levels
Hysterosalpingogram	Assessment of uterus and fallopian tubes for obstructions using transuterine injection of contrast material and radiography; performed 1-2 days after cessation of menses	No obstruction evident
Laparoscopy (pelvic endoscopy)	Visualization of reproductive organs using a laparoscope inserted within the pelvic cavity through the abdomen to assess structure or determine presence of adhesions, endometriosis, tumors, or infection	Normal structure and position of organs
Hysteroscopy	Visualization of uterine cavity using modified cystoscope inserted through cervical os; best done during first 14 days of cycle	Absence of intrauterine lesions

FSH, Follicle-stimulating hormone; *TSH,* thyroid-stimulating hormone; *WBC,* white blood cell.

TABLE 23-4 SERUM HORMONE VALUES

HORMONE	VALUE
Serum progesterone	Normal = >10 ng/dl, presumptive evidence of ovulation; draw level between days 20-25 of 28-day cycle or 6-10 days postovulation <10 ng/ml = inadequate luteal function <3 ng/ml suggests anovulation
Serum testosterone	Normal = 300-1200 ng/dl; must be interpreted with serum LH and FSH levels
Resulting from diurnal and pulsatile pattern, need serial blood draws	Low values in male hypogonadism
Serum FSH and LH	FSH = <22 international units/L
Resulting from diurnal and pulsatile pattern, need serial blood draws	LH = 4-24 international units/L High levels in males indicate primary testicular disease; low levels in males indicate hypogonadism caused by hypothalamic-pituitary dysfunction

FSH, Follicle-stimulating hormone; *LH,* luteinizing hormone.

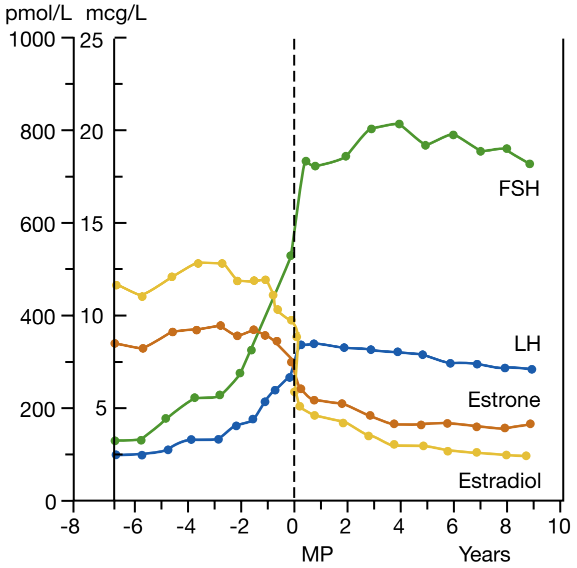

FIGURE 23-20 **The Perimenopausal Hormone Transition.** Mean circulating hormone levels. *FSH,* Follicle-stimulating hormone; *LH,* luteinizing hormone.

2 to 8 years.[1,52] Five to 10 years before menopause, approximately 90% of women note mild to extreme variability in frequency and quality of menstrual flow. Changes in hormones occur during this time including erratically higher estradiol levels, decreased progesterone levels (in normal ovulatory, short luteal phase, or anovulatory cycles), and a disturbed ovarian-pituitary-hypothalamic feedback relationship with higher LH levels. A decrease in the sensitivity of the target tissue receptors and the development of perimenopausal symptoms commonly are experienced. Symptoms usually begin with a lengthening of the menstrual cycle, which correlates with anovulatory cycles. Unpredictable or irregular ovulation uniformly precedes menopause.[53] The perimenopause experience varies among women and from cycle to cycle in the same woman. Estradiol levels remain in the normal to slightly elevated range until about 1 year before menopause.[1]

- *Ovarian changes:* Beginning in utero, the number of follicles steadily decreases through activation, maturation, and atresia. Starting in the late 30s, 10 to 15 years before menstruation ceases, this process accelerates until the supply of follicles is depleted.[54] This accelerated loss correlates with increased FSH stimulation, delayed and attenuated LH surges, and a decrease in inhibin. Increased FSH stimulation seems to accelerate follicular loss, declining inhibin production, slightly elevated estradiol levels, and decreasing anti-müllerian hormone. Attenuated LH surges are associated with impaired hypothalamic responses to estradiol positive feedback[55] (Figure 23-20 and Box 23-2). The ovarian response to high FSH recruits increasing numbers of follicles; these follicles only partially develop, with a net effect of irregular ovulation, lower progesterone levels, depleted follicle reserve, and infertility. The ovaries begin to decrease in size around age 30; this decrease accelerates after age 60.[1,55] Of the 500,000 follicles present at the onset of puberty, the number dwindles to approximately 1000 with menopause. Table 23-5 summarizes endocrine events occurring during

BOX 23-2 CHANGES IN OVARIAN FOLLICULOGENESIS DURING THE PERIMENOPAUSE LEADING TO ENDOGENOUS OVERSTIMULATION

- ↑ FSH → ovarian hyperstimulation → ↑ number of follicles recruited (net effect of follicular depletion) → ↑ estradiol
- ↓ Follicular reserve → ↓ inhibin and ↑ activin in FP and LP → ↑ FSH → ↑ number of follicles recruited, partial development, infrequent ovulation → ↑ estrogen (E_2) and ↓ progesterone

FP, Follicular phase; *FSH,* follicle-stimulating hormone; *LP,* luteal phase.

TABLE 23-5 ENDOCRINE EVENTS ASSOCIATED WITH PERIMENOPAUSE

HORMONE CHANGES	EFFECTS
Estradiol (E_2) levels	Erratic and intermittent increase
Mean FP level 1 greater than mean FP level in younger women	First in FP (inverse relationship between length of FP and estradiol level)
FP level may be greater than midcycle peak level in fertile women	Later during premenstrual phase
Ovulatory cycles	Short or insufficient LP (decreased fertility)
Progesterone levels	Decreased in ovulatory cycle; minimal during anovulatory cycles
Anovulatory cycles	Increased to about 50%; perhaps more in later perimenopause
FSH levels	Variable, then increased
LH levels	Normal initially, then increased
Inhibin levels	Correlate with progesterone levels

FP, Follicular phase; *FSH,* follicle-stimulating hormone; *LH,* luteinizing hormone; *LP,* luteal phase.

TABLE 23-6 POSTULATED PERIMENOPAUSAL TRANSITION TIMELINE

PHASE	MENSTRUAL PHYSIOLOGY	HORMONAL CHANGES	SYMPTOMATOLOGY
A	Regular, ovulatory cycles Short cycles, short FP	Intermittent ↑ E_2 FSH usually normal Intermittent ↑ FP FSH Low inhibin	Increased breast tenderness, mood swings, fluid retention, premenstrual symptoms Early morning night sweats (vasomotor symptoms) Weight gain, migraine headaches, heavy flow
B	Regular cycles with disturbances in ovulation Short LP Insufficient LP Anovulatory cycles	Intermittent ↑ FP FSH E_2 often ↑ Inhibin inappropriately low	Heavy flow ↑ Premenstrual symptoms ↑ Dysmenorrhea Predictable or ↑ vasomotor symptoms before flow
C	Onset of perimenopause Alternating short, long, or skipped cycles	E_2 often quite ↑ E_2 normal or low ↑ FSH (slight) ↑ LH Low inhibin	Vasomotor symptoms during waking hours Vasomotor symptoms more persistent, remain cyclic before flow
D	Onset of oligomenorrhea 50% of cycles anovulatory Heavy flow may predict onset of oligomenorrhea	↑ Progesterone with ovulation Persistent ↓ FSH ↑ LH ↑ E_2 Low inhibin	↑ Vasomotor symptoms ↑ Signs/symptoms of high estrogen after long periods without flow Flow light but unpredictable
E	Final menstrual period plus 1 year	↑ FSH and LH ↓ or normal E_2 Consistent low inhibin ↓ Progesterone	↑ Intensity and frequency of vasomotor symptoms (although vasomotor symptoms may disappear) ↓ Cramps and premenstrual-type symptoms without subsequent flow ↓ Breast, mood, and fluid symptoms

E_2, Estradiol; *FP*, follicular phase; *FSH*, follicle-stimulating hormone; *LP*, luteal phase.

the perimenopause. Table 23-6 provides a template to visualize the complex physiology of the perimenopause and the dynamic changes that occur during this time.

- *Uterine changes:* Uterine changes occur primarily in the endometrium. The increase in anovulatory cycles allows for proliferative growth of the endometrium. The longer exposure to estrogen alone results in greater thickness of the endometrium, and 50% of perimenopausal women will experience dysfunctional uterine bleeding that is heavy and unpredictable. Increased endometrial bleeding is correlated with a change from ovulatory to anovulatory cycles and is associated with unopposed high estrogen levels the week before menses. Estrogen causes endometrial tissue to thicken. However, without corresponding stromal support from progesterone, estrogen production leads to heavier periods, menorrhagia (heavy bleeding), or metrorrhagia (midcycle bleeding)[6] (Table 23-7). In the past this has put women at high risk for hysterectomy. Newer treatment includes progesterone administration or endometrial ablation by laser or electrocautery. New methods of decreasing the function of the endometrial tissue are being developed.
- *Systemic changes:* **Vasomotor flushes** are characterized by a rise in skin temperature, dilation of peripheral blood vessels, increased blood flow in the hands, increased skin conductance, and a transient increase in heart rate followed by a temperature drop and profuse perspiration over the area of flush distribution. This usually occurs in the face and neck and may radiate into the chest and other parts of the body. Night sweats, dizziness, nausea, headaches, or palpitations

TABLE 23-7 IMPACT OF HIGH ESTROGEN LEVELS ON MENSTRUAL CYCLE AND SYMPTOMATOLOGY

ASSOCIATED PHYSIOLOGIC CHANGE	SIGNS/SYMPTOMS
Short follicular phase (FP)	Short cycles
Long FP	Long cycles
Thickened endometrium*	Heavy, long, or unpredictable flow (including clotting and flooding)*
Increase in glandular cells without stromal support produced by progesterone → unstable endometrium	Midcycle spotting Menorrhagia
Possible increased production of prostaglandins within endometrial tissue	Metrorrhagia Dysmenorrhea Breast tenderness, modularity, enlargement Water retention Emotional stress; new or unpredictable mood swings Weight gain Vasomotor symptoms New onset of migraine headaches; exacerbation of headaches Increased premenstrual symptoms

*Symptoms aggravated by anovulatory cycles; leads to dysfunctional uterine bleeding (see Chapter 24).

may accompany the flush. These flushes can vary in frequency, intensity, and duration and are experienced by up to 85% of perimenopausal to postmenopausal women from 1 to 15 years (mean 1 to 5 years). The physiology of vasomotor flushes is poorly understood. One theory proposes that rapid changes in estrogen may result in loss of negative feedback over hypothalamic noradrenaline synthesis, the primary neurotransmitter involved in thermoregulation.[56] Estrogen modulates adrenergic receptors. The decrease in estrogen in menopause is thought to decrease the number of receptors leading to increased noradrenaline levels and hot flushes. Interestingly, emerging evidence shows that the intensity of vasomotor flushes may be associated with increased risk for cardiovascular disease.[57]

- *Menopause:* Menopause is defined by the point that marks 12 consecutive months of amenorrhea. This means that it is determined retrospectively after a woman has not had a menstrual period for 1 year. It is characterized by loss of ovarian function, low estrodiol and progesterone levels, high FSH and LH levels, and decreased follicular inhibin secretion[49,58] (see Figure 23-20). Less androgens are produced but sensitivity to them is increased because of the lost opposition of estrogen.
- *Breast tissue changes:* Glandular breast tissue becomes involuted; fat deposits and connective tissue increase; and breasts are reduced in size and firmness.
- *Urogenital tract changes:* The ovaries shrink; the uterus atrophies; and the vagina shortens, narrows, and loses some elasticity. Lubrication of the vagina diminishes and vaginal pH increases, creating higher incidence of vaginitis. The cervix atrophies, cervical os shrinks; vaginal epithelium atrophies; labia majora and minora become less prominent; some pubic hair is lost; urethral tone declines along with muscle tone throughout the pelvic area; urinary frequency or urgency, urinary tract infections, and incontinence are associated with estrogen deficiency. Regular sexual activity and orgasm may diminish some of these changes. Sexually active women have less vaginal atrophy.
- *Skeletal changes:* Postmenopausal bone mass is reduced, leading to increased brittleness and porosity and increases the risk osteoporosis and fracture. Healthy bone is maintained through a balance of breakdown and reformation. Estrogen promotes positive bone mass during the childbearing years; however, once menopause occurs with the resultant low estrogen levels, the balance tips toward reabsorption and reduced bone mass.[59]
- *Cardiac change:* The risk of coronary heart disease (CHD) increases significantly after menopause. Estrogen is known to foster favorable lipid profiles and to have beneficial effects on vessel endothelium through production of nitric oxide. Once postmenopausal, blood pressure and LDL levels rise, central adiposity and weight increases, and HDL levels lower, together increasing the risk of CHD.[60,61]
- *Other changes:* Emotional stress with unpredictable mood swings, weight gain, migraine headaches, and insomnia often accompany the change in estrogen levels.[62,63] Lower estrogen levels decrease skin thickness and diminish skin elasticity, thereby causing increased skin dryness and wrinkling.[64]

Aging and the Male Reproductive System

Men maintain reproductive capacity longer than women. There is no known discrete event, comparable to menopause, that characterizes aging of the male reproductive system, although the term *andropause* is sometimes used to describe the changes associated with male aging. Gradual changes do occur, and aging in the male reproductive system is characterized by hypogonadism, testosterone deficiency, erectile dysfunction, and proliferative disorders of the prostate gland[65] (see Chapter 25). Aging changes are also influenced by chronic diseases and use of medications.

Components of male sexual behavior include both sexual drive and erectile and ejaculatory capacity. Libido, or sexual drive, is a complex phenomenon that requires a baseline hormonal milieu but is influenced significantly by health status and environmental, social, and psychologic factors. In men older than 40 years, organic factors and chronic disease (e.g., vascular, endocrine, and neurologic disorders) are involved in more than half of the cases of male sexual dysfunction. Aging causes specific physical changes that may influence erectile and ejaculatory capabilities. Alterations in sexual response include the need for longer stimulation to achieve full erection; slower and less forceful ejaculation, with less pelvic muscle involvement; decreased vasocongestive response; and longer refractory period (time during which erection and ejaculation are not possible), up to 24 hours in some men.

The testes undergo several age-related structural changes, including decreased weight, atrophy, and softening. Degenerative changes in the seminiferous tubules may include thickening of the basement membrane; increase in lumen size; germ cell (spermatogonium) arrest and a decrease in spermatogenic activity; and collapse of tubules, followed by complete obstruction caused by sclerosis and fibrosis. Areas of mild to severe degenerative change may be interspersed with areas having intact tubules. These morphologic changes may result from atherosclerosis (arterial clogging) in the testicular vascular bed.[66] Alterations of the seminiferous tubules do not appear to diminish sperm counts (20 million sperm per milliliter of semen is estimated as the minimum concentration for fertility),[67] but they do reduce fertility because a greater percentage of the sperm lack motility or have structural abnormalities.

Aging probably causes changes in the production of male sex hormones, levels of SHBG, and responsiveness of target tissues. Hormone synthesis by the testes and testicular responsiveness to the gonadotropins (FSH and LH) are diminished, and pituitary secretion of these gonadotropins is elevated.[68] The reduced levels of testosterone may be related to alterations in the Leydig cells, the testosterone producers of the testes. The number of Leydig cells and their function decreases as age increases, perhaps because of decreased arterial perfusion of the testes and decreased responsiveness to LH.[69] Even if testosterone levels are not decreased, older men may have less unbound testosterone in their blood, decreasing the amount of unbound

hormone available to stimulate target tissues. Decreased testosterone levels have several effects, including functional deterioration of the accessory sex organs (the prostate gland, seminal vesicles, epididymis, and ductus deferens); loss of muscle mass, strength, and endurance; increased visceral fat, osteopenia, and cognitive decline; and, in many men, decrease in libido. This last effect also may be caused by alterations in other variables that affect libido.[70] Modifiable risk factors for low testosterone and symptoms of androgen deficiency include health status and waist circumference.[71]

SUMMARY REVIEW

Development of the Reproductive Systems

1. Differentiation of female and male genitalia begins around weeks 7 to 8 of embryonic development, when the gonads of genetically male embryos begin to secrete male sex hormones, primarily testosterone. Until that time the primitive reproductive organs of males and females are homologous (the same).
2. The structure and function of male and female reproductive systems are controlled by the hypothalamic-pituitary-gonadal (HPG) axis, a set of complex neurologic and hormonal interactions that accelerate at puberty and lead to sexual maturation and reproductive capability.
3. Extrahypothalamic factors cause the hypothalamus to secrete GnRH, which stimulates the anterior pituitary to secrete gonadotropins—FSH and LH—that stimulate the gonads (ovaries or testes) to secrete female or male sex hormones. Paracrine hormones (inhibin, activin, and follistatin) influence the positive and negative feedback loops that occur along the HPG axis.
4. Production of primitive female gametes (ova) occurs solely during fetal life. From puberty to menopause, one female gamete matures per menstrual cycle. Production of the male gametes (sperm) begins at puberty; after that, millions are produced daily, usually for life. Females release a mature ova at the time of puberty.

The Female Reproductive System

1. The function of the reproductive system is to produce mature ova and, when fertilized, to protect and nourish them through embryonic and fetal life, and expel them at birth.
2. The external female genitalia are the mons pubis, labia majora, labia minora, clitoris, vestibule (urinary and vaginal openings), Bartholin glands, and Skene glands.
3. The internal female genitalia are the vagina, uterus, fallopian tubes, and ovaries.
4. The vagina is a fibromuscular canal that receives the penis during sexual intercourse and is the exit route for menstrual fluids and products of conception. The vagina leads from the introitus (its external opening) to the cervical portion of the uterus.
5. The uterus is the hollow, muscular organ in which a fertilized ovum develops. The uterine walls have three layers: the endometrium (lining), myometrium (muscular layer), and perimetrium (outer covering, which is continuous with the pelvic peritoneum). The endometrium proliferates (thickens) and sloughs off in response to cyclic hormonal changes. The cervix is the narrow, lower portion of the uterus that opens into the vagina.
6. The two fallopian tubes extend from the uterus to the ovaries. Their function is to conduct ova from the spaces around the ovaries to the uterus. Fertilization normally occurs in the distal third of the fallopian tubes.
7. From puberty to menopause, the ovaries are the site of (1) ovum maturation and release and (2) production of female sex (estrogen and progesterone) and male (androgens) hormones. Female sex hormones predominate and are involved in sexual differentiation and development, the menstrual cycle, pregnancy, and lactation. Androgens in women contribute to prepubertal growth spurt, pubic and axillary hair growth, and activation of sebaceous glands.
8. Developing ovarian follicles (structures that enclose the ovum) produce estrogen (primarily estradiol). The corpus luteum, the structure that develops from the ruptured ovarian follicle after ovulation or ovum release, produces progesterone. Androgens are produced within the ovarian follicle, adrenal glands, and adipose tissue.
9. The average menstrual cycle lasts 27 to 30 days and consists of three phases, which are named for ovarian and endometrial changes: the follicular/proliferative phase, the luteal/secretory phase, and the ischemic/menstrual phase.
10. Ovarian events of the menstrual cycle are controlled by gonadotropins. High FSH levels stimulate follicle and ovum maturation (follicular phase), then a surge of LH causes ovulation, which is followed by development of the corpus luteum (luteal phase).
11. Ovarian hormones control the uterine (endometrial) events of the menstrual cycle. During the follicular/proliferative phase of the ovarian cycle, estrogen produced by the follicle causes the endometrium to proliferate (proliferative phase) and induces the LH surge and progesterone production in the granulosa layer. During the luteal/secretory phase, estrogen maintains the thickened endometrium, and progesterone causes it to develop blood vessels and secretory glands (secretory phase). As the corpus luteum degenerates, production of both hormones drops sharply, and the "starved" endometrium degenerates and sloughs off, causing menstruation, the ischemic/menstrual phase.
12. Cyclic changes in hormone levels also cause thinning and thickening of the vaginal epithelium, thinning and thickening of cervical secretions, and changes in basal body temperature.

Structure and Function of the Breast

1. Until puberty the female and male breasts are similar, consisting of a small underdeveloped nipple, some fatty and fibrous tissue, and a few ductlike structures under the areola.

SUMMARY REVIEW—cont'd

At puberty, however, a variety of hormones (estrogen, progesterone, prolactin, growth hormone, insulin, cortisol) cause the female breast to develop into a system of glands and ducts that is capable of producing and ejecting milk.

2. The basic functional unit of the female breast is the lobe, a system of ducts that branches from the nipple to milk-producing units called lobules. The lobules contain alveolar cells, which are convoluted spaces lined with epithelial cells that secrete milk and subepithelial cells that contract, moving the milk into the system of ducts that leads to the nipple.
3. Each breast contains 15 to 20 lobes, which are separated and supported by Cooper ligaments.
4. Milk production occurs in response to prolactin, a hormone that is secreted by alveolar epithelial cells in larger amounts after childbirth. Milk ejection is under the control of oxytocin which causes contraction of myoepithelial cells.
5. During the reproductive years breast tissue undergoes cyclic changes in response to hormonal changes of the menstrual cycle.
6. Prior to puberty the male breast development is similar to female development. Lack of high levels of estrogen and progesterone prevents further development of the male breast.

The Male Reproductive System

1. The function of the male reproductive system is to produce male gametes (sperm) and deliver them to the female reproductive tract.
2. The external male genitalia are the testes, epididymides, scrotum, and penis. The internal genitalia are the vas deferens, ejaculatory duct, prostatic and membranous sections of the urethra, seminal vesicles, prostate gland, and Cowper glands.
3. The testes (male gonads) are paired glands suspended within the scrotum. The testes have two functions: spermatogenesis (sperm production) and production of male sex hormones (androgens, chiefly testosterone).
4. The epididymis is a long coiled tube arranged in a comma-shaped compartment that curves over the top and rear of the testis. The epididymis receives sperm from the testis and stores them while they develop further. Sperm travel the length of the epididymis and then are ejaculated into the vas deferens.
5. The scrotum is a skin-covered fibromuscular sac that encloses the testes and epididymides, which are suspended within the scrotum by the spermatic cord. The scrotum keeps these organs at optimal temperatures for sperm survival (about 1° to 2° C lower than body temperature) by contracting in cold environments and relaxing in warm environments.
6. The penis is a cylindric organ consisting of three longitudinal compartments (two corpora cavernosa and one corpus spongiosum) and the urethra. The urethra runs through the corpus spongiosum. The corpora cavernosa and corpus spongiosum consist of erectile tissue. Externally the penis consists of a shaft and a tip, which is called the glans. The glans contains sebaceous glands and the opening of the urethra and is covered by a flap of skin (the foreskin).
7. The penis has two functions: delivery of sperm to the female vagina and elimination of urine. These two fluids are never in the urethra at the same time.
8. Sexual intercourse is made possible by the erectile reflex, in which tactile or psychogenic stimulation of the parasympathetic nerves causes arterioles in the corpora cavernosa and corpus spongiosum to dilate and fill with blood, causing the penis to enlarge and become firm.
9. Emission, which occurs at the peak of sexual arousal, is the movement of semen from the epididymides to the penis. Ejaculation, which is a continuation of emission, is the pulsatile ejection of semen from the penis. Both emission and ejaculation involve rhythmic contractions of smooth muscle within the internal glands and ducts.
10. The prostate gland is about the size of a walnut and surrounds the urethra. Prostatic secretions are alkaline and contribute to the ejaculate.
11. Cowper glands (bulbourethral glands) secrete mucus in the urethra and add fluid to the ejaculate.
12. Spermatogenesis is a continuous process because spermatogonia, the primitive male gametes, undergo continuous mitosis within the seminiferous tubules of the testes. Some of the spermatogonia develop into primary spermatocytes, which divide meiotically into secondary spermatocytes and then spermatids. The spermatids develop into sperm with the help of nutrients and hormonal signals from Sertoli cells.
13. Production of the male sex hormones is controlled (like production of the female sex hormones) by the HPG axis and by complex feedback mechanisms. The male hormones are produced steadily, with diurnal variations.

Tests of Reproductive Function

1. Diagnostic tests are performed to evaluate fertility.
2. Evaluation of fertility includes reproductive hormone assays and assessment of structural alteration or infections and the determination of normal ovulation or adequate sperm motility and count.

Aging and Reproductive Function

1. In women the transition from fertility to menopause (perimenopause) starts about 2 to 8 years before the last menstrual period and ends the following year. During this transition period the ovaries produce erratic and high levels of estrogen that contribute to such symptoms as hot flashes, breast tenderness and nodularity, and migraine headaches. Menstrual cycles shorten and then become irregular as anovulation occurs. Menstruation ceases, and women move into menopause.
2. Men maintain reproductive capacity into their later years. In some men there are gradual changes with testosterone deficiency, hypogonadism, proliferative disorders of the prostate, and erectile dysfunction.

CHAPTER OUTLINE

Alterations of the reproductive system span a wide range of concerns, from delayed sexual development and suboptimal sexual performance to structural and functional abnormalities. Many common reproductive disorders carry potentially serious physiologic or psychologic consequences. Sexual or reproductive dysfunction, such as impotence or infertility, can dramatically affect self-concept, relationships, and overall quality of life. Conversely, organic and psychosocial problems, such as alcoholism, depression, situational stressors, chronic illness, and medications, can affect ovulation and menstruation, sexual performance, and fertility and may be risk factors for the development of some types of reproductive tract cancers.[1] Breast cancer is the second leading cause of cancer death in women. Diagnosis and treatment of reproductive system disorders are complicated because of the stigma and symbolism associated with the reproductive organs and the emotion-laden beliefs and behaviors related to reproductive health.[2] Treatment and diagnosis for related problems may be delayed because of embarrassment, guilt, fear, or denial.

ABNORMALITIES OF REPRODUCTIVE TRACT DEVELOPMENT

As discussed in Chapter 23, normal development of the female reproductive tract requires absence of testosterone during embryonic/fetal life. The resulting fusion of the two paramesonephric (müllerian) ducts produces the normal cervix and the uterus with an internal cavity. The distal portions of the paramesonephric ducts remain independent and form the two fallopian/uterine tubes. Alterations in the normal process include errors in cellular sensitivity to testosterone (androgen insensitivity) or failures of cell line migration, resulting in changes in structure of the reproductive organs.

Androgen insensitivity occurs in its most extreme form in about 1 in 20,000 people[3] and it is discussed briefly in this chapter because of the often-resulting female phenotype, despite a male genotype. Children with complete androgen insensitivity may have testes palpable within the labia majora but are often not diagnosed until puberty.[4] Breast development may be

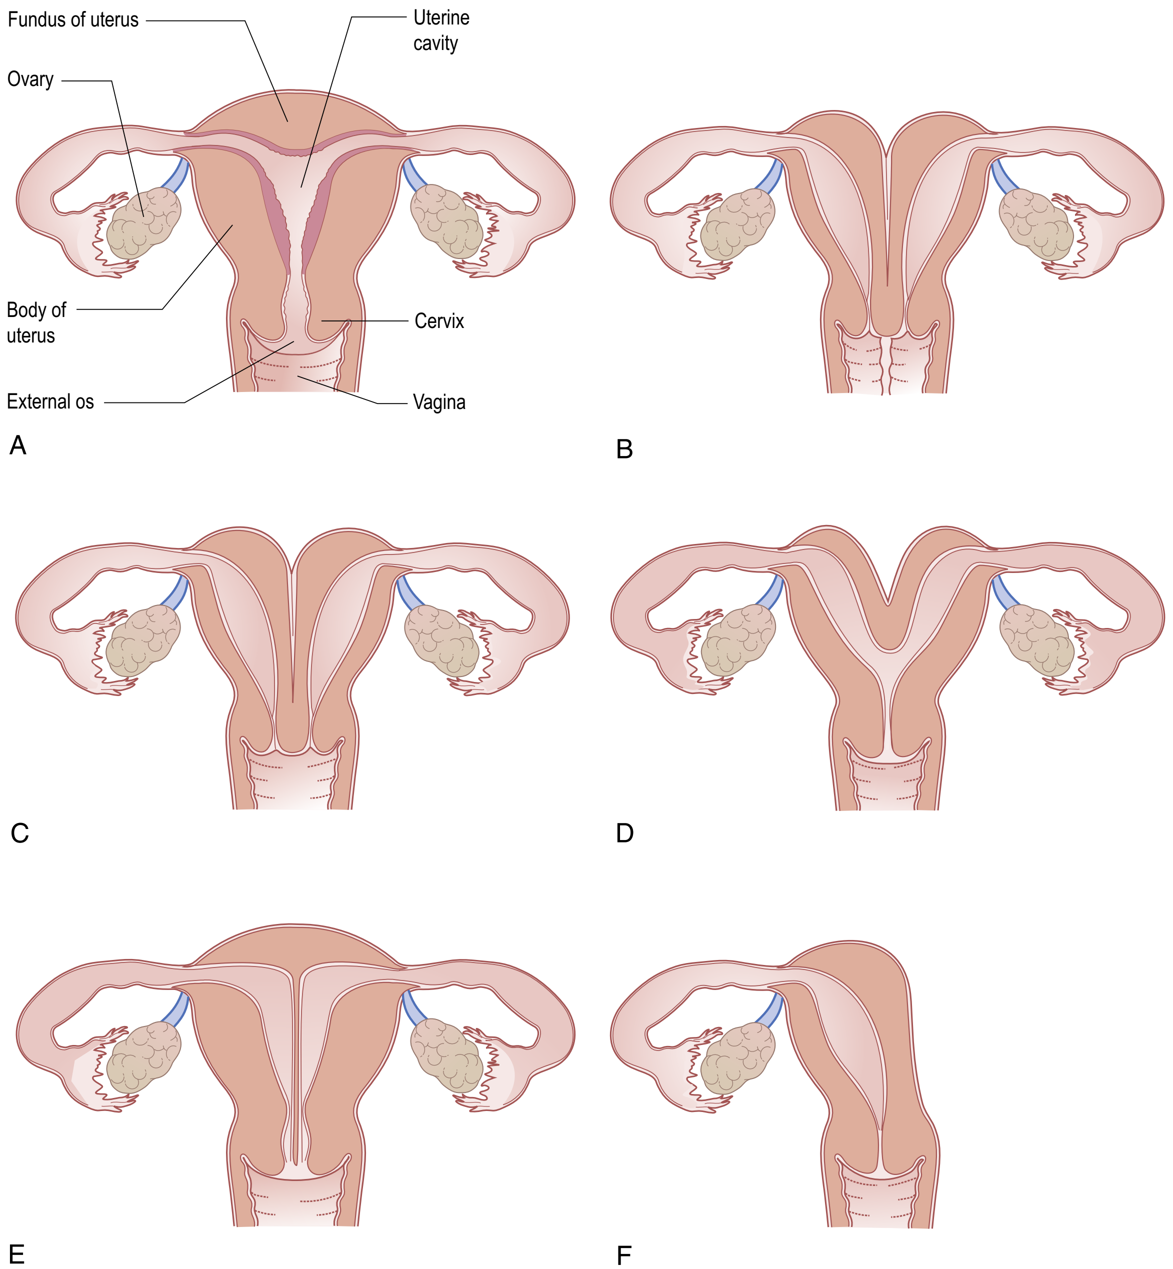

FIGURE 24-1 **Uterine Malformations.** Congenital uterine abnormalities. **A,** The normal configuration of the uterus and the ovaries. **B,** Double uterus with a double vagina and **C,** a single vagina. **D,** Bicornuate uterus. **E,** A uterus with a midline septum. **F,** Unicornuate uterus. (From de Bruyn R: *Pediatric ultrasound*, ed 2, London, 2010, Churchill Livingstone.)

normal, but pubic and axillary hair is often sparse and menarche does not occur because of the absence of a cervix, uterus, and ovaries.[4] A short vagina that ends blindly also may be present. Milder forms of androgen insensitivity (also a common cause of male infertility)[3] are much more common and have less dramatic phenotypic manifestations with many affected having normal male genitalia. A genetic karyotype reveals a male, genotype (XY).[4]

Other abnormalities of the uterus, cervix, and fallopian/uterine tubes have multi-factorial origins, often the result of an interaction between genetic predisposition and environmental factors. Such interactions result in müllerian duct abnormalities.[5] Some medications, chemicals, and toxins have been implicated as a direct cause of uterine abnormalities. For instance, diethylstilbestrol (DES) was prescribed from 1938 until 1971 as a drug to prevent miscarriages.[6] Although it was not effective at preventing miscarriage, DES did affect cell development and cause abnormal internal reproductive anatomy in exposed fetuses,[6] causing uterine malformations and a predisposition to cancer.

Most uterine abnormalities stem from abnormal cell migration in the müllerian ducts during key moments in fetal development (Figure 24-1). About 5% of the general female population has some sort of uterine abnormality but the rate is much

higher in populations of women who have experienced infertility or miscarriage.[7] Uterine abnormalities are rarely diagnosed until the woman has trouble becoming pregnant or carrying a baby to term because the uterus is capable of menstruation but may have difficulty supporting a growing fetus.[5]

Uterine malformations are usually diagnosed by ultrasound during pregnancy or with magnetic resonance imaging (MRI). Their prognosis depends of the severity of the malformation and the location and size of the placenta and fetus. Some abnormalities can be surgically corrected to improve the outcome of subsequent pregnancies.[5] Abnormalities of the lower genital tract also can result in women having two vaginas or a vaginal septum (a thin membrane dividing the vaginal vault). For most women this does not create functional problems but can be surgically corrected if needed.

ALTERATIONS OF SEXUAL MATURATION

The process of sexual maturation, or puberty, is marked by the development of secondary sexual characteristics, rapid growth, and, ultimately, the ability to reproduce. A variety of congenital and endocrine disorders can disrupt the timing of puberty, or sexual maturation. These disorders may cause puberty to occur too late (delayed puberty) or too early (precocious puberty). Both types involve a disrupted onset of sex hormone production by the gonads.

The age of puberty is multifactorial involving genetic and environmental components. Girls of African descent and Hispanic/Latina girls begin puberty up to 1 year sooner than their non-African and non-Latina counterparts.[8] Obesity decreases the age at onset of puberty by about 6 months. The normal range for the onset of puberty is now 8 to 13 years of age. Although there are conflicting and inconsistent reports, the age of pubertal onset appears to be decreasing for girls.[8] This earlier onset appears primarily in breast development, not age of menarche. On average breast development begins at age 10.4 for white girls and 9.5 years for black girls. The average age for menarche is 12.6 years for white girls and 12.1 for black girls. However, 5% of white girls and 15% of all girls will begin puberty before age 8.[8] Both early puberty, known as precocious puberty, and delayed puberty have implications for the child's social interactions and self-esteem.

Delayed Puberty

About 3% of children in North America experience delayed development of secondary sex characteristics.[9] One of the first signs of puberty in girls is usually thelarche, or breast development. Thelarche should begin by the time a girl is 13 years old. Puberty is considered delayed if there are no clinical signs of puberty by age 13 in girls (2 standard deviation [SDs] above the mean age of pubertal onset). Clinical diagnosis also can be made in the absence of menarche by age 15 or 16.

In 95% of cases, delayed puberty is a physiologic (constitutional) delay in which hormonal levels are normal and the hypothalamic-pituitary-gonadal (HPG) axis is intact, but maturation is happening slowly. This physiologic delay tends to be familial, is not as common in girls as it is in boys, and is frequently diagnosed retrospectively once pubertal progression is complete.[10]

Many clinicians recommend intervention (i.e., exogenous sex steroid administration) in physiologic cases of delayed puberty to reduce the psychologic effects (e.g., self-esteem issues, embarrassment) often associated with delayed puberty. The other 5% of cases are caused by a disruption of the HPG axis of various etiologies, including any chronic condition that delays bone aging (i.e., celiac disease, anorexia, hypothyroidism)[10,11] (Table 24-1).

Human gonadal function is partially controlled by luteinizing hormone (LH) and follicle-stimulating hormone (FSH), the release of which is regulated by the pulsatile secretion of hypothalamic gonadotropin-releasing hormone (GnRH).[12,13] The G-protein–coupled receptor 54 (GPR54) has been identified as the gatekeeper gene for activation of the GnRH axis. GPR54 is required for the normal function of this axis, and data suggest that the ligand kisspeptin-1 may act as a neurohormonal regulator of the GnRH axis.[14]

The mechanisms of childhood inhibition of GnRH release and activation are poorly understood but appear to involve

TABLE 24-1 FREQUENCY AND COMMON CAUSES OF DELAYED PUBERTY OTHER THAN CONSTITUTIONAL DELAY OF GROWTH AND PUBERTY

DELAYED PUBERTY	HYPERGONADOTROPIC HYPOGONADISM	PERMANENT HYPOGONADOTROPIC HYPOGONADISM	FUNCTIONAL HYPOGONADOTROPIC HYPOGONADISM
Frequency (%)			
Boys	5-10	10	20
Girls	25	20	20
Common causes	Turner syndrome, gonadal dysgenesis, chemotherapy, or radiation therapy	Tumors or infiltrative diseases of the central nervous system, GnRH deficiency (isolated hypogonadotropic hypogonadism, Kallmann syndrome), combined pituitary-hormone deficiency, chemotherapy, or radiation therapy	Systemic illness (inflammatory bowel disease, celiac disease, anorexia nervosa, or bulimia), hypothyroidism, excessive exercise

From Palmert MR, Dunkel L: *N Engl J Med* 366(5):443–453, 2012.
GnRH, Gonadotropin-releasing hormone.

feedback inhibition by sex steroids and presumably other central nervous system (CNS) pathways.[14] Given the numerous etiologies contributing to the occurrence of delayed puberty, a thorough evaluation should be conducted that includes physical examination and medical and family history that specifically targets known contributors to delayed puberty. Laboratory workup may consist of x-ray studies for bone age, measurement of thyroid function, serum levels of prolactin and adrenal and gonadal steroids, radioimmunoassay of plasma gonadotropins, and screening for systemic disorders. Adolescents with high gonadotropin levels require a karyotype to rule out genetic causes, and those with low levels need skull imaging (lateral skull film, computed tomography [CT], or MRI) to rule out pituitary or other CNS infiltrate or tumor. Treatment of delayed puberty depends on the cause; the goal of treatment is the development of secondary sex characteristics and fertility, when possible. Insufficient sex hormone secretion can be corrected by hormone replacement therapy, such as estrogen. Idiopathic hypogonadotropic hypogonadism is treated with synthetic GnRH or sex hormone administration, or both, and may be lifelong.[11]

Precocious Puberty

Precocious puberty is a rare event, affecting about 1 in 10,000 girls and fewer than 1 in 50,000 boys. Precocious puberty has been redefined as sexual maturation before age 6 in black girls or age 7 in white girls, and before age 9 in boys.[15] This reflects a trend toward earlier puberty, primarily for breast development in girls (see What's New? Precocious Puberty). There have been many postulated causes of precious puberty (Box 24-1), including increased obesity, an increase in protein consumption,[16,17] and the growing prevalence of molecular compounds known as endocrine disruptors in common household products.[18] However, because precocious puberty can be a sign of pathology, all cases of precocious puberty require thorough evaluation.

Precocious puberty may be partial, complete, or mixed types (Box 24-2) and can be further categorized into central (GnRH dependent) and peripheral (GnRH independent)

WHAT'S NEW?

Precocious Puberty

Studies implicate obesity, leptin, ghrelin, and environmental endocrine disruptor chemicals (EDCs) as possible contributors to precocious puberty in girls. Obesity may affect the production and secretion of leptin and ghrelin, powerful communicators of satiety, hunger, metabolic rate, and in timing of puberty. EDCs may mimic, block, or alter the normal signaling systems involved in sex hormone secretion, uptake, and use. EDCs include agrochemicals, widespread industrial compounds, and persistent pollutants.

BOX 24-1 CAUSES OF PRECOCIOUS PUBERTY

Central (Gonadotropin-Releasing Hormone [GnRH] Dependent)

- Idiopathic
- Central nervous system (CNS) disorders
  - Congenital anomalies (hydrocephalus)
  - Hypothalamic hamartoma
  - Postinflammatory/infectious condition
  - Trauma
  - Tumors (hypothalamic, pineal, other)
- Hypothyroidism (severe)
- Imprinted gene (MKRN3)

Peripheral Puberty (GnRH Independent)

- Adrenal hyperplasia or tumor
- Environmental endocrine disruptors
- Exogenous sex steroid exposure
- Exogenous anabolic steroids
- Familial Leydig cell hyperplasia
- Gonadal tumors or cysts
- Human chorionic gonadotropin (hCG)–secreting tumors (hepatoblastomas, intracranial lesions)
- McCune-Albright syndrome
- Testotoxicosis

BOX 24-2 PRIMARY FORMS OF PRECOCIOUS PUBERTY

Complete Precocious Puberty

- Premature development of appropriate characteristics for the child's sex
- Hypothalamic-pituitary-ovarian axis working normally but prematurely
- In about 10% of cases, lethal central nervous system tumor may be the cause

Partial Precocious Puberty

- Partial development of appropriate secondary sex characteristics
- Premature thelarche (breast budding) seen in girls between 6 months and 2 years of age
- Does not progress to complete puberty (ovulation and menstruation)
- Premature adrenarche (growth of axillary and pubic hair) tends to occur between 5 and 8 years of age
- Can progress to complete precocious puberty; may be caused by estrogen-secreting neoplasms or may be a variant of normal pubertal development

Mixed Precocious Puberty

- Causes the child to develop some secondary sex characteristics of the opposite sex
- Common causes: adrenal hyperplasia or androgen-secreting tumors

Data from Burchett MLR et al: Endocrine and metabolic diseases. In Burns CE et al, editors: *Pediatric primary care*, St Louis, 2009, Saunders; Jospe N: Disorders of pubertal development. In Osborn LM et al, editors: *Pediatrics,* Philadelphia, 2005, Mosby.

(see Box 24-1). **Central precocious puberty** is GnRH dependent and occurs when the HPG axis is working normally but prematurely. Besides the premature development of secondary sex characteristics, precocity causes premature closure of the epiphysis of long bones, which results in lifelong short stature.[10] Central precocious puberty results from failure of central inhibition of the GnRH pulse generator (the gonadostat). The diagnosis of central precocious puberty is one of exclusion.[10] Because a CNS lesion may be missed, children with presumed central precocious puberty require long-term surveillance. Peripheral puberty is GnRH independent and develops when sex hormones are produced by some mechanism other than stimulation by the gonadotropins. Sex steroid–producing tumors (i.e., gonadal tumors), testotoxicosis, and exposure to exogenous sex steroids (i.e., hormonal contraceptives and environmental endocrine disruptors) are some of the causes (see Box 24-1). Mutations in the imprinted gene MKRN3 was recently reported as a cause of central precocious puberty.[18a]

Partial precocious puberty is the partial development of appropriate secondary sex characteristics alone or in combination. A girl with incomplete precocious puberty might undergo thelarche or pubarche and, rarely, premature menarche. Premature thelarche is seen in girls between 6 months and 2 years of age. Premature pubarche tends to occur between ages 5 and 8 years. Premature pubarche is usually the consequence of an early increase in the adrenal androgens that leads to early growth of pubic hair and possibly a transient acceleration in growth and bone maturation that has no significant effect on timing of puberty or final height. Sparse hair growth on the genitalia, in the absence of thelarche or menarche, does not represent precocious puberty.

The diagnosis and cause of premature development are often straightforward.[8] A thorough history and physical examination are done to determine the velocity of the process and to rule out life-threatening CNS, ovarian, or adrenal neoplasms. Family occurrence helps exclude tumors. Children with precocious puberty also have a tendency toward obesity.[8]

Treatment for all forms of precocious puberty includes identifying and removing the underlying cause or administering appropriate hormones (see Boxes 24-1 and 24-2). If needed, precocious puberty can be reversed. Management goals include diagnosing and treating intracranial disease; arresting maturation until developmentally appropriate; maximizing eventual adult height; reducing emotional problems. The most common form, central precocious puberty, is usually treated with potent GnRH agonist analogs, which induce reversible, selective suppression of the HPG axis. Because many of these children are obese and childhood obesity is predictive of morbidity in adolescence and adulthood, it is important for clinicians to include assessment and management of obesity as part of the treatment for central precocious puberty.

Complete precocious puberty refers to the onset and progression of all pubertal features (i.e., thelarche, pubarche, and menarche). **Mixed precocious puberty** (virilization of a girl or feminization of a boy) causes the child to develop some secondary sex characteristics of the opposite sex. This condition is usually evident at birth and is rare in older children (Box 24-3).

BOX 24-3 CAUSES OF MIXED PRECOCIOUS PUBERTY

Female (Virilization)

Congenital adrenal hyperplasia
Androgen-secreting tumors
- Adrenal
- Ovarian
- Teratoma
- Exogenous androgens

Male (Feminization)

Estrogen-producing tumors
- Adrenal
- Teratoma
- Hepatoma
- Testicular

Exogenous estrogens
Increased peripheral conversion of androgens to estrogens

From Jospe N: Disorders of pubertal development. In Osborn LM et al, editors: *Pediatrics,* Philadelphia, 2005, Mosby.

DISORDERS OF THE FEMALE REPRODUCTIVE SYSTEM

Hormonal and Menstrual Alterations

Primary Dysmenorrhea

Primary dysmenorrhea is painful menstruation associated with the release of prostaglandins in ovulatory cycles, but not with pelvic disease. Approximately 50% of all women experience dysmenorrhea, 10% of whom are incapacitated for 1 to 3 days because of pain severity. Primary dysmenorrhea usually begins with the onset of ovulatory cycles, around age 15 or 16 years with prevalence highest during adolescence.[19] In contrast, **secondary dysmenorrhea** is related to pelvic pathology (i.e., ovarian cysts, endometriosis) which manifests in later reproductive years and may occur any time in the menstrual cycle.[20]

PATHOPHYSIOLOGY. Primary dysmenorrhea is attributed to excessive endometrial prostaglandin production.[20,21] Women with painful periods produce 10 times as much prostaglandin F ($PGF_2\alpha$), a potent myometrial stimulant and vasoconstrictor, as asymptomatic women. Elevated levels of prostaglandins (especially $PGF_2\alpha$ and $PGE_2\alpha$) cause uterine hypercontractility, decreased blood flow to the uterus, and increased nerve hypersensitivity, thus resulting in pain.[20] Women with dysmenorrhea may have up-regulated cyclo-oxygenase (COX) enzyme activity, which contributes to increased synthesis of prostaglandins. Furthermore, leukotriene production is elevated further contributing to increased levels of pain.[20] Prostaglandins are primarily released during the first 48 hours of menstruation, when symptoms are the most intense. Women who are anovulatory because they use oral contraceptives rarely have primary dysmenorrhea. Secondary dysmenorrhea results from disorders such as endometriosis (the most common cause), endometritis (infection), pelvic inflammatory disease, obstructive uterine or vaginal anomalies, uterine fibroids, polyps, tumors, ovarian cysts, pelvic congestion syndrome, or nonhormonal intrauterine devices (IUDs).[20]

CLINICAL MANIFESTATIONS. The chief symptom of dysmenorrhea is pelvic pain associated with the onset of menses. The pain often radiates into the groin and may be accompanied by backache, anorexia, vomiting, diarrhea, syncope, and headache. The latter symptoms are caused by entry of prostaglandins and prostaglandin metabolites into the systemic circulation. Usually the discomfort associated with primary dysmenorrhea begins shortly before the onset of menstruation and persists for the first 1 to 3 days of menstrual flow.[20]

EVALUATION AND TREATMENT. Primary dysmenorrhea can be differentiated from secondary dysmenorrhea by a thorough history and pelvic examination. Nonsteroidal anti-inflammatory medication (NSAIDs, e.g., ibuprofen) is the treatment of choice as these reduce COX enzyme activity, thus prostaglandin production. NSAIDs work in the majority of women with primary dysmenorrhea and are most effective if started at the first sign of bleeding or cramping.[22] In women who desire contraception, dysmenorrhea may be relieved with hormonal contraceptives.[23] Hormonal contraception stops ovulation and creates an atrophic endometrium, thereby decreasing prostaglandin synthesis and myometrial contractility. Regular exercise and stress reduction are thought to prevent or reduce symptoms.[24] Other nonpharmacologic approaches with some evidence of effectiveness in pain relief include local application of heat; acupuncture;[25] high-frequency transcutaneous electrical nerve stimulation (TENS); supplements, such as thiamine and vitamin E; and Chinese herbal treatment.[26]

Amenorrhea

Amenorrhea means lack of menstruation, and the most common causes (aside from pregnancy) are caused by hypothalamic dysfunction, polycystic ovarian syndrome, hyperprolactinemia, and ovarian failure.27 **Primary amenorrhea** is the failure of menarche and the absence of menstruation by age 13 years without the development of secondary sex characteristics or by age 15 regardless of the presence of secondary sex characteristics (see p. 802 for discussion of delayed puberty).[28] Primary amenorrhea differs from delayed puberty in that most cases of delayed puberty require only reassurance, but when the diagnosis of primary amenorrhea is reached, a thorough evaluation is needed. **Secondary amenorrhea** is the absence of menstruation for a time equivalent to three or more cycles in women who have previously menstruated. Pregnancy is the most common condition to rule out prior to further evaluation.

PATHOPHYSIOLOGY. There are numerous classifications of the etiologies of primary amenorrhea. One approach to understanding the pathophysiology is through compartmentalization. *Compartment IV disorders* include CNS disorders, in particular hypothalamic disorders. In some of the congenital syndromes that cause primary amenorrhea, the hypothalamic-pituitary-ovarian (HPO) axis is dysfunctional. The hypothalamus is unable to synthesize GnRH, so the pituitary fails to secrete LH and FSH. Therefore, the ovary does not receive the hormonal signals required to stimulate estrogen production, and ovulation and menstruation do not occur. Because the ovarian hormones are absent, estrogen-dependent sex characteristics do not develop.

Compartment III disorders are disorders of the anterior pituitary, including tumors. Some anatomic defects of the CNS, whether congenital or acquired, impinge on the hypothalamic-pituitary unit so as to interfere with or interrupt the secretion of GnRH or FSH and LH. Examples of such defects include hydrocephalus, craniopharyngiomas, and other space-occupying lesions of the CNS. Again the target organ, the ovary, does not receive the necessary signals, and ovulation and menstruation do not occur. In some cases these lesions develop between the onset and conclusion of puberty. Therefore, skeletal growth may occur and secondary sex characteristics may develop, but sexual maturation is interrupted before menarche.

Compartment II disorders involve the ovary and are often linked with genetic abnormalities. These include gonadal dysgenesis (Turner syndrome), androgen insensitivity syndrome (AIS), formerly known as *testicular feminizing syndrome* or *male pseudohermaphroditism.* Turner syndrome involves the lack of two functional and complete X chromosomes in at least some body tissues (45,X/46,XX; structural X or Y abnormalities; mosaicism),[29] which results in the ovaries lacking gametes and ovarian failure. Without primitive gametes and follicles, follicular development and estrogen secretion cannot occur. Lack of estrogen accounts for failure of secondary sex characteristic development and amenorrhea, although there are high levels of circulating FSH and LH.[29]

In AIS, the individual is male genetically but female morphologically. The individual does not develop male genitalia because even though testosterone is produced in the fetus as a result of the presence of the Y chromosome, the cells are not sensitive to testosterone because androgen receptors are absent in target cells forming the reproductive tract.[30] In individuals with AIS, the gonads are found either in the abdomen or in the inguinal canal, and they may produce both androgens and estrogens. Because target tissues lack androgen receptors but have estrogen receptors, most individuals with AIS have female external genitalia and female secondary sex characteristics. With the exception of a small vagina, internal female genitalia are absent, accounting for amenorrhea and infertility.[30]

Compartment I disorders are anatomic defects of the outflow tract associated with primary amenorrhea. They include congenital absence of the vagina and uterus and congenital uterine hypoplasia (infantile uterus). Genetically normal females without a uterus or vagina usually have normal ovarian function. Therefore, skeletal growth occurs and secondary sex characteristics develop in the proper sequence, but menstruation does not occur because the uterus is too small or malformed to produce substantial endometrium.

CLINICAL MANIFESTATIONS. The major clinical manifestation of primary amenorrhea is the absence of the first menstrual period. The cause of the amenorrhea determines whether secondary sex characteristics and height are affected.

EVALUATION AND TREATMENT. Diagnosis of primary amenorrhea is based on history and physical examination and whether secondary sexual characteristics are present or absent. Absence of these sexual characteristics indicates that a girl or woman has never been exposed to estrogen. If ovarian steroid hormone

levels are low, the individual has the appearance of an immature female. Physical examination may show structural or physiologic alterations of the reproductive tract as outlined at the beginning of the chapter. Laboratory studies may be required to document karyotype, abnormal levels of gonadotropins, and ovarian hormones. Diagnostic imaging is used to document structural abnormalities (see Figure 24-1).

Treatment involves correction of any underlying disorders and hormone replacement therapy to induce the development of secondary sex characteristics as necessary (see p. 802 for a discussion of delayed puberty). Although surgical alteration of the genitalia may be undertaken to correct structural abnormalities, surgery should be delayed until the affected individual can make a truly informed decision. Hormonal manipulation or embryo transplantation may make pregnancy possible for women with primary amenorrhea who have a normal uterus.

Secondary Amenorrhea

A wide variety of disorders and physiologic conditions are associated with secondary amenorrhea. Besides disease, secondary amenorrhea can be triggered by dramatic weight loss, whether the loss results from malnutrition or excessive exercise. Secondary amenorrhea is common during early adolescence and the perimenopausal period, pregnancy, and lactation. The most common causes (after pregnancy) are thyroid disorders (e.g., hypothyroidism), hyperprolactinemia, HPO interruption

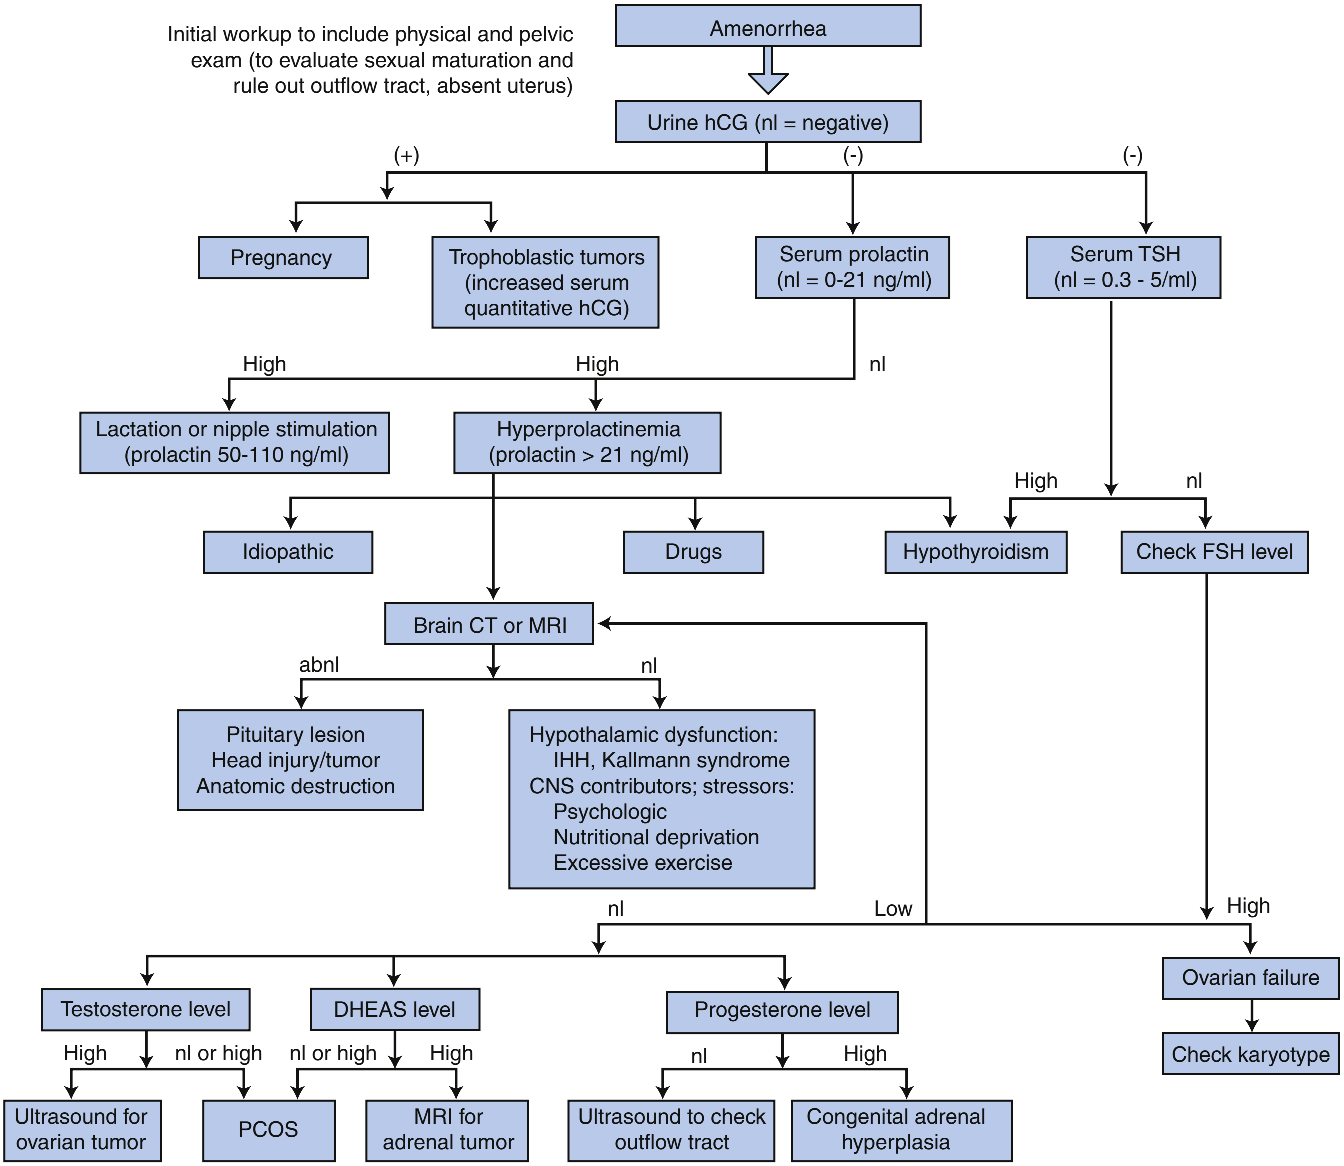

FIGURE 24-2 **Diagnosis of Amenorrhea.** Pregnancy is the most common cause of amenorrhea. *CNS,* Central nervous system; *CT,* computed tomography; *DHEAS,* dehydroepiandrosterone sulfate; *FSH,* follicle-stimulating hormone; *hCG,* human chorionic gonadotropin; *IHH,* idiopathic hypogonadotropic hypogonadism; *MRI,* magnetic resonance imaging; *nl,* normal; *PCOS,* polycystic ovary syndrome; *TSH,* thyroid-stimulating hormone. (Adapted from Schorge JO et al, editors: *Williams gynecology,* New York, 2008, McGraw-Hill.)

secondary to excessive exercise, stress, weight loss, and polycystic ovary syndrome (PCOS).

PATHOPHYSIOLOGY. The causes of secondary amenorrhea are summarized in Figure 24-2. In women with normal ovarian steroid hormone levels, secondary amenorrhea may be caused by structural abnormalities (müllerian anomalies), Asherman syndrome (removal of the endometrial decidua basalis), or removal of the uterus. In women with elevated ovarian steroid hormone levels, inhibited ovulation leads to amenorrhea. An excess of ovarian hormones disrupts feedback relationships within the HPO axis, preventing ovulation. Depressed ovarian hormone levels, which are associated with a variety of clinical disorders, also cause amenorrhea by preventing ovulation. Lack of ovulation, termed **anovulation,** may result from increased levels of prolactin, decreased levels of gonadotropins, irregular secretion of gonadotropins, or abnormally low levels of CNS neurotransmitters (i.e., dopamine and GnRH). Any of these variables alters the feedback effects that the ovarian hormones have on the hypothalamus and pituitary.

High levels of prolactin are physiologic during lactation because it increases milk production and suppresses ovulation, preventing closely spaced pregnancies. However, high levels of prolactin not related to lactation are abnormal and will disrupt the menstrual cycle. **Hyperprolactinemia** (overproduction of prolactin by the pituitary) may have indirect effects that lead to decreased secretion of GnRH by the hypothalamus. The result is a reduction in FSH and LH secretion followed by anovulation and secondary amenorrhea. Hyperprolactinemia should be diagnosed through blood testing that specifically tests for both normal-size and large molecular prolactin (macroprolactin). Hyperprolactinemia can have many causes including medication side effects, hypothyroidism, excessive nipple stimulation, and pituitary tumors[31] (see pp. 724 and 837 for additional information).

CLINICAL MANIFESTATIONS. The major manifestation of secondary amenorrhea is the absence of menses after previous menstrual periods. Infertility, vasomotor flushes, vaginal atrophy, acne, osteopenia, and **hirsutism** (abnormal hairiness) also may be present, depending on the underlying cause of the amenorrhea.

EVALUATION AND TREATMENT. Pregnancy is the most common cause of amenorrhea and must be ruled out prior to other evaluations. The menstrual cycle also may stop or become irregular in response to stress, extreme exercise, large dietary changes, eating disorders, or sleep abnormalities. A thorough history of the woman's life and stressors is important in assessing amenorrhea. Diagnosis of the organic cause of secondary amenorrhea involves the identification of underlying hormonal or anatomic alterations. A woman with secondary amenorrhea and normal secondary sex characteristics should have a complete history and physical examination. After ruling out pregnancy and performing an in-depth history, initial laboratory evaluation includes measurement of thyroid-stimulating hormone (TSH) and prolactin levels (Figure 24-3). Elevated prolactin levels warrant further investigation, including a complete medication history, TSH, and brain CT or MRI if warranted.[31] If these initial tests are normal, further testing would include measurement of gonadotropins (FSH), estrogen and testosterone, ultrasonography of the outflow tract and ovaries or adrenal MRI, or both.

Treatment of amenorrhea depends on the cause and the woman's psychologic need for cycle stability. Treatments may include replacing deficient hormones (e.g., estrogens, thyroid

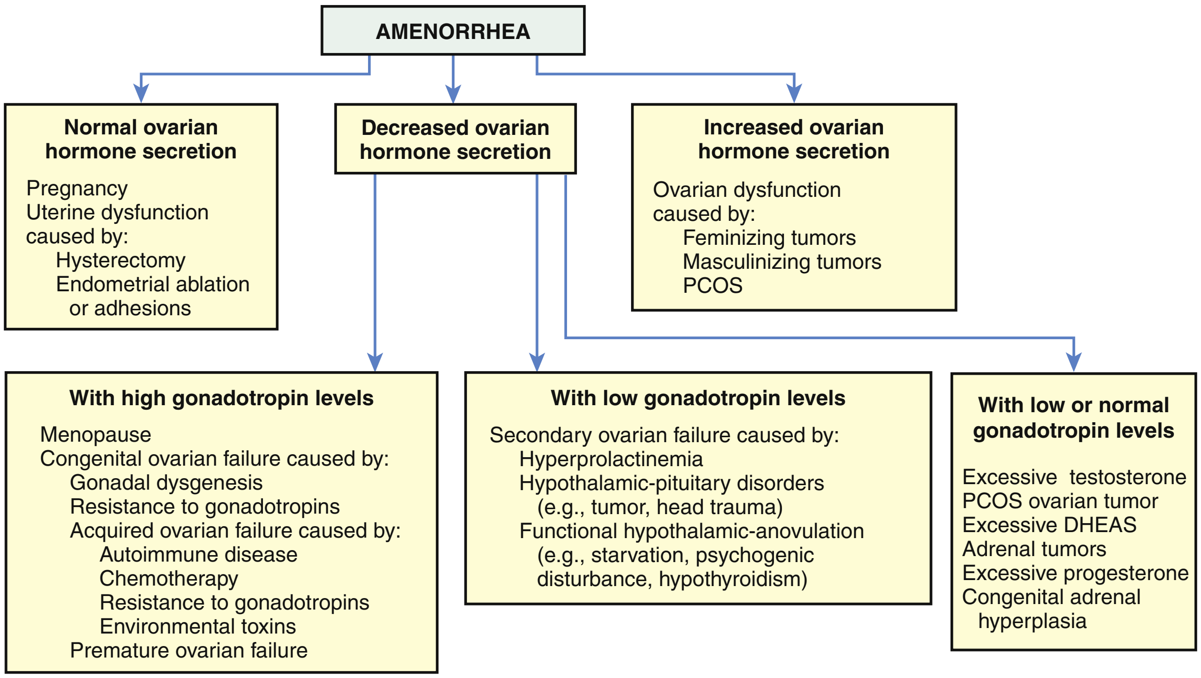

FIGURE 24-3 Causes of Secondary Amenorrhea. Of note, hypothyroidism is a relatively common condition and should be ruled out as the cause of hyperprolactinemia before more extensive evaluation (i.e., computed tomography or magnetic resonance imaging) occurs. *DHEAS,* Dehydroepiandrosterone sulfate; *PCOS,* polycystic ovary syndrome.

TABLE 24-2 ABNORMAL MENSTRUAL BLEEDING

TERM	DEFINITION
Polymenorrhea	Cycles shorter than 3 wk; may indicate disturbance in endocrine control of ovulation
Oligomenorrhea	Cycles longer than 6-7 wk; may indicate disturbance in endocrine control of ovulation
Metrorrhagia	Intermenstrual bleeding or bleeding of light character occurring irregularly between cycles; may be a sign of organic disease
Hypermenorrhea	Excessive flow; may be a sign of organic disease
Menorrhea	Prolonged duration of flow
Menorrhagia	Increased amount and duration of flow
Menometrorrhagia	Prolonged flow associated with irregular and intermittent spotting between bleeding episodes

hormone, glucocorticoids, gonadotropins) or correcting underlying pathology (e.g., tumor removal).[32,33] A diagnosis of PCOS might be treated with an insulin-sensitizing agent, such as metformin, as well as ovulation-inducing drugs if fertility is desired (a discussion of PCOS is on p. 810).

Some treatments for amenorrhea prevent pregnancy, whereas others may restore fertility; the choice of treatment may be influenced by the woman's childbearing plans. After pathologies have been corrected and the menstrual cycle stabilized, fertility may return. Occasionally, women with secondary amenorrhea may need additional ovulation-inducing drugs to assist conception, whereas others are able to conceive naturally.[33]

Abnormal Uterine Bleeding

Menstrual irregularity or abnormal bleeding patterns (Table 24-2) account for approximately 33% of all gynecologic visits. Abnormal bleeding can be caused by a disruption in the HPG axis, abnormalities of the uterus or endometrium, or bleeding disorders. Anovulatory cycles (failure to ovulate) because of various etiologies (age, stress, endocrinopathy) are the most common cause of cycle irregularity. Other causes include uterine tumors, polyps, ovarian cysts, complications of pregnancy, and bleeding disorders (e.g., von Willebrand disease). Common causes of abnormal uterine bleeding based on age group and frequency are listed in Table 24-3. Pathophysiology and treatment options vary and are based on etiology.[34]

Dysfunctional uterine bleeding (DUB) is heavy or irregular bleeding in the absence of organic disease, such as submucous fibroids, endometrial polyps, blood dyscrasias, pregnancy, infection, or systemic disease. The diagnosis of DUB is made once these other causes have been excluded. DUB affects 15% to 20% of all women at some time during their menstrual life and accounts for 70% of all hysterectomies and almost all endometrial ablation procedures.[35] Perimenopausal women are by far the most affected by DUB.

PATHOPHYSIOLOGY. The majority of abnormal uterine bleeding, commonly known as dysfunctional bleeding, is due to lack of ovulation.[34] Normal, regular periods are the result of a complex interplay between the hypothalamus, the pituitary, the ovary, and the uterine endometrium (see Chapter 23). Disruptions in this system can affect the amount and structure of the uterine endometrium, causing it to shed irregularly or heavily. Although DUB may occur at any time during the reproductive years, 20% of cases occur in adolescents, and more than 50% of cases occur in perimenopausal women ages 40 to 50 years because women at the edges of the reproductive years are more likely to ovulate irregularly. The formation of a follicle and its rupture to release an ovum is an important component of the menstrual cycle. As the follicle forms, it produces estrogen, which causes proliferation of the endometrium. Following ovulation, the remaining portions of the follicle, known as the corpus luteum, release progesterone. The progesterone acts on the proliferating endometrium to limit growth and cause changes in the vasculature of the endometrium, which limits bleeding during endometrial shedding.

If a follicle forms but never releases the ovum, the follicle may continue to produce estrogen (estradiol [E_2]) encouraging

TABLE 24-3 COMMON CAUSES OF ABNORMAL (VAGINAL/GENITAL) BLEEDING IN DESCENDING ORDER OF FREQUENCY

AGE GROUP	CAUSE
Prepubescence	Sexual assault Trauma Foreign bodies Precocious puberty
Adolescence	Anovulation (immature hypothalamic-pituitary-ovarian axis) Trauma and sexual abuse
Reproductive years	Pregnancy Pelvic inflammatory disease Coagulation disorder Hormonal contraceptives Endometriosis Anovulation IUDs Ovarian cysts Uterine polyps/tumors PCOS Bleeding disorders (e.g., von Willebrand) Trauma/rape
Perimenopause	Anovulation Malignancy Pregnancy Endometriosis Benign neoplasms (myomas, adenomyosis)
Postmenopause	Malignancy
Other: Non–age specific	Chronic conditions Adrenal conditions Thyroid disorders Liver disease Diabetes mellitus Obesity Hypertension

IUD, Intrauterine device; *PCOS,* polycystic ovary syndrome.

endometrial proliferation beyond the normal 14-day time window. In addition, the lack of progesterone causes the thickened endometrium to be unable to shed in a predictable fashion without excessive blood loss. Women who fail to ovulate experience irregularities in their menstrual bleeding related to the lack of progesterone and, in some cases, an excess of estrogen.

Many conditions are associated with irregular ovulation. Women at the edges of their reproductive life span, both young and old, are more likely to experience anovulatory cycles. In older women this is a result of having fewer viable follicles for ovulation (see Chapter 23 for a description of the many hormonal changes associated with the time before and just after menopause). Other conditions associated with chronic anovulation include PCOS, in which follicles begin to form but never reach maturation and rupture; obesity because adipose tissue excretes estrogen, which can suppress the HPG axis; hyperthyroidism and hypothyroidism; and estrogen-secreting ovarian neoplasms.

Without ovulation, menstrual flow may become irregular (metrorrhagia) and excessive (menorrhagia) or both (menometrorrhagia), resulting from the large quantity of tissue available for bleeding and the random breakdown of tissue that results in exposure of vascular channels. In the absence of adequate progesterone levels, usual endometrial control mechanisms are missing, such as vasoconstrictive rhythmicity, tight coiling of spiral vessels, and orderly collapse, and stasis does not occur. Unopposed estrogen induces a progression of endometrial responses beginning with proliferation, hyperplasia, and adenomatous hyperplasia; over a course of many years, unopposed estrogen may end with atypia and carcinoma.

Abnormal menstrual bleeding also can result from defects of the corpus luteum, resulting in progesterone deficiencies or from abnormalities of the uterus or cervix, such as endometrial polyps, uterine fibroids, or even uterine or cervical cancers. (These conditions are covered in more detail later in the chapter.) Coagulation defects also can cause heavy and abnormal uterine bleeding and should be suspected in younger women with a history of extensive bruising.

CLINICAL MANIFESTATIONS. Abnormal uterine bleeding is characterized by unpredictable and variable bleeding. Especially during perimenopause, abnormal bleeding also may involve greatly increased menstrual flow and the passage of large clots, leading to excessive blood loss. Excessive bleeding can lead to iron deficiency anemia and associated symptoms (fatigue, shortness of breath).

EVALUATION AND TREATMENT. The first step in assessing abnormal bleeding is to determine the cause of bleeding. If an organic cause can be found, the focus is on eliminating the pathology or mitigating its effects. To determine the cause of the bleeding, a complete and thorough history and physical examination is needed. The woman's age and risk factors for other abnormal conditions are important in assessing the likely cause of the bleeding. If no cause can be found, it is usually assumed that the bleeding is caused by lack of regular ovulation because this is the cause of the majority of abnormal bleeding. Irregular menstrual bleeding because of anovulation is often referred to as DUB. Treatment goals include preventing or controlling abnormal bleeding, identifying underlying disease, and inducing regular menstrual cycles. Treatment varies greatly by the age of the woman and her desire for current and future fertility.

NSAIDs, such as ibuprofen and naproxen, are often first-line treatments for excessive menstrual bleeding because they reduce prostaglandin synthesis within the endometrial tissues, which causes vasoconstriction and decreased menstrual blood loss. NSAIDs can reduce menstrual bleeding significantly with minimal side effects.[36] For best effect they should be taken in the few days preceding the beginning of the menstrual period and be continued through the days of heaviest bleeding. NSAIDs are not as effective in controlling menstrual blood loss as hormonal therapies but they are readily available without a prescription.[36]

Young women and those of childbearing age with abnormal bleeding are often treated with hormonal therapies to override the HPG axis and mimic normal menstrual bleeding or suppress it entirely. Common treatments include oral contraceptive pills that contain both estrogen and progesterone, long-term treatment with medroxyprogesterone (Depo-Provera) (though the U.S. Food and Drug Administration [FDA] black box warning about potential bone loss has drastically curtailed the use of this therapy), and the levonorgestrel intrauterine device (LNG-IUD). The LNG-IUD has a dual indication from the FDA for both birth control and suppression of abnormal menstrual bleeding. The device releases a steady amount of progesterone directly into the uterus to stabilize and suppress the uterine lining. In addition, the progesterone works to suppress the HPG axis and prevent ovulation. There is no strong evidence to differentiate whether estrogen and progesterone or progesterone alone is superior in the treatment of abnormal uterine bleeding; the woman should be allowed to select a treatment regimen that is compatible with her life and needs.[37]

Women who are greater than 35 years old and smoke cigarettes may not be candidates for oral contraceptive pills as the estrogen increases their risk of cardiovascular incidents, such as myocardial infarction. However, the LNG-IUD can still be used because it contains only progesterone. The LNG-IUD is widely used as a first step in controlling perimenopausal bleeding because it can be inserted in a clinic office and is easily removed if the treatment is ineffective. The LNG-IUD decreases blood loss by 86% to 97% by decreasing endometrial proliferation and has similar success rates as more invasive procedures.[38] Women who do not wish to have future pregnancies also can opt for treatments that permanently suppress their uterine lining. These treatments include ablation, where the lining is burned to prevent future proliferation of the endometrial cells, and complete removal of the uterus in hysterectomy.[38] If a woman is menopausal, and has not had a menstrual period for greater than 1 year, all vaginal bleeding should be investigated to rule out uterine and other cancers. Appropriate initial evaluation includes ultrasound and endometrial biopsy to rule out uterine cancer.[39]

Women with coagulation disorders may have excessive menstrual bleeding because they have a genetic predisposition to bleeding or because they are taking anticoagulant medications to overcome a genetic predisposition to excessive clotting.[40] To control their menstrual bleeding, these women can opt for cycle suppression. Provision of birth control for these women is important because pregnancy may be risk to their health.[41]

Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) has at least two of the following conditions: oligo-ovulation or anovulation, elevated levels of androgens, or clinical signs of hyperandrogenism and polycystic ovaries. Polycystic ovaries do not have to be present to diagnose PCOS, and conversely their presence alone does not establish the diagnosis. PCOS remains one of the most common endocrine disturbances affecting women, especially young women, and is a leading cause of infertility in the United States, where prevalence rates are estimated at between 4% and 12%, afflicting between 3.2 and 5.4 million young women.[42] PCOS appears to be familial, and various features of the syndrome may be differentially inherited.[43,44] Confusing the issue is the frequency, expression, and timing of PCOS symptoms and diagnosis. From 22% to 30% of women have polycystic ovaries on ultrasound, with 80% having one or more symptoms of the syndrome; 80% of women with normal ovaries also experience one or more PCOS symptoms. Signs and symptoms of women with PCOS may change over time, with metabolic syndrome becoming more prominent with age. In addition, polycystic ovaries may be associated with Cushing syndrome, acromegaly, premature ovarian failure, simple obesity, congenital adrenal hyperplasia, thyroid disease, androgen-producing adrenal tumors or ovarian tumors (Figure 24-4), and syndromes with hyperprolactinemia. Thus diagnosing PCOS can be difficult. In addition, several diagnostic criteria are proposed by different agencies, resulting in nonstandard application of the diagnosis.[45]

PATHOPHYSIOLOGY. Although the underlying cause of PCOS is unknown, a genetic basis is suspected. Initial identification of genes involved in steroid biosynthesis, androgen biosynthesis, and insulin receptors within the ovary indicate genetic involvement. No single factor fully accounts for the abnormalities of PCOS.[44,46-48] A hyperandrogenic state is a cardinal feature in the pathogenesis of PCOS. However, glucose intolerance/insulin resistance (IR) and hyperinsulinemia often run parallel and markedly aggravate the hyperandrogenic state, thus contributing to the severity of signs and symptoms of PCOS.[44,49] Obesity adds to and worsens IR. Although 50% of normal weight women with PCOS have IR, all obese women with PCOS do. Insulin stimulates androgen secretion by the ovarian stroma and reduces serum sex hormone–binding globulin (SHBG) directly and independently. The net effect is an increase in free testosterone levels. Excessive androgens affect follicular growth, and insulin affects follicular decline by suppressing apoptosis and enabling follicles, which would normally disintegrate, to survive[50] (Figure 24-5). Further, there appears to be a genetic ovarian defect in PCOS, which makes the ovary either more susceptible to or sensitive to insulin's stimulation of androgen production. Recent research suggests that decreased intraovarian receptors for estrogen receptor-α or insulin-like growth factor 1 (IGF-1), increased leptin levels, or direct IR within selective ovarian cells (fibroblasts) may contribute to this phenomenon.[50] Intrauterine and early childhood environments may also contribute to the development of PCOS (see What's New? Early Programming for PCOS?).

Weight gain tends to aggravate symptoms, whereas weight loss may ameliorate some of the endocrine and metabolic

WHAT'S NEW?

Early Programming for PCOS?

A fetal environment containing abnormal levels of pollutants, hormones, and other factors yet undefined can induce epigenetic modifications of the DNA and increased risk for adult disease. Female fetuses exposed to testosterone at levels normally found with male fetuses appear programmed to develop altered TGF-β signaling and increased risk of hyperinsulinemia and hyperandrogenism related to PCOS.

Kosova G, Urbanek M, *Mol Cell Endocrinol* 373(1-2):29–38, 2013; Witchel SF et al: *Endocrine* 42(3):526–534, 2012; Xita N, Tsatsoulis A: *Ann NY Acad Sci* 1205:148–155, 2010.

events and thus decrease symptoms. Women with PCOS tend to have increased leptin levels (leptin levels are increased in thin as well as overweight women with PCOS).[51] Leptin influences the hypothalamic pulsatility of GnRH and consequent interaction along the entire HPO axis. Feedback from the polycystic ovary is disturbed because of changes in ovarian steroid and nonsteroidal (inhibins and related proteins) hormones.

In PCOS there is dysfunction in follicle development.[50] Inappropriate gonadotropin secretion triggers the beginning of a vicious cycle that perpetuates anovulation. Typically, levels of FSH are low or below normal and LH levels and LH bioactivity are elevated. An increased frequency of GnRH pulses appears to cause increased frequency of LH pulses.[52,53] Persistent LH elevation causes an increase in androgens (dehydroepiandrosterone sulfate [DHEAS] from the adrenal glands and testosterone, androstenedione, and DHEAS from the ovary). Androgens are converted to estrogen in peripheral tissues, and increased testosterone levels cause a significant reduction (approximately 50%) in SHBG, which in turn causes increased levels of free estradiol. Elevated estrogen levels trigger a positive-feedback response in LH and a negative-feedback response in FSH. Because FSH levels are not totally depressed, new follicular growth is continuously stimulated, but not to full maturation and ovulation. The accumulation of follicular tissue in various stages of development allows an increased and relatively constant production of steroids in response to gonadotropin stimulation. Thus PCOS is characterized by excessive production of both androgen and estrogen.

Increased androgen secretion by the ovaries contributes to premature follicular failure (atresia) and persistent anovulation. In turn, persistent anovulation causes enlarged polycystic ovaries characterized by a smooth, pearly white capsule. This characteristic appearance is caused by an increase of surface area and increased volume of up to 2.8 times, doubling of growing and atretic follicles, thickening of the tunica (outermost area) by 50%, increasing cortical stromal thickening by one third and a fivefold increase in subcortical stroma, and escalating hyperplasia. With advancing age, menstrual irregularities may improve while metabolic syndrome and type 2 diabetes mellitus increases. Women with PCOS have a three times greater incidence of uterine cancer in later life than normally cycling women related to the anovulatory lack of progesterone in PCOS. Without treatment for anovulation, women with PCOS have a 9% lifetime risk for endometrial cancers related to the effects of unopposed estrogen.[54]

CLINICAL MANIFESTATIONS. Clinical manifestations of PCOS usually appear within 2 years of puberty but may appear after a variable period of normal menstrual function and, possibly, pregnancy. The symptoms are related to anovulation and hyperandrogenism and include dysfunctional bleeding or amenorrhea, hirsutism, acne, and infertility. Approximately 41% of women with PCOS are obese.[46] Box 24-4 contains a list of signs and symptoms, summary of hormonal disturbances, and complications of PCOS. In addition, women with PCOS are more likely to experience sleep apnea than unaffected women, which results in impaired sleep and may reduce their overall quality of life.[45]

BOX 24-4 CLINICAL MANIFESTATIONS OF POLYCYSTIC OVARY SYNDROME

Presenting Signs and Symptoms (% of Women Affected)

Obesity (41%)
Menstrual disturbance (70% [i.e., dysfunctional uterine bleeding])
Oligomenorrhea (47%)
Amenorrhea (19%)
Regular menstruation (48%)
Hyperandrogenism (69% to 74%)
Infertility (73% of anovulatory infertility)
Asymptomatic (20% of those with PCOS)

Hormonal Disturbances

Increased insulin (independent of obesity)
Decreased SHBG
Increased androgens (testosterone, androstenedione)
Increased DHEA (occurs in 50% of women)
Increased LH (genetic variant LH-β subunit)
Increased prolactin
Increased leptin, especially in obesity (independent of insulin)
Suggested decreased insulin-like growth factor (IGF-1) receptors on theca cells
Possible decreased estrogen receptors (intraovarian and along hypothalamic-pituitary axis)

Possible Late Sequelae

Dyslipidemia: increased low-density lipoproteins, decreased high-density lipoproteins, increased triglycerides
Diabetes mellitus (30% of women with or without obesity develop type 2 diabetes mellitus by age 30)
Cardiovascular disease; hypertension
Endometrial hyperplasia and carcinoma (anovulatory women are hyperestrogenic)

Other

Women with PCOS are at increased risk of gestational diabetes mellitus, pregnancy-induced hypertension, preterm birth, and perinatal mortality

EVALUATION AND TREATMENT. Diagnosis of PCOS is based on evidence of androgen excess, chronic anovulation, and inappropriate gonadotropin secretion. Tests for impaired glucose tolerance are recommended. As stated, polycystic ovaries do not have to be present and, conversely, their presence alone does not establish the diagnosis. Goals of treatment include reversing signs and symptoms of androgen excess, instituting cyclic menstruation, restoring fertility, and ameliorating any associated metabolic or endocrine, or both, disturbances.[55,56] Traditionally, treatment of PCOS focused on correcting anovulation and the effects of hyperandrogenism with combined oral contraceptives (COCs), antiandrogens, and fertility agents. With a greater understanding of the role that IR and hyperinsulinemia play in this disease, insulin sensitizers, such as metformin,[50,57] may be used to decrease insulin, prevent diabetes and heart disease (by reducing microvascular events), and restore fertility if desired. Progesterone therapy is recommended to oppose estrogen's effects on the endometrium and as a means to initiate monthly withdrawal bleeding (at the expense of continued hirsutism). For infertile women desiring pregnancy, clomiphene citrate, an antiestrogen, can be used to facilitate ovulation, although better effects are achieved (75% ovulation rates and 30% to 40% pregnancy rates) if therapy is combined with an insulin sensitizer.[58-60]

Women who are primed with human chorionic gonadotropin (hCG) before in vitro fertilization have greater success in achieving and maintaining pregnancy (58% to 82%).[58] Only a small reduction of weight has shown a restoration of ovulation and increased insulin sensitivity by 71% in obese women with PCOS. Lifestyle changes are therefore encouraged, particularly weight loss and exercise. Reduction of IR by loss of abdominal fat appears crucial in restoring ovulation.[61] However, lifestyle changes alone have not been shown to reverse the hyperlipidemia and hyperinsulinemia of PCOS, and pharmacologic treatment is often needed to prevent later health complications.[62] Management of PCOS is a near lifelong process because the effects of the syndrome persist past childbearing years. Appropriate primary care is needed to control the systemic features of PCOS so that it has minimal impact on a woman's life.

Premenstrual Disorders

Premenstrual syndrome (PMS) and **premenstrual dysphoric disorder (PMDD)** are the cyclic recurrence (in the luteal phase of the menstrual cycle) of distressing physical, psychologic, or behavioral changes that impair interpersonal relationships or interfere with usual activities.[52] The prevalence of PMS and PMDD is difficult to determine, in part because of the wide-ranging nature of accepted symptoms. Symptoms of PMS and PMDD begin after ovulation during the luteal phase and persist up to 4 days into the menstrual cycle.[63]

It has been estimated that 91% of women experience some form of distress around their menstrual period but a much smaller number, as low as 3.1%, meet the criteria for PMDD.[64] Sources vary but suggest that around 30% of women experience enough distress to interrupt their daily life and routine.[65]

The psychologic and physiologic changes of PMS/PMDD occur in the luteal phase of ovulatory cycles and are linked with the complex hormonal changes of the menstrual cycle. There are many theories on the cause(s) of the disorder, including that the fall in estrogen following ovulation and the immediate rise in progesterone interacts with hormones and neurotransmitters to cause symptoms.[66] However, the mechanisms involved are not known and may involve an individual sensitivity to the hormones more than hormonal levels. Furthermore, the neurotransmitters serotonin, gamma-aminobutyric acid (GABA), and noradrenaline may have mediating or moderating roles on symptom manifestation. These neurotransmitters have demonstrated interactions with estrogen and progesterone and *all* of these are neuroactive with known mood and behavior effects, including negative mood, irritability, aggression, and impulse control.[66] Sex steroids also interact with the renin-angiotensin-aldosterone system (RAAS), which could explain some PMS/PMDD signs and symptoms (e.g., water retention, bloating, weight gain). A predisposition to PMS runs in families, perhaps because of genetics or shared environment. Although research is limited, evidence supports a relationship between the severity and frequency of premenstrual symptoms and reports of low general well-being, history of major affective disorder, and personality characteristics, such as perfectionism, increased stress, poor nutrition, lack of exercise, low self-esteem, history of sexual abuse, and family conflict.[64] In turn, when premenstrual symptoms are perceived as distressing, the quality of interpersonal relationships and self-image are negatively affected.

CLINICAL MANIFESTATIONS. The pattern of symptom frequency and severity is more important than specific complaints. Nearly 300 physical, emotional, and behavioral symptoms have been attributed to PMS/PMDD. Emotional symptoms, particularly depression, anger, irritability, and fatigue, have been reported as the most prominent and the most distressing, whereas physical symptoms seem to be the least prevalent and problematic. Underlying physical or psychologic disease may be aggravated premenstrually and must be diagnosed and treated independently from PMS/PMDD.

EVALUATION AND TREATMENT. Diagnosis of PMS/PMDD is based on prospective health history and symptoms. Diagnostic criteria for PMDD are presented in Box 24-5. Because the cause of PMS is not known and cannot be reduced to a single biologic

BOX 24-5 AMERICAN COLLEGE OF OBSTETRICIANS AND GYNECOLOGISTS (ACOG) CRITERIA: PMDD

A problem with premenstrual dysphoric disorder (PMDD) diagnosis is that many women with clinically relevant premenstrual syndrome/premenstrual dysphoric disorder (PMS/PMDD) symptoms do not meet the full criteria of the *Diagnostic and Statistical Manual of Mental Disorders-IV* (DSM-IV). The ACOG attempts to rectify this problem by using the following definitions: "Presence of at least one psychological or physical symptom that causes significant impairment and is confirmed by means of prospective ratings (i.e., 2 cycles of a symptom diary)."

Data from American College of Obstetricians and Gynecologists: *ACOG Pract Bull* 15, 2000; Yonkers KA et al: *Lancet* 371(9619): 1200–1210, 2008.

NUTRITION & DISEASE

Premenstrual Syndrome

Women who are affected by premenstrual syndrome (PMS) often look for ways to decrease their symptoms. Dietary interventions that can help are multiple: eating six small meals each day; increasing intake of complex carbohydrates, fiber, and water; and decreasing caffeine, alcohol, refined sugar, and animal fat consumption. A low-fat vegetarian diet has been associated with decreased symptoms, possibly because of an increase in serum sex hormone–binding globulin concentration that lowers serum estrogen levels. It also may be helpful to limit sodium intake, and some limited evidence suggests that moderate doses (50 mg/day) of vitamin B_6 may reduce emotional symptoms of depression, irritability, and tiredness. This finding needs to be confirmed.

Some researchers have suggested links between serotonin, endorphins, and high sugar intake and PMS risk. One interesting craving is chocolate. Some researchers suggest that a craving for chocolate is an unconscious desire for a compound called phenylethylamine (PEA) in chocolate that stimulates the release of the neurotransmitter dopamine, which regulates mood.

Data from Barnard ND et al: *Obstet Gynecol* 95(2):245, 2000; Mahan LK, Escott-Stump S: *Krause's food, nutrition, and diet therapy,* ed 10, Philadelphia, 2000, Saunders; Mura Kami K et al: *Nutrition* 24(6):554–561, 2008.

explanation, and because the occurrence and severity of PMS are mediated by lifestyle and social and psychologic factors, treatment for PMS is symptomatic. Nonpharmacologic therapies, with or without medication, tend to be more effective in controlling symptoms than medication alone (see Nutrition & Disease: Premenstrual Syndrome). Initial treatment focuses on validation of the premenstrual experience, education on PMS and self-help techniques, and elimination of contributing factors or treatment of coexisting or underlying disorders.

After a trial of nonpharmacologic therapies or if criteria for PMDD are met, medications may be beneficial. Two major forms of treatment that have been well substantiated through research include the use of hormonal cycle regulation and use of selective serotonin reuptake inhibitor (SSRI) antidepressants.

If a woman does not desire immediate fertility, hormonal cycle regulation may be beneficial in regulating her menstrual cycle and decreasing the amount of circuiting steroidal hormones. The oral contraceptive pill containing estrogen and progesterone has shown benefits in decreasing PMS/PMDD.[67] Pills containing drospirenone have been shown to be particularly helpful in decreasing bloating and other PMS/PMDD signs[68] but have an increased risk of blood clots when compared with pills using another form of progestin.[69] Oral contraceptive pills also can be used continuously for up to 3 months to decrease the frequency of menstrual periods and PMS/PMDD.[67] SSRIs have been well studied for use in prevention and treatment of PMS/PMDD.[70] They relieve symptoms in about 60% to 90% of women and may be given continually or only during the premenstrual period but may have undesired side effects such as sexual problems.

In severe cases, menses can be abolished using GnRH agonists. However, if GnRH analogs are prescribed, continuous estrogen replacement therapy should be used to avoid side effects of "medical menopause."[71]

Infection and Inflammation

Infections of the genital tract may result from exogenous or endogenous microorganisms. Exogenous pathogens are most often sexually transmitted (see Chapter 26). Endogenous causes of infection include microorganisms that are normally present in the vagina, bowel, or vulva. Infection occurs if these microorganisms migrate to a new location or overproliferate or if the immune system and other defense mechanisms are impaired.

A number of skin disorders can affect the vulva. They include reactive dermatitis, contact dermatitis, psoriasis, and impetigo. (See Chapter 46 for a discussion of skin disorders.) Many infectious disorders that affect the vulva and vagina are sexually transmitted; these disorders are described in Chapter 26.

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is an acute inflammatory process caused by infection. PID may involve any organ, or combination of organs, of the upper genital tract—the uterus, fallopian tubes, or ovaries—and, in its most severe form, the entire peritoneal cavity. Inflammation of the fallopian tubes is termed **salpingitis** (Figure 24-6); inflammation of the ovaries is

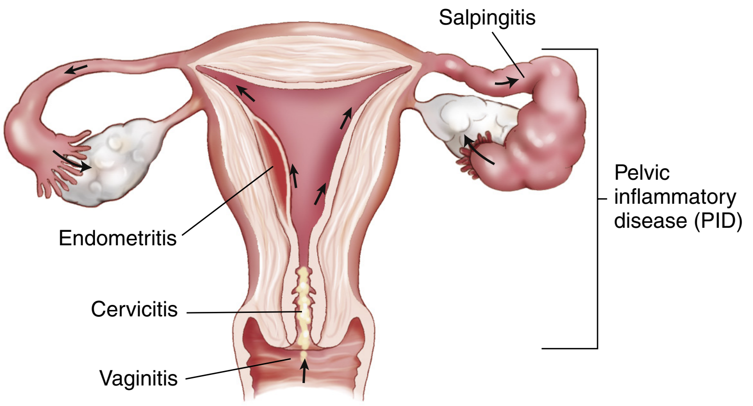

FIGURE 24-7 **Ascension of Pelvic Inflammatory Disease (PID).** Microorganisms from the lower genital tract ascend into the endometrium, fallopian tubes, and peritoneum to cause endometritis-salpingitis-peritonitis (pelvic inflammatory disease). The *arrows* indicate the "flow" of microorganisms from the lower genital tract to the upper genital tract. This is noted as an ascending infection in the text. (Adapted from Brooks ML: *Exploring medical language,* ed 8, St Louis, 2012, Mosby.)

called **oophoritis.** Sexually transmitted microorganisms, such as chlamydia and gonorrhea, that migrate from the vagina to the uterus, fallopian tubes, and ovaries cause most cases of PID. The ascension of these microorganisms into the upper genital tract may be facilitated by disruptions in the normal vaginal flora.[72] Some cases of PID occur after invasive procedures, such as IUD placement, when microorganisms are pushed up into the upper genital tract.[73]

Pelvic inflammatory disease is very common in the United States and around the world and has both immediate and long-term health implications for women. Infections of the upper reproductive tract cause changes to the delicate cells of the fallopian/uterine tubes, which can affect fertility and increase the risk of ectopic pregnancy.[74]

PATHOPHYSIOLOGY. The development of upper genital tract infections is mediated by the failure of a number of defense mechanisms that usually are effective in preventing PID. Virulence of the organism, size of the inoculum, and defense status of the individual determine whether an infectious process results. Gonorrhea and chlamydia are the main infectious causes of PID.[75,76] These microorganisms can infect the vagina and cervix but do not ascend into the upper genital tract and cause PID (Figure 24-7). However, when the normal vaginal microbial flora is disrupted the pathogens can more easily ascend through the cervix. Many anaerobic bacteria have been implicated in increasing the risk of PID because they alter the pH of the vaginal environment and may decrease the integrity of the mucus blocking the cervical canal. Bacterial vaginosis (BV) is present in up to 66% of women with PID and other anaerobes, such as *Bacteroides,* and *Gardnerella vaginalis, Haemophilus influenzae,* and genital tract mycoplasmas *(Mycoplasma hominis, Mycoplasma genitalis* and *Ureaplasma urealyticum)* are frequently isolated from women with PID (see Chapter 26 for further discussion of BV). *Escherichia coli* may contribute to pelvic infections in older women. Therefore, although gonorrhea and chlamydia are the main pathogens in PID, the disease is really polymicrobial in origin and is treated with a broad spectrum of antibiotics to ensure that all the causative agents are eliminated.[75,76]

Once the infection is established within the uterus and fallopian/uterine tubes, gonorrhea or chlamydia, or both, may induce changes in the columnar epithelium that lines the upper reproductive tract, causing permanent damage and facilitating invasion by other microorganisms. The resultant inflammatory response causes localized edema and occasionally necrosis of the area. Gonorrhea gonococci attach to the fallopian tubes and excrete a substance toxic to the tubal mucosa, causing further inflammation and damage. Chlamydia enters the tubal cells and replicates, bursting the cell membrane as it reproduces, causing permanent scarring. Gonorrhea and chlamydia can spread to the abdominal cavity through the openings of the fallopian/uterine tubes. Other mechanisms that may contribute to PID include lymphatic drainage with parametrial spread of the infection.

Luckily, the rate of mortality from PID in the United States is fairly low. However, PID infection results in permanent changes to the ciliated epithelium of the fallopian or uterine tubes. A recent study found that one episode of mild, subclinical PID resulted in a 40% decrease in later pregnancy rates, and multiple episodes of PID further increase the risk of infertility.[72] Scarring caused by PID greatly increases the risk of later ectopic pregnancy by up to 10-fold.[77] Scarring and adhesions also can result in chronic pelvic pain[77] and, potentially, an increased risk of later uterine cancer.[78]

CLINICAL MANIFESTATIONS. The clinical manifestations of PID vary from sudden, severe abdominal pain with fever to no symptoms at all. An asymptomatic cervicitis may be present for some time before PID develops. Of women with salpingitis, 67% to 75% may have a subclinical infection. The first sign of the ascending infection may be the onset of low bilateral abdominal pain, most often characterized as dull and steady with a gradual onset. Symptoms are more likely to develop during or immediately after menstruation. The pain of PID may worsen with walking, intercourse, or other activities involving movement. Other manifestations of PID include dysuria (difficult or painful urination) and irregular bleeding.

BOX 24-6 DIAGNOSTIC CRITERIA FOR PELVIC INFLAMMATORY DISEASE

Minimum Criteria (One or More Needed for Diagnosis)

Cervical motion tenderness, *or*
Uterine tenderness, *or*
Adnexal tenderness

Additional Criteria That Increase Specificity of Diagnosis

Fever >38.3° C (101° F)
Mucopurulent cervical or vaginal discharge
Numerous white blood cells on saline wet prep
Elevated C-reactive protein
Elevated erythrocyte sedimentation rate
Documented infection with *Chlamydia trachomatis* or *Neisseria gonorrhoeae*

Definitive Criteria (*Not* Needed for Treatment)

Transvaginal ultrasound, magnetic resonance imaging, *or*
Doppler studies showing thickened and fluid-filled tubes
Laparoscopic visualization of PID-related abnormalities

Data from: Centers for Disease Control and Prevention: *MMWR* 59(RR-12), 2010; Yudin MH, Ross JDC: Pelvic Inflammatory disease. In Zenilman JM, Shahmanesh M, editors: *Sexually transmitted diseases*, pp 67–76, Sudbury, MA, 2012, Jones & Bartlett Learning.
PID, Pelvic inflammatory disease.

EVALUATION AND TREATMENT. PID often has limited or vague clinical symptoms, leading to undertreatment and long-term health effects.[72] Because PID is a substantial health risk to a woman, the Centers for Disease Control and Prevention (CDC) encourage clinicians to consider PID as a likely diagnosis when a sexually active woman has abdominal or pelvic tenderness and *one* of the following: cervical motion tenderness, uterine tenderness, or adnexal tenderness.[75] Box 24-6 lists the diagnostic criteria for PID. No labs or studies are needed to begin treatment, however, additional information can improve the specificity of diagnosis.[75] Abdominal pain in women can have many causes, and it is important to rule out other diagnoses (Figure 24-8); however, further studies to rule out other diagnoses can be done while treating for PID.[75]

Because of the significance of the complications of PID, rapid treatment is recommended even before the causative pathogen can be identified. Because treatment is empiric, it needs to be effective against a broad range of pathogens, especially chlamydia, gonorrhea, and anaerobic bacteria.[75] Treatment is usually outpatient unless the woman has symptoms of advanced infection, cannot take oral medications, is pregnant, or other pathologies cannot be excluded. The CDC-recommended outpatient regimen is shown in Box 24-7.[79] Although alternative treatment regimens are available, the growing antibiotic

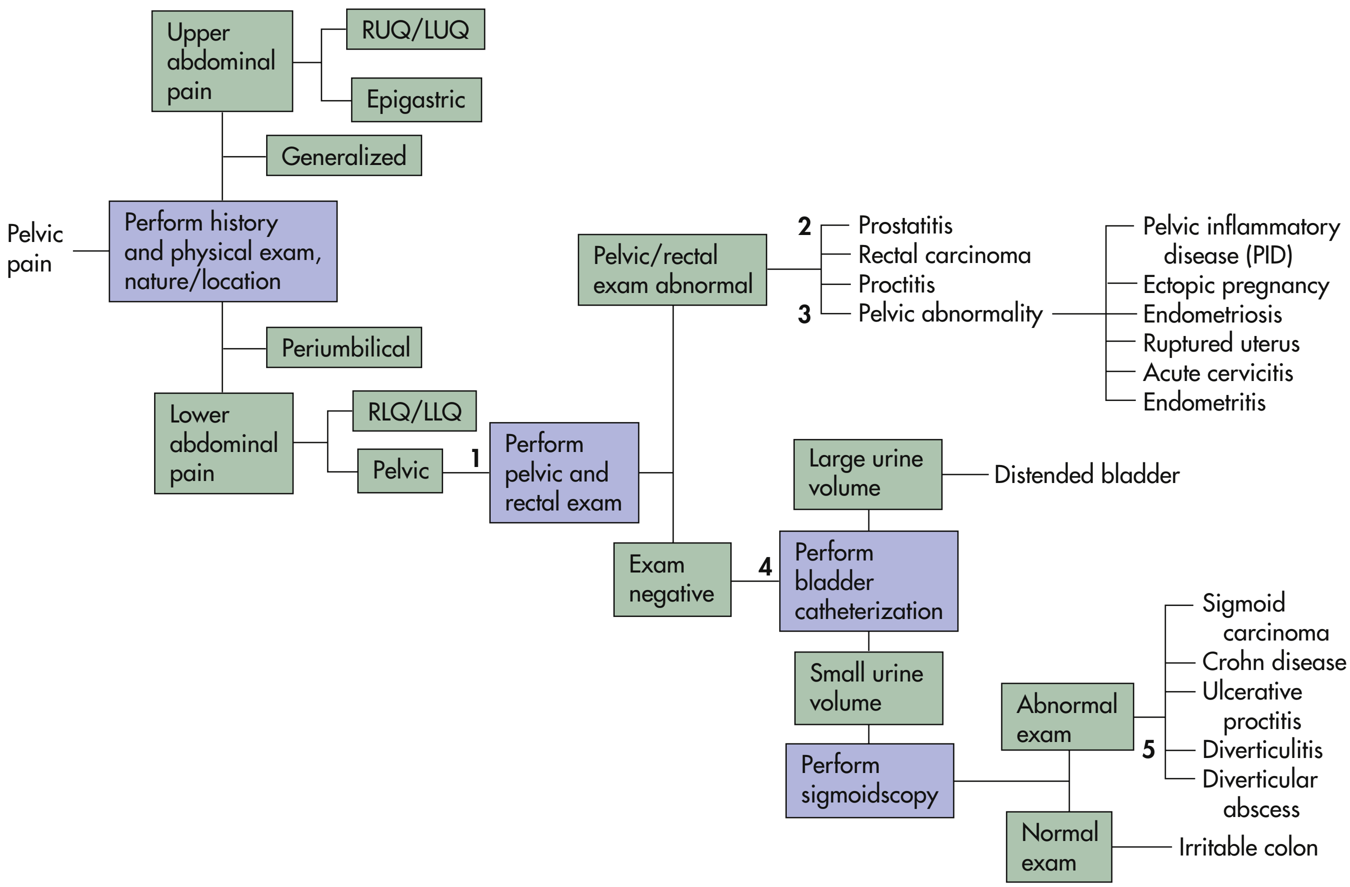

FIGURE 24-8 Diagnostic Algorithm for Pelvic Pain. *LLQ,* Left lower quadrant; *LUQ,* left upper quadrant; *RLQ,* right lower quadrant; *RUQ,* right upper quadrant.

BOX 24-7 CDC RECOMMENDED ORAL TREATMENT FOR PELVIC INFLAMMATORY DISEASE

Ceftriaxone: 250 mg IM in a single dose
Doxycycline: 100 mg orally twice a day for 14 days
WITH or WITHOUT
Metronidazole: 500 mg orally twice a day for 14 days

Data from Workowski KA, Berman S, Centers for Disease Control and Prevention (CDC): *MMWR Recom Rep* 59(RR-12):1–110, 2010; Centers for Disease Control and Prevention (CDC): *MMWR Morb Mortal Wkly Rep* 61(31):590–594, 2012.

resistance of gonorrhea limits antibiotic choices. The CDC is closely monitoring gonorrhea's antibiotic sensitivity and updates treatment guidelines periodically to reflect new information.[79] The most up-to-date treatment guidelines can be found on the CDC website.

Sexual partners of women with PID also should also receive treatment, even if they are asymptomatic. Women receiving treatment should be reevaluated by their care provider in 3 days to ensure antibiotic treatment is effective.[75] Because women with a history of PID are at increased risk for ectopic pregnancy, they should seek care as soon as they know they are pregnant because ectopic pregnancy is a major cause of maternal mortality.[74]

Vaginitis

Vaginitis is irritation of the vagina that can be caused by a variety of microorganisms, irritants, pathologies, or a disruption of the normal flora of the vagina. Vaginitis is characterized by an increase in white blood cells on saline wet prep examination. Vaginal irritation without white blood cells is known as **vaginosis**.[80] The major causes of vaginitis are overgrowth of normal flora, sexually transmitted diseases, and vaginal irritation related to low estrogen levels during menopause (a condition known as atropic vaginitis).[81]

The irritation of vaginitis is related to an alteration in the vaginal environment, including changes in skin integrity, immune reaction, and particularly vaginal pH. The pH of the vagina depends on cervical secretions and the presence of normal flora that help maintain an acidic environment. A neutral or alkaline pH normally occurs before puberty, after menopause, and during pregnancy. The acidic nature of vaginal secretions during the reproductive years provides protection against a variety of sexually transmitted pathogens (see Chapter 26). Changes in the vaginal pH may predispose a woman to infection. Many substances and conditions can alter vaginal pH including douching; use of soaps, spermicides, feminine hygiene sprays, semen, or deodorant menstrual pads or tampons; and conditions associated with increased glycogen content of vaginal secretions, such as pregnancy or diabetes. Antibiotics can destroy normal vaginal flora, facilitating overgrowth of *Candida albicans*, causing a yeast vaginitis.

Normally vaginal discharge is a clear, milky, or cloudy secretion with a slippery or clumpy texture. It is nonirritating, has a mild smell, and may yellow after drying. Throughout the menstrual cycle the amount and texture of a woman's discharge change in response to hormonal fluctuation. Vaginal secretions increase at the time of ovulation, during pregnancy (because of increased estrogen levels), and with sexual arousal; just before menstruation, vaginal discharge becomes thick and sticky. Unusual changes in the amount, color, or texture of vaginal discharge may signal an infection, especially if the discharge is copious, malodorous, or irritating. Irritation of the vaginal area may be the result of many factors.

Diagnosis of the cause of vaginitis is based on history, physical examination, and examination of the discharge by wet mount; treatment by physical symptoms alone is inadequate.[81] Treatment involves developing and maintaining an acidic environment, relieving symptoms (usually pruritus), and administering antimicrobial or antifungal medications to eradicate the infectious organism. If the infection can be sexually transmitted, a woman's partner also will be treated. Research suggests that probiotics, especially *Lactobacillus crispatus*, can encourage normal vaginal flora and decrease the incidence of vaginitis in women at risk for vaginitis.[82,83]

Cervicitis

Cervicitis is a nonspecific term used to describe inflammation of the cervix. The CDC defines cervicitis as having two diagnostic signs: a purulent or mucopurulent discharge from the cervical os or endocervical bleeding, or both, induced by gently introducing a cotton swab into the cervix.[75] Cervicitis can have infectious or noninfectious causes. Chemicals and substances introduced into the vagina can cause cervicitis as well as disruptions in the normal vaginal flora. However, there are conflicting definitions of cervicitis used clinically and in research.[84] Age and risk factors are important in assessing a woman with cervicitis. Younger women are at risk for sexually transmitted infections (STIs) and should be tested for chlamydia, gonorrhea, and trichomonas. Older women with cervicitis may have STIs but are at risk for irritation from abnormal vaginal flora related to low vaginal estrogen levels.

Mucopurulent cervicitis (MPC) usually is caused by one or more sexually transmitted pathogens, such as *Trichomonas*, gonorrhea, *Chlamydia*, *Mycoplasma*, or *Ureaplasma*. Infection causes the cervix to become red and edematous. A mucopurulent (mucus- and pus-containing) exudate drains from the external cervical os, and the individual may report vague pelvic pain, bleeding, or dysuria. The cervix often becomes friable, bleeding easily during sexual intercourse or with pelvic examinations and Papanicolaou (Pap) smears. Because mucopurulent cervicitis is a symptom of PID, women at risk for STIs, especially those less than 26 years old, should receive treatment for PID while awaiting results of microbial testing.[75] If the woman is not at risk for STIs, a thorough evaluation often reveals another cause for the inflammation.

Vulvodynia

Vulvodynia (also referred to as vulvitis, vestibulitis, or vulvovestibulitis) is chronic pain and inflammation of the vulva or vestibule, or both. In many cases it may represent several disorders without an identifiable cause. Vulvodynia is fairly common,

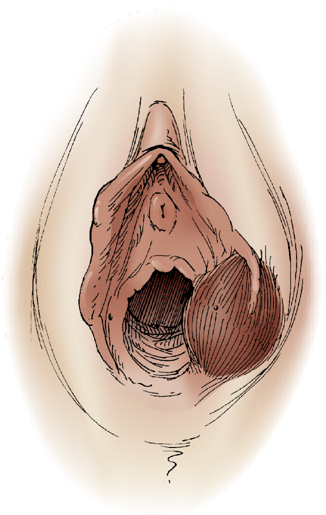

FIGURE 24-9 Inflammation of Bartholin Gland. (Modified from Gershenson DM et al: *Operative gynecology,* ed 2, Philadelphia, 2001, W.B. Saunders. In Fuller JK: *Surgical technology,* ed 6, Philadelphia, 2013, Saunders.)

affecting approximately 8% of women at some point in life.[85] Whereas the inflammation of vulvodynia may be caused by contact dermatitis (i.e., exposure to soaps, detergents, lotions, sprays, shaving, menstrual pads/tampons, perfumed toilet paper, tight-fitting clothes), the condition may be more complex and represent abnormalities in multiple systems, including vestibular mucosa, pelvic floor musculature, and CNS pain regulatory pathways.[86] The condition may also represent an autoimmune reaction, similar to fibromyalgia. Genetic and psychologic links have also been proposed and studied.[86] The mechanisms are poorly understood; thus vulvodynia is difficult to evaluate and treat. Vulvodynia can be classified as generalized or localized and provoked and unprovoked.[86] Assessment includes ruling out and treating conditions that may contribute to or cause vulvar inflammation (e.g., *Candida,* STI, seborrhea, psoriasis, lichen sclerosus, and contact dermatitis) and testing for vulvodynia with a cotton-tipped swab along the inner edge of the labia minora.

Women are advised to avoid potential irritants and to wear loose, cotton clothing. Vulvodynia may increase susceptibility to vaginal infection; likewise, it may be caused by vaginal infections (e.g., candidiasis, trichomoniasis) that spread to the labia, where they cause inflammation and edema. Studies on treatments are limited but suggest that women may benefit from behavioral treatment, topical lidocaine (Xylocaine), topical or systemic antidepressants, Botox injections into the affected nerve, or vestibulectomy.[86,87] Other skin diseases, such as tinea cruris, psoriasis, lichen sclerosus, and inflammation of the apocrine (sweat) glands, can involve the vulva (see Chapter 46).

Bartholinitis

Bartholinitis, or **Bartholin cyst,** is an inflammation of one or both of the ducts that lead from the introitus (vaginal opening) to the Bartholin/greater vestibular glands (Figure 24-9). The usual causes of bartholinitis are microorganisms that infect the lower female reproductive tract, such as streptococci, staphylococci, and sexually transmitted pathogens.

Infection or trauma causes inflammatory changes that narrow the distal portion of the duct, leading to obstruction and stasis of glandular secretions. The obstruction, or cyst, varies from 1 to 8 cm in diameter and is located in the posterolateral portion of the vulva. The cyst may be reddened and painful, and pus may be visible at the opening of the duct. Any exudate should be cultured and tested for gonorrhea and chlamydia. The individual may have symptoms of the initiating infection, fever, and malaise. Diagnosis of a Bartholin cyst is based on the clinical manifestations and the identification of infectious microorganisms.

Most Bartholin cysts are asymptomatic and require no treatment. However, if they are uncomfortable or show signs of infection, treatment is advised to prevent abscess formation. Treatment is controversial but involves broad-spectrum antibiotics for suspected infection. Some clinicians also attempt to drain the cyst using hot soaks, needle aspiration, insertion of a catheter, or marsupialization of the infected gland. No one treatment has proved to be superior in symptom relief and prevention of recurrence.[88]

Pelvic Organ Prolapse

The bladder, urethra, and rectum are supported by the endopelvic fascia and the perineal muscles, particularly the levator ani group. This muscular and fascial tissue loses tone and strength with aging and may fail to maintain the pelvic organs in the proper position. The pelvic area contains many organs and has the force of gravity and the abdominal contents pushing down on it. If the pelvic fascia and musculature is not firm, the pelvic organs to move to fill any space voids. With weak support, the bladder and rectum tend to push into the vagina and vaginal wall. The vagina is an opening in the pelvic musculature for intercourse and childbirth. (Chapter 23 contains a discussion of pelvic support structures.) However, as gravity acts on the pelvis, this opening becomes a weakness in the musculature support of the entire pelvic cavity and without proper support from the vaginal muscles and fascia, the uterus and bulging vaginal walls can begin to herniate through the vaginal opening.

Pelvic organ prolapse (POP) is the descent of one or more of the following: the vaginal wall, the uterus, or the apex of the vagina (after a hysterectomy).[89] Up to 61% of women have some version of POP on physical examination. However, most women have no symptoms. As the degree of prolapse increases, women feel more vaginal pressure. When prolapse becomes severe, the function of the surrounding organs can be altered. For instance, as the bladder is pulled posterior, incontinence and incomplete voiding become more common. As the bowel bulges into the vaginal space, defecation becomes more difficult. The severity of POP and its symptoms increase with age, and half of women older than age 50 have symptoms of POP. By 2050 it is estimated that 43.8 million women will have symptoms of POP.[90]

POP is thought to be caused by direct trauma, such as childbirth or pelvic surgery or damage to pelvic innervation, particularly the pudendal nerve. A strong familial tendency and possibly a multifactorial genetic component place some women at risk for the development of prolapse. Black and Asian women have the lowest risk of POP, and Hispanic women appear to

BOX 24-10 EVALUATION OF PELVIC ORGAN PROLAPSE (BADEN-WALKER HALFWAY SCORING SYSTEM)

Grade 0: Normal position, no prolapse
Grade 1: Descent halfway to the hymen
Grade 2: Descent reaches the hymen
Grade 3: Descent halfway past hymen
Note: Any type of prolapse (posterior, apical, anterior vaginal, uterine, etc.) can be graded using this system.

From Baden WF, Walker TA: *Clin Obstet Gynecol* 15:1070–1072, 1972.

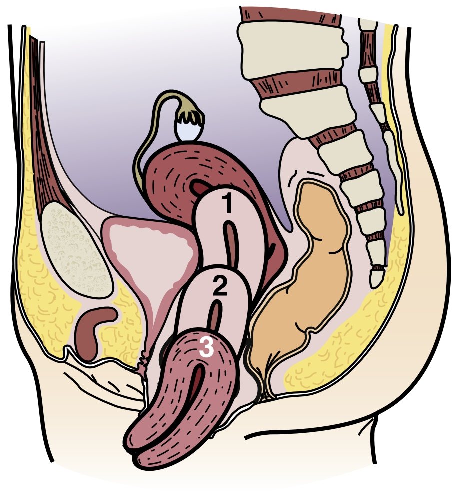

FIGURE 24-10 Degrees of Uterine Prolapse. **Grade 1** is minimal and rarely requires correction; **Grade 2** prolapse has moderate symptoms, and **Grade 3** prolapse is severe. The uterus is so low that the cervix protrudes from the vagina. (From Phillips N: *Berry & Kohn's operating room technique,* ed 12, Philadelphia, 2013, Mosby.)

have the highest risk.[91] Risk factors in nulliparous women are occupational activities that require heavy lifting or chronic medical conditions, such as chronic lung disease or refractory constipation. Some have neural abnormalities that interfere with the innervation of the levator ani. A list of risk factors is contained in Box 24-8.

The trend is to use terminology that describes physical examination findings, thus avoiding assumptions about structural involvement (Box 24-9). The terms *cystocele* and *rectocele* may be used when the structures involved (bladder, rectum) have been definitively identified (i.e., an anterior vaginal wall prolapse may or may not be a cystocele involving the urinary bladder) (see Figure 24-11, p. 819). Examining the woman in multiple positions and straining maximally provides the best information about the degree of pelvic organ relaxation.[89] Physical examination may be augmented with imaging by ultrasound, or magnetic resonance. Several systems are used to describe prolapse. One in widespread clinical use is based on physical examination findings (see Box 24-9) and uses a grading system to describe the extent of the prolapse (Box 24-10). Subjective reports regarding the symptoms and effects of POP can be assessed through direct questioning or questionnaires such as the Pelvic Floor Impact Questionnaire or the Pelvic Floor Distress Inventory.

Uterine prolapse is decent of the cervix or entire uterus into the vaginal canal (Figure 24-10). In severe cases the uterus falls completely through the vagina and protrudes from the introitus. Symptoms of other pelvic floor disorders also may be present. Treatment depends on the severity of symptoms and the physical condition of the woman. A common first-line treatment is a **pessary,** which is a removable mechanical device that holds the uterus in position. The pelvic fascia may be strengthened through Kegel exercises (repetitive isometric tightening and relaxing of the pubococcygeal muscles) or by estrogen therapy in menopausal women. Maintaining a healthy body mass index (BMI), preventing constipation, and treating chronic cough may help as well. Surgical repair with or without hysterectomy is the treatment of last resort. Women should be active participants in the decision-making surrounding treatment because they need to balance expectations for improvement with potential side effects.[92]

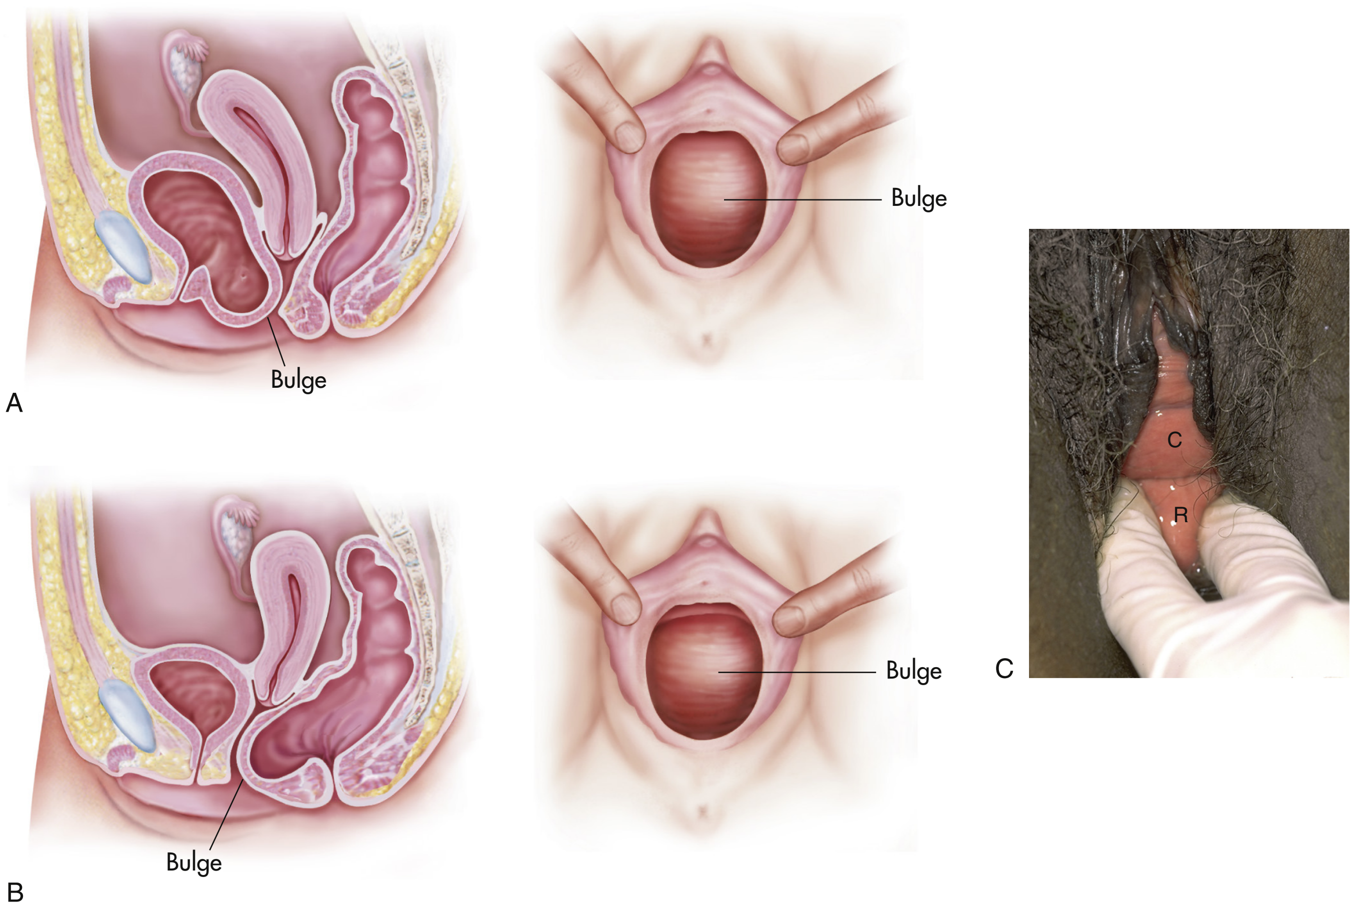

FIGURE 24-11 **Cystocele and Rectocele. A,** Grade 2: anterior vaginal wall prolapse. **B,** Grade 2: posterior wall prolapse. **C,** Photo showing cystocele *(C)* and rectocele *(R)*. (**A** and **B** from Seidel H et al: *Mosby's guide to physical examination,* ed 4, St Louis, 1999, Mosby. **C** from Seidel HM et al: *Mosby's guide to physical examination,* ed 7, St Louis, 2011, Mosby.)

Figure 24-11 shows vaginal prolapse caused by cystocele and rectocele. **Cystocele** is descent of a portion of the posterior bladder wall and trigone into the vaginal canal and usually is caused by the trauma of childbirth. In severe cases the bladder and anterior vaginal wall bulge outside the introitus. Usually symptoms are insignificant in mild to moderate cases. Increased bulging and descent of the anterior vaginal wall and urethra can be aggravated by vigorous activity, prolonged standing, sneezing, coughing, or straining and can be relieved by rest or assumption of a recumbent or prone position. If the prolapse is large, women may complain of vaginal pressure. Occasionally a cystocele causes significant residual urine and an increased rate of bladder infections.

Medical management can include vaginal pessary, Kegel exercises (prophylactic use produces the best outcome), and estrogen therapy for postmenopausal women. Surgical correction is used for severe anatomic injury unresponsive to medical treatment (see What's New? Vaginal Mesh).

A **rectocele** is the bulging of the rectum and posterior vaginal wall into the vaginal canal. During childbirth women may sustain damage that can lead to a rectocele, but symptoms usually do not occur until several years after menopause.[89] Familial and genetic predisposition and bowel habits contribute to rectocele development. Lifelong chronic constipation and straining may

WHAT'S NEW?

Vaginal Mesh

Because pelvic organ prolapse is often a result of weakened pelvic fascia and musculature, a surgical mesh was developed to improve pelvic support. This mesh was designed to be placed surgically along the area needing support. The goal was to have the woman's tissues grow through the mesh and provide consistent, long-term support. However, women who received the surgical mesh had a high rate of complications, including infection and persistent post-operative pain. In many cases the mesh eroded through the tissue, protruding into the vagina and perforating other organs. In addition, the mesh may shrink over time causing vaginal shortening, tightening, and pain.

Some large studies have shown a benefit from mesh use for some women. However, once implanted, the mesh is difficult to remove if not effective, resulting in long-term pain and the need for intensive surgeries and repairs. The U.S. Food and Drug Administration has issued several warnings about the mesh to caution women and practitioners and encourage fully informed consent about the risks and benefits of mesh placement.

Data from U.S. Food and Drug Administration: FDA safety communication: UPDATE on serious complications associated with transvaginal placement of surgical mesh for pelvic organ prolapse, 2010. Available at http://www.fda.gov/MedicalDevices/Safety/AlertsandNotices/ucm262435.htm. Accessed January 21, 2013; Maher C et al: *Cochrane Database Syst Rev* (4):CD004014, 2010.

BOX 24-11 PELVIC ORGAN PROLAPSE: SYMPTOMS AND TREATMENTS

SYMPTOMS	TREATMENT
Urinary Sensation of incomplete emptying of bladder Urinary incontinence Urinary frequency/urgency Bladder "splinting" to accomplish voiding	Depending on age of woman and cause and severity of the condition: Isometric exercise to strengthen the pubococcygeal muscle (Kegels) Estrogen to improve tone and vascularity of fascial support (postmenopausal) Pessary (a removable device) to hold pelvic organs in place
Bowel Constipation or feeling of rectal fullness or blockage Difficult defecation Stool or flatus incontinence	**Surgical** Reconstructive: autologous grafts; synthetic mesh/sling Obliterative (most extreme) Weight loss Avoidance of constipation Treatment of cough/lung conditions
Urgency Manual "splinting" of posterior vaginal wall to accomplish defecation	
Pain and Bulging Vaginal, bladder, rectum Pelvic pressure, bulging, pain Lower back pain	
Sexual Dyspareunia Decreased sensation, lubrication, arousal	

produce or aggravate a rectocele. Although most rectoceles are asymptomatic, larger ones cause vaginal pressure, rectal fullness, and incomplete bowel evacuation. If rectoceles are severe, defecation is difficult and can be facilitated by applying manual pressure to the posterior vaginal wall. Medical treatment focuses on the management and prevention of constipation and, if needed, the use of a pessary. Rectocele alone (without associated enterocele, uterine prolapse, and cystocele) seldom requires surgery.[92]

An **enterocele** is herniation of the rectouterine pouch into the rectovaginal septum (between the rectum and posterior vaginal wall). It can be congenital or acquired. Congenital enterocele rarely causes symptoms or progresses in size. Enteroceles also can result from a muscular weakness caused by previous surgery, especially surgeries through the vagina, or pelvic relaxation disorders, such as uterine prolapse, cystocele, and rectocele. Most large enteroceles are found in grossly obese and older adults and can be complicated by rupture or complete eversion of the vagina with trophic ulceration, edema, and fibrosis. Treatment is surgical. Box 24-11 summarizes the symptoms and treatments of POP.

Benign Growths and Proliferative Conditions

Benign Ovarian Cysts

Benign cysts of the ovary may occur at any time during the life span, but are most common during the reproductive years and, in particular, at the extremes of those years (Figure 24-12). An increase in benign ovarian cysts occurs when hormonal imbalances are more common, around puberty and menopause.[93]

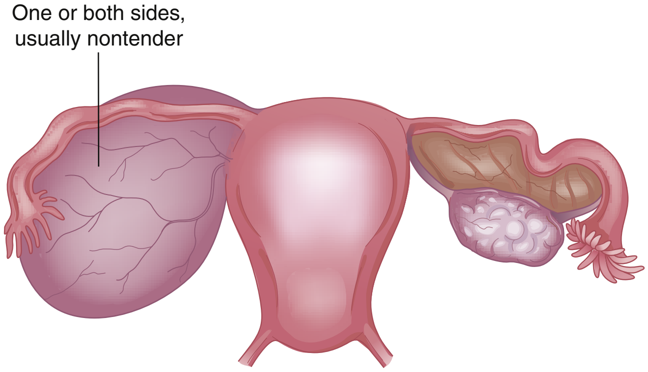

FIGURE 24-12 Ovarian Cyst.

However, ovarian masses can occur during fetal development and throughout childhood as well.[94]

Benign ovarian cysts are quite common and are the fourth leading diagnosis for gynecologic hospital admissions.[95] Two common causes of benign ovarian enlargement in ovulating women are follicular cysts and corpus luteum cysts. These cysts are called **functional cysts** because they are caused by variations of normal physiologic events. Follicular and corpus luteum cysts are usually unilateral. They are typically 5 to 6 cm in diameter but can grow as large as 8 to 10 cm. Most women are asymptomatic.

Benign cysts of the ovary are produced when a follicle or a number of follicles are stimulated but no dominant follicle develops and completes the maturity process. Every month about 120 follicles are stimulated, but in most cycles only one succeeds in ovulating a mature ova. Normally, during the early follicular phase of the menstrual cycle, follicles of the ovary respond to hormonal signals from the pituitary gland. The pituitary produces FSH to mature follicles in the ovary. As the follicles enlarge, granulosa cells in the follicle multiply and secrete estradiol (a form of estrogen). As a dominant follicle develops, it secretes higher levels of estradiol, which stimulates the LH surge that comes from the pituitary. A small cyst on the ovary during the follicular phase is normal. The LH surge stimulates the follicle to rupture, releasing the ova and transforming the granulosa cells of the dominant follicle into the corpus luteum. If the dominant follicle develops properly before ovulation, the corpus luteum becomes vascularized and secretes progesterone. Progesterone arrests development of other follicles in both ovaries in that cycle. LH, proteolytic enzymes, and prostaglandins trigger follicular rupture and release of the ovum.

Follicular cysts can be caused by a transient condition in which the dominant follicle fails to rupture or one or more of the nondominant follicles fail to regress. This disturbance is not well understood. It may be that the hypothalamus does not receive or send a message strong enough to increase FSH levels needed to develop or mature a dominant follicle. The hypothalamus monitors blood levels of estradiol and progesterone; when FSH is low, estradiol does not increase enough to stimulate LH. Evidence indicates that when progesterone is not being produced, the hypothalamus releases GnRH to increase the FSH level.[96] FSH continues to stimulate follicles to mature, and the granulosa cells grow and, presumably, estradiol increases. This abnormal cycle continues to stimulate follicular size and causes follicular cysts

to develop. Clinical symptoms of follicular cysts or even a single cyst are bloating, swollen and tender breasts, and heavy or irregular menses. After several subsequent cycles in which hormone levels once again follow a regular cycle and progesterone levels are restored, cysts usually are absorbed or regress.

Follicular cysts can vary in size and symptoms from one episode to the next and often can recur. Most are fluid filled; the more solid an ovarian cyst, the greater the chance of malignancy. Follicular cysts can be treated with oral contraceptives because they block the HPG axis, effectively quieting the ovary.

A **corpus luteum cyst** is normally formed by the granulosa cells left behind after ovulation. This cyst is highly vascularized but limited in size and spontaneously regresses as part of the normal menstrual cycle. However, an abnormal or hemorrhagic cyst may develop because of a hormonal imbalance in low LH and progesterone levels causing an inadequate development of the corpus luteum. In some cases, however, large cysts can rupture, causing hemorrhage.[33]

Corpus luteum cysts are less common than follicular cysts, but luteal cysts typically cause more symptoms, particularly if they rupture. Manifestations include dull pelvic pain and amenorrhea or delayed menstruation, followed by irregular or heavier than usual bleeding. Rupture occasionally occurs and can cause massive bleeding with excruciating pain; immediate surgery may be required. Corpus luteum cysts usually regress spontaneously in nonpregnant women. A corpus luteum cyst is a normal finding within the first trimester of pregnancy as the corpus luteum produces progesterone to support the pregnancy until the placenta is established.[97] Following the development of a large, painful, or hemorrhagic cyst, oral contraceptives can be used to suppress ovarian function and prevent future cysts.

Dermoid cysts are ovarian teratomas that contain elements of all three germ layers; they are common ovarian neoplasms. These growths may contain mature tissue including skin, hair, sebaceous and sweat glands, muscle fibers, cartilage, and bone. Dermoid cysts are usually asymptomatic and are found incidentally on pelvic examination. However, cysts should be carefully evaluated for removal because they have malignant potential.[98]

Torsion of the ovary is a rare complication of ovarian cysts or tumors or enlargement of the ovary and can occur in girls or women. If a cyst is large enough it can cause the ovary to twist on its ligaments, pinching off blood supply to the ovary and causing extreme pain. Ovarian torsion is rare but is a gynecologic emergency. Individuals present with acute, severe unilateral abdominal or pelvic pain. Ovarian torsion is treated surgically.[99]

Endometrial Polyps

An **endometrial polyp** is a benign mass of endometrial tissue, covered by a surface epithelium, and contains a variable amount of glands, stroma, and blood vessels. Endometrial polyps can occur anywhere within the uterus. Polyps are morphologically diverse and usually classified as hyperplastic, atrophic (or inactive), or functional. In the last case, the surface epithelium may be "out of phase" with other endometrial tissue. Hyperplastic polyps are often pedunculated and may be mistaken for endometrial hyperplasia or, if large, adenosarcoma (Figure 24-13).

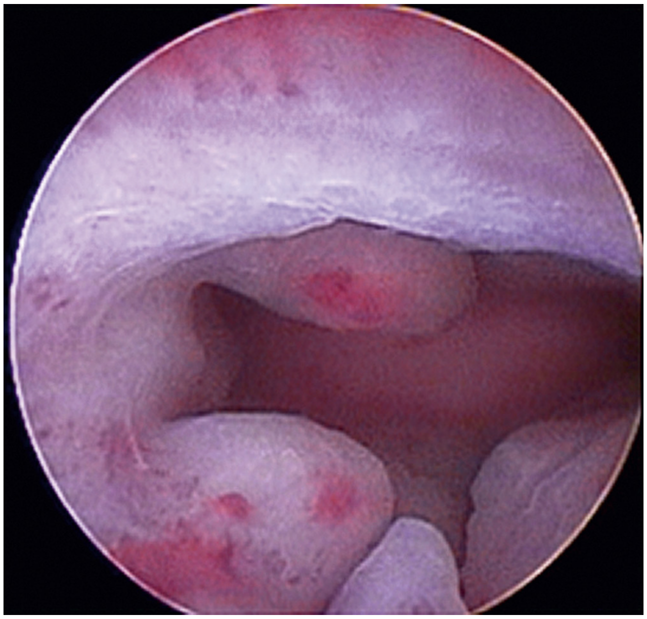

FIGURE 24-13 Uterine Polyps Visible Through Hysteroscopy. (From Cheng C et al: *J Minim Invasive Gynecol* 16[6]:739–742, 2009.)

Although polyps most often develop in women between ages 40 and 50, they can occur at all ages. These are often related to estrogen stimulation. As many as 35% of women with abnormal uterine bleeding are found to have polyps.[100]

Endometrial polyps are a common cause of intermenstrual or excessive menstrual bleeding. Diagnosis is made by transvaginal sonography or hysteroscopy. Risk factors include obesity, tamoxifen use, hypertension, and estrogenic states (i.e., anovulatory cycles and unopposed estrogen). Malignancy is rare (up to 4.7% of polyps have evidence of malignancy) and polyps that cause abnormal bleeding have twice the rate of malignancy of asymptomatic polyps.[101] Coexistence of a separate endometrial atypical hyperplasia or adenocarcinoma is common. Uterine polyps have a high rate of spontaneous resolution but have been associated with suboptimal fertility.[102] Polypectomy can be performed through hysteroscopy for symptomatic women, for those at risk for malignancy, or women who are struggling to conceive.

Leiomyomas

Leiomyomas, commonly called **myomas** or **uterine fibroids,** are benign smooth muscle tumors in the myometrium (Figure 24-14). Leiomyomas are the most common benign tumors of the uterus, affecting as many as 70% to 80% of all women, and most remain small, asymptomatic, and clinically insignificant.[103] Prevalence increases in women ages 30 to 50 but decreases with menopause. The incidence of leiomyomas in black and Asian women is two to five times higher than that in white women.[103] Complications related to leiomyomas are the number one reason for gynecologic hospitalizations.[95]

The cause of uterine leiomyomas is unknown, although their size appears to be related to estrogen, progesterone, growth factors, angiogenesis, and apoptosis. There is a genetic component to fibroids, and the leiomyomas exhibit chromosomal

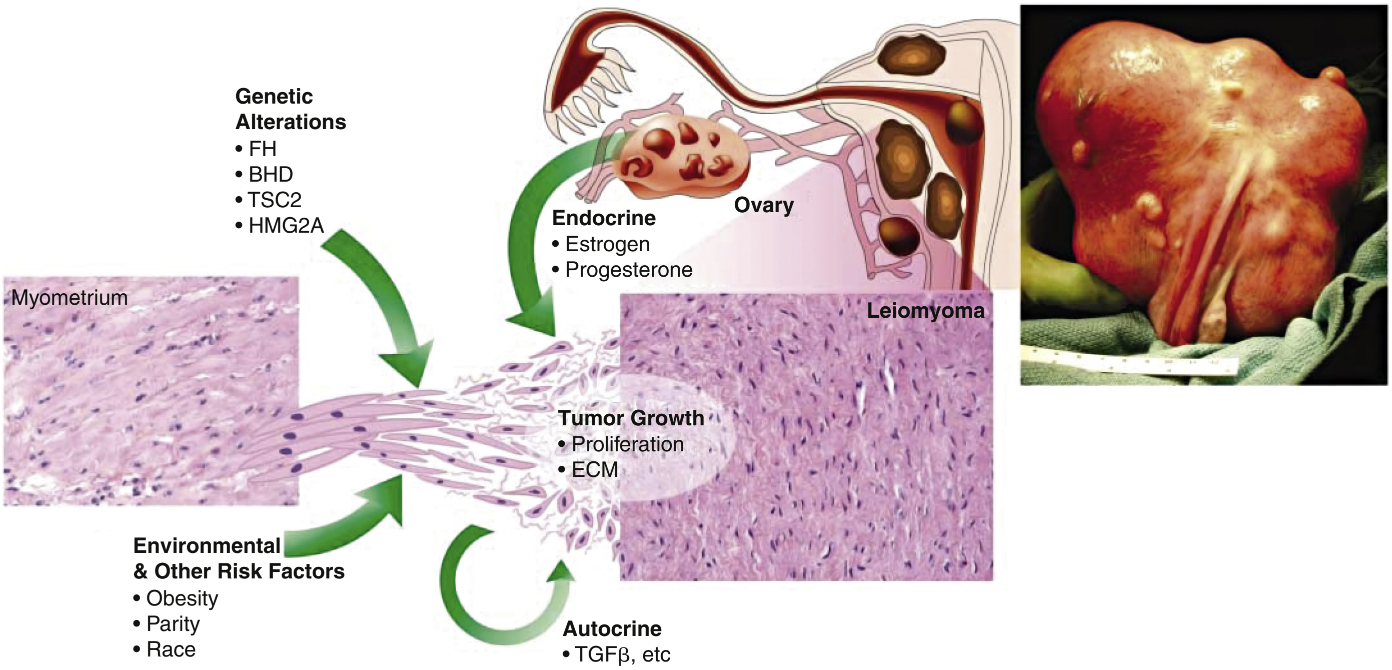

FIGURE 24-14 **Etiology of Uterine Leiomyomas.** Leiomyomas are heterogeneous in their natural history and etiology. Hereditary defects in *FH, BHD,* and *TSC2* genes and somatic alterations affecting *HMG2A* genes contribute to the development of leiomyomas, as do risk factors such as obesity, parity, and race. Tumor growth occurs by an increase in tumor cell number and extracellular matrix production and is promoted by both endocrine and autocrine growth factors. (From Walker CL, Stewart EA: *Science* 308:1589–1592, 2005.)

changes within their tissues.[103] Leiomyomas are estrogen- and progesterone-sensitive and are found to have increased numbers of estrogen receptors.[104] Uterine leiomyomas are not seen before menarche, and those that develop during the reproductive years generally decrease in size after menopause. Occurrence is multifactorial but often linked with estrogen exposure. Tumors in pregnant women may enlarge rapidly but often decrease in size after the end of the pregnancy. Risk factors for fibroids include nulliparity, obesity, PCOS, diabetes mellitus, black race, and hypertension.[104]

PATHOPHYSIOLOGY. Most leiomyomas occur in multiples in the fundus of the uterus, although they may occur singly and throughout the uterus. Leiomyomas are classified as subserous, submucous, or intramural according to their location within the various layers of the uterine wall (Figure 24-15). Uterine leiomyomas are usually firm and surrounded by a connective tissue layer. Unlike cancer, leiomyomas are unable to cause blood vessel proliferation to support their growth. Degeneration and necrosis may occur when a large leiomyoma outgrows its blood supply; the ensuing tissue necrosis causes pain.

CLINICAL MANIFESTATIONS. The major clinical manifestations of leiomyomas are abnormal uterine bleeding, pain, and symptoms related to pressure on nearby structures. Fibroids also may contribute to infertility and subfertility. The leiomyoma may distort the uterine cavity and increase the endometrial surface area. This increase may account for the increased menstrual bleeding that is associated with leiomyomas. Pain is not an early symptom but tends to occur with the devascularization of larger leiomyomas. It is also associated with blood vessel compression that limits blood supply to adjacent structures. Symptoms of abdominal pressure are slow to develop, apparently because the tumor is relatively slow growing, enabling adjacent structures to adapt to pressure. Pressure on the bladder may contribute to urinary frequency, urgency, and dysuria. Pressure on the ureter may cause it to become distended "upstream" from the pressure point; rectosigmoid pressure may lead to constipation. A sensation of abdominal or genital heaviness may be felt with larger tumors.

EVALUATION AND TREATMENT. Uterine leiomyomas are suspected when the bimanual examination discloses uterine enlargement and irregular, nontender nodularity of the uterus. Pelvic sonography or MRI confirms diagnosis.[104] Treatment depends on the symptoms, tumor size, age, reproductive status, overall health of the individual, and the woman's preference.[103] Most myomas are asymptomatic and can be managed by observation only. Medical treatment for symptomatic women not desiring pregnancy is aimed at shrinking the myoma, or reducing symptoms, or both. Some leiomyomas shrink in response to oral contraceptives, however, oral contraceptive pills (OCPs) may enhance growth, so should be monitored carefully. An LNG-IUD may be helpful for women who wish to reduce their bleeding and decrease the size of the tumors, if their uterine cavity is not completely blocked by large fibroids. GnRH agonists are usually a temporary management for those close to menopause or as a presurgical treatment. GnRH side effects related to decreased estrogen, including hot flashes and osteoporosis, limit its usefulness. Various selective estrogen receptor modulators have been studied in conjunction with GnRH agonists and appear effective.[103] Progesterone receptor agonists, such as mifepristone (RU486), also have shown some effectiveness in shrinking

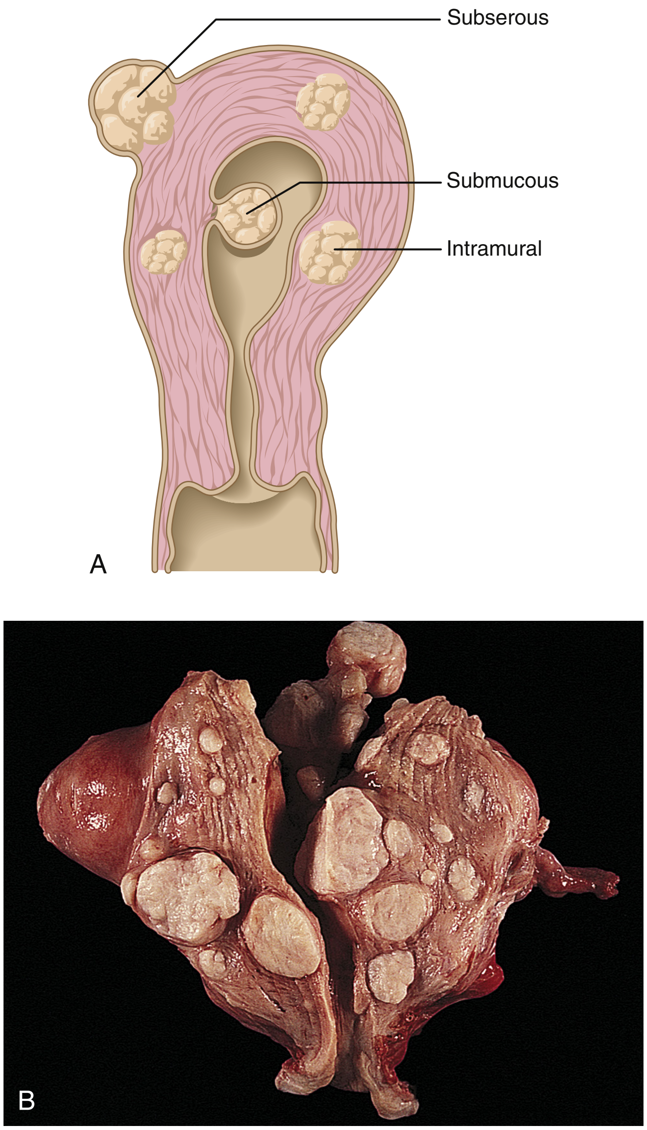

FIGURE 24-15 Leiomyomas. **A,** Uterine section showing whorl-like appearance and locations of leiomyomas, which are also called uterine fibroids. **B,** Multiple leiomyomas in sagittal section. Typical, well-circumscribed, solid, light gray nodules distort uterus. (**B** from Damjanov I, Linder J: *Pathology: a color atlas,* St Louis, 2000, Mosby.)

leiomyomas. Surgical treatments are commonly used but may be decreasing in frequency. Hysterectomy is commonly performed for bleeding and pain related to fibroids. Myomectomy, or removal of the fibroid from the muscle of the uterus, may be less invasive than a full hysterectomy and remains the standard of cure for women wishing to preserve their fertility. Newer less-invasive treatments that show promise include uterine artery embolization, mifepristone, and MRI-guided ultrasonography to coagulate areas of the fibroid, causing tissue destruction and involution. The benefits and risks of each therapy should be carefully explored with women who experience severe symptoms.[103]

Adenomyosis

Adenomyosis is the presence of islands of endometrial glands surrounded by benign endometrial stroma within the uterine myometrium. Endometrial cells migrate into the myometrial layer because of an unknown mechanism. Estrogen and progesterone likely play a role and, perhaps, metaplasia of müllerian tissue. Unlike endometriosis, this tissue does not respond to cyclic hormone changes. It is more commonly found during the late reproductive years; however, because adenomyosis is generally diagnosed after hysterectomy, time of diagnosis may not correspond with incidence. Adenomyosis has been found in up to 48% of hysterectomy specimens from otherwise normal women; rates are higher for women taking tamoxifen.[105] Parity also increases the risk for adenomyosis. Adenomyosis may be asymptomatic or may be associated with abnormal menstrual bleeding, dysmenorrhea, uterine enlargement, and uterine tenderness during menstruation. Secondary dysmenorrhea becomes increasingly severe as disease progresses. On bimanual examination the uterus is diffusely enlarged, globular, and most tender just before or after menstruation. Diagnosis is confirmed with ultrasound or MRI.[106] Treatment is symptomatic, similar to dysmenorrhea (i.e., NSAIDs, combined oral contraceptives [COCs], and perhaps LNG-IUDs). Surgical treatment includes resection of localized areas of adenomyosis (though this is difficult) or, if severe, hysterectomy. Uterine artery embolization and LNG-IUDs have shown good initial results but need further testing.[107,108]

Endometriosis

Endometriosis is the presence of functioning endometrial tissue or implants outside the uterus. Like normal endometrial tissue, the ectopic (out of place) endometrium responds to the hormonal fluctuations of the menstrual cycle.

The incidence of endometriosis is difficult to determine, particularly in asymptomatic adolescent and fertile women. It is estimated that 11% of reproductive-age women have endometriosis, though for most it is mild.[109] In addition, as many as 50% of women evaluated for pelvic pain, infertility, or a pelvic mass are diagnosed as having endometriosis. Moreover, the frequency and severity of symptoms do not correlate well with the extent or site of lesions.[109] A large study has found that women with endometriosis are at greater risk for cancers, especially ovarian cancer.[110]

The cause of endometriosis is not known, but several theories have been proposed. In 1927 Sampson[111] proposed that endometriosis is caused by the implantation of endometrial cells during **retrograde menstruation,** in which menstrual fluids move through the fallopian tubes and into the pelvic cavity (Figure 24-16). It is now known that retrograde menstruation occurs in almost all women; however, not all women develop endometriosis.

Another theory is that women with endometriosis have impaired cellular and humoral immunity. Alterations in cytokine and growth factor signaling have been identified. Cytotoxic T-cell and natural killer (NK) cell activity has been found to be depressed. At the same time, increased numbers of macrophages appear to be stimulating endometrial cell proliferation outside the uterus. An autoimmune response is also suspected.[112] Such alterations may cause the body to tolerate ectopic implantation of endometrial cells. Researchers also have proposed that endometrial cells spread through the lymphatic

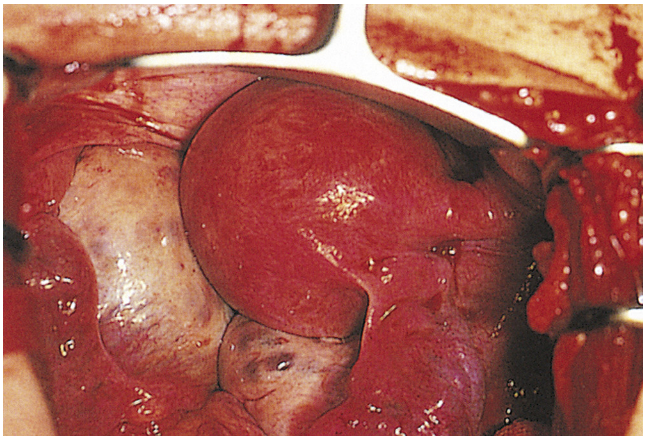

FIGURE 24-16 **Endometriosis.** The uterus is distended, and retrograde spill of menstrual loss has led to the development of endometriosis *(dark purple patches)*. (From Symonds EM, Macpherson MBA: *Color atlas of obstetrics and gynecology,* London, 1994, Mosby-Wolfe.)

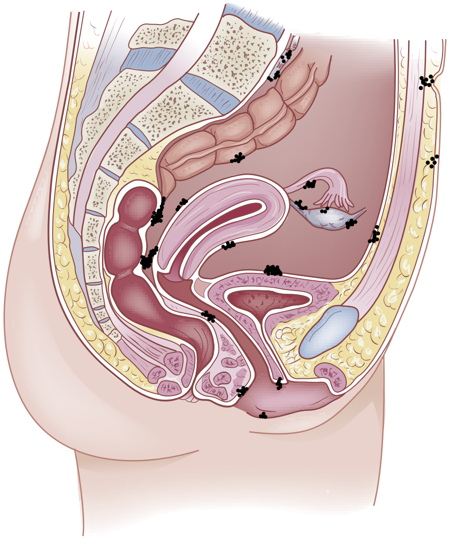

FIGURE 24-17 **Pelvic Sites of Endometrial Implantation.** Endometrial cells may enter the pelvic cavity during retrograde menstruation.

or vascular systems or that multipotential cells in the epithelial coverings of reproductive organs are somehow stimulated to develop into endometrial and metaplastic cells. A genetic predisposition to endometriosis has been documented. Some genetic polymorphisms have been identified.

PATHOPHYSIOLOGY. Endometrial implants can occur throughout the body but generally occur in the pelvic and abdominal cavities. The most common sites of implantation are the ovaries, uterine ligaments, rectovaginal septum, and pelvic peritoneum (Figure 24-17). Other sites of implantation are the sigmoid colon, small intestine, rectum, appendix, bladder, uterus, vulva, vagina, cervix, lymph nodes, extremities, pleural cavity, lungs, laparotomy scars, and hernial sacs.

Cyclic changes depend on the blood supply of the implants and the presence of glandular and stromal cells. Given that blood supply is sufficient, the ectopic endometrium proliferates, breaks down, and bleeds with the normal menstrual cycle. The bleeding causes inflammation, triggering a cascade of cellular inflammatory mediators, including cytokines, chemokines, growth factors, and protective factors such as secretory leukocyte protease inhibitor and superoxide dismutase.[112] The inflammation may lead to fibrosis, scarring, adhesions, and pain.

CLINICAL MANIFESTATIONS. The clinical manifestations of endometriosis can mimic other disease processes (i.e., PID, irritable bowel syndrome, ovarian cysts). Symptoms are variable in frequency and severity and include primarily infertility and pain,[112] dysmenorrhea, dyschezia (pain on defecation), dyspareunia (pain on intercourse), and, less commonly, constipation and abnormal vaginal bleeding. If implants are located within the pelvis they can cause an asymptomatic pelvic mass having irregular, movable nodules and a fixed, retroverted uterus. Most symptoms of endometriosis can be explained by the proliferation, breakdown, and bleeding of the ectopic endometrial tissue with subsequent formation of adhesions. In most instances, however, the degree of endometriosis is not related to the frequency or severity of symptoms.[109] Dysmenorrhea, for example, does not appear to be related to the degree of endometriosis. With involvement of the rectovaginal septum or the uterosacral ligaments, dyspareunia develops. Dyschezia occurs with bleeding of ectopic endometrium in the rectosigmoid musculature and subsequent fibrosis.

Twenty-five percent to 40% of women with infertility have endometriosis. The link between endometriosis and infertility is strong, yet the degree of disease and infertility is not as closely associated. That is, women with untreated minimal to mild disease may have high pregnancy rates or may experience infertility.[112] The exact mechanism for infertility in women with endometriosis is unknown. Infertility may result from mechanical interference with ovulation or ovum transport through the fallopian tube because of adhesions and the effects of inflammation and cytokine activity. However, the infertility also could be a result of the underlying autoimmune disorder that caused the endometriosis.[112] There are conflicting reports regarding the effect of endometriosis on sperm activity. An increased phagocytosis of spermatozoa by macrophages has been observed. The uterine endometrium in women with endometriosis appears to have an overactive response to estrogen and an underactive response to progesterone, impairing the endometrial receptivity to blastocyst implantation, decreasing the chance of successful pregnancy.[113]

EVALUATION AND TREATMENT. A presumptive diagnosis can be made based on clinical manifestations but laparoscopy is required for definitive diagnosis of endometriosis. A uniform classification system that includes both extent and severity has been developed (Table 24-4) but still does not correlate well with a woman's symptoms. Treatment is aimed at preventing or decreasing progression and spread, alleviating pain, and restoring fertility. Current therapies include suppression of ovulation with noncyclic estrogen-progestin COCs, depomedroxyprogesterone acetate (DMPA), danazol (which diminishes midcycle LH surge), GnRH agonists/analogs (to block the menstrual cycle), gestrinone (a 19-nortestosterone derivative and antiprogestational steroid), mifepristone (RU486) (an

TABLE 24-4 CLASSIFICATION SYSTEM FOR ENDOMETRIOSIS (REQUIRES LAPAROSCOPIC VISUALIZATION)

STAGE	DEGREE OF INVASIVENESS
I	Minimal
II	Mild
III	Moderate

Data from *Fertil Steril* 67(5):817–821, 1997.
Classification system also documents the location of lesions and presence of adhesions.

antiprogestational and antiglucocorticoid agent that can inhibit ovulation and disrupt endometrial integrity), and atrophy of endometrium with progestins, including DMPA, oral progestins, or an LNG-IUD.[112,114] A newer therapy is an injectable GnRH antagonist, which produces immediate inhibition of gonadotropin release but does not have substantially improved success rates when compared with other therapies.[115] Conservative surgical treatment includes laparoscopic removal of endometrial implants with conventional or laser techniques and presacral neurectomy for severe dysmenorrhea. Effectiveness may be increased when medical regimens are combined with surgical techniques. All treatments have risks or side effects, and recurrent symptoms develop in the majority of women within a few years, even with surgical treatments. Women should be fully informed about all options and carefully weigh the risk-to-benefit ratio of nonreversible treatments.[114]

Cancer

Malignant tumors of the female reproductive system are common. Cancers of the female reproductive tract can often grow large before causing pain because the pelvis and abdomen are poorly innervated and designed to accommodate a growing fetus. Reproductive tract cancers are more likely to be diagnosed early if there are symptoms. Uterine cancer is the fourth leading cancer diagnosis in women but is only the eighth leading cause of death in part because symptoms of vaginal bleeding prompt women to seek treatment. Ovarian cancer, on the other hand occurs less frequently, at 3% of total cancer diagnoses in women, but is the fifth leading cause of death from cancer related to its lack of symptoms and difficult detection.[1] Cervical cancer also has minimal symptoms until late in the process, but is easy to detect early with Pap smears. Three percent of cancers in women begin in the cervix but the death rate from cervical cancer has plummeted since the advent of screening techniques.[1]

Cervical Cancer

Cancer of the cervix is the leading cancer-related death in most of Africa, Central America, and South-Central Asia; however, it has a lower prevalence in the United States.[1,116] In the United States, the rates of invasive cancer have steadily decreased (a 75% reduction since the 1960s) and mortality rates caused by cervical cancer have declined (more than 45% since the early 1970s) largely because of the increased prevalence and frequency of cervical cancer screening with the Pap smear. In 2013, the American Cancer Society estimated 12,340 new cases of cervical invasive cancer and 4030 cervical cancer deaths.[1]

PATHOGENESIS. It is established that cervical cancer is almost exclusively caused by cervical human papillomavirus (HPV) infection. Infection with "high-risk" (oncogenic) types of HPV (predominantly 16 and 18) is a necessary precursor to development of the precancerous cell changes, known as dysplasia, of the cervix that leads to invasive cancer (also see Chapter 12). Precancerous dysplasia, also called *cervical intraepithelial carcinoma (CIN)* and *cervical carcinoma in situ (CIS),* is a more advanced form of the cell changes. Luckily, these cell changes can be detected noninvasively through examination of the cervical cells. The cells can be destroyed to prevent cancer development if dysplasia can be detected early.

Fifty percent of adolescents and young women acquire HPV (predominantly high-risk types) within 3 years of initiation of sexual intercourse, and it is estimated that 8.8% of all women ages 14 to 59 have persistent infection with high-risk HPV strains[117] (also see Chapter 26). Young women are especially vulnerable to HPV because of their cervical anatomy. There are two main cell types of the cervix: squamous epithelium cells and columnar epithelial cells. Squamous epithelial cells in older women cover the portions of the cervix that protrude into the vagina, and columnar epithelial cells line the inner portions of the cervical canal. The line where the two cells types meet, known as the transformation zone, is very vulnerable to the oncogenic effects of HPV. The location of the transformation zone changes as girls and women age and in response to estrogen and vaginal pH changes. In girls and young women a large portion of their cervix is covered with columnar epithelium, a condition known as squamous metaplasia.[118] As women age, the transformation zone moves as the squamous epithelium covers the surface of the cervix. Therefore, the younger a woman is when she contacts HPV, the more sensitive cervical cells are exposed. This is one reason vaccinations against HPV are aimed at women prior to the initiation of sexual activity.[118]

Most HPV infections are cleared by the immune system; the vast majority of infections do not cause cervical cancer. For this reason, screening for cervical cancer prior to age 21 is not recommended. Previous efforts at early screening resulted in many young women receiving treatments on their cervix. These treatments destroyed or removed cervical cells and in many cases altered the structural integrity of the cervix, resulting in an increase in preterm births in women treated without substantially decreasing the later rates of cervical cancer.[119]

It is unknown why some women are able to clear HPV infection and others cannot. Smoking has been shown to increase the risks of persistent infection and later development of cervical cancer.[120] In addition, certain gene polymorphisms on the genes that control epidermal growth factor increase the risk that HPV infection will lead to invasive cancer.[121] Anything that affects the integrity of the immune system may affect the later risk of cervical cancer including poor nutrition and chronic stress.[122] HIV infection greatly increases the risk that women infected with HPV will develop cervical cancer, and women with HIV should be screened for cervical cancer more

FIGURE 24-18 Cervical Carcinoma In Situ. Typical transformation zone, where the columnar (grapelike) epithelium is replaced by metaplastic epithelium. At its outer edge the metaplastic epithelium adjoins the squamous epithelium, which extends into the vagina. (From Coppleson M, Pixley E, Reid B: *Colposcopy: a scientific approach to the cervix in health and disease,* Springfield, IL, 1971, Charles C Thomas.)

frequently than women without HIV.[123] In addition, infection with *Chlamydia trachomatis* has been correlated with later risk for cancer.[120] It is hoped that the widespread use of the HPV vaccine in boys and girls will decrease rates of invasive cervical, genital, and anal cancers over the next several decades.[124]

Carcinoma in situ is most likely to develop in the squamous-columnar junction—the transformation zone—where the columnar epithelium of the cervical lining meets the squamous epithelium of the outer cervix and vagina (Figure 24-18). In this zone, columnar epithelium is constantly being replaced by squamous epithelium in a process known as *metaplasia.* Metaplasia is thought to be affected by hormonal levels; change in cervical epithelium is not understood as well as endometrial tissue change in response to fluctuating hormones. Because metaplastic cells are at increased risk of incorporating foreign or abnormal genetic material, neoplastic changes are most common in the transformation zone.

Many chromosomes may contain genes that relate to HPV-linked cervical cancer.[125] Like other cancers, cervical cancer requires the accumulation of genetic alterations for carcinogenesis to occur. However, the discrete tumor-suppressor gene locations have yet to be identified.[125] Several chromosome regions with recurrent loss of heterozygosity (LOH) have been identified (also see Chapter 12). In addition, other genes may influence a woman's receptivity to HPV.[121] For instance, HPV

WHAT'S NEW?

Cervical Cancer Screening in the Developing World

The problem with the use of the conventional Papanicolaou (Pap) smear in screening for cervical cancer is the low sensitivity of the test, which ranges between 44% and 77%. This means that a large number of cervical abnormalities (23% to 56%) can be missed with a single test! Thus the success of Pap smear screening in reducing cervical cancer in the United States lies in the frequency of screenings and that cervical cancer is a slowly progressive condition. However, a high frequency of Pap smear screenings is often not feasible, either economically, socially, culturally, or logistically, in many countries and in some regions leads to much higher rates of invasive cervical cancer for women in such populations or locales. Multiple, large, well-conducted studies have demonstrated that human papillomavirus (HPV) testing is considerably more sensitive (between 97% and 98%) than either conventional or liquid-based Pap testing. HPV infection is known to be the required precursor to cervical cancer. With sensitive HPV tests now widely available, requiring less frequent screening (every 3 to 5 years), the future of cervical cancer screening may rely on HPV screening, not on conventional cervical cytology testing.

In settings where there is not even adequate infrastructure for HPV testing, several studies have shown that simple visualization with acetic acid (VIA) can be used to diagnosis women with HPV infection and then immediately provide onsite cryotherapy to reduce rates of later cervical cancer. Although not ideal, this approach shows promise in low-resources settings, especially when the baseline rate of HIV infection is high, because it allows women to be screened and treated on the same visit.

Data from Hoppenot C, Stampler K, Dunton C: *Obstet Gynecol Surv* 67(10):658–667, 2012.

may up-regulate the E6 oncoprotein in certain gene sequences, causing a greater production of vascular epidermal growth factor, which allows the tumor to promote blood vessel growth toward the proliferating cells, fueling growth.[121,126]

CLINICAL MANIFESTATIONS. Cervical neoplasms are predominantly asymptomatic; therefore, regular Pap test or HPV screening is necessary for early detection (see Chapter 26 for screening frequency guidelines). About 90% of cervical cancer cases can be detected through early use of regular screening tests (see What's New? Cervical Cancer Screening in the Developing World). If symptoms exist, they may include vaginal bleeding or abnormal discharge. Bleeding is variable and may occur after intercourse or between menstrual periods. Vaginal discharge is a less common presenting symptom and may be serosanguineous or yellowish with a foul odor. Bleeding and discharge are subtle and are likely to be disregarded by premenopausal women. Postmenopausal women are more likely to seek medical attention if these signs appear. Advanced disease may cause urinary or rectal symptoms and pelvic or back pain along with anemia.

EVALUATION AND TREATMENT. Women should be screened for cervical cancer and risk for future cervical cancer through Pap smear and HPV testing.[127] HPV testing is now recommended at the same time as the Pap smear because it is noninvasive and identifies women at later risk for cellular abnormalities leading to cancer. HPV is often detectable for more than a decade prior to any noticed cellular changes.[127]

A Pap smear involves noninvasively taking a cell sample from the surface of the cervix during a pelvic examination using a

speculum to allow for visualization of the cervix. Cervical cytology is most accurate if cells are obtained from both the endo- and ectocervix, which involves placing the collection device (a small brush or broom) into the cervical os. These cells are then sent to a laboratory for analysis. When dysplasia is detected, further testing is indicated for diagnosis. Colposcopy involves examining the cervix visually and taking needed biopsies. An acetic acid (vinegar) solution is applied to the cervix, making areas of HPV infection stand out in a white color, known as *aceto-white*. The cervix is then viewed under magnification for aceto-white areas, changes in the epithelium, and the presence of abnormal vascular patterns.[128] Abnormal areas of the cervix are biopsied. Because the vulnerable transformation zones move into the cervical canal as a woman ages, the endocervix is sampled using curettage for diagnosis (Table 24-5).

The progressive neoplastic changes of cervical cells are classified on a continuum from cervical intraepithelial neoplasia (dysplasia), to cervical carcinoma in situ (full epithelial thickness of the cervix is involved), to invasive carcinoma (see Tables 23-5 and 23-6). Various terms are used to describe the cellular changes in the cervix based on how the cells were obtained. Screening for cervical cancer is done with a Pap smear, and the cytology report describes Pap smear findings; these terms are outlined on the left side of Table 23-5. If a Pap smear has abnormal findings, a biopsy of the affected tissue is taken during a colposcopy. The biopsy reveals the actual extent of the lesion within the cervix. Terminology used in pathology reports is listed on the right side of Table 23-5. Pathology reports that involve cancer changes begin with the abbreviation CIN or CIS.

Cervical dysplasia is replacement of some epithelial cells by atypical neoplastic cells, and is "staged" depending on the depth of epithelial involvement (Figure 24-19). Risk of progression to invasive carcinoma rises steadily with the severity of dysplasia; however, women with intact immune systems are likely to resolve dysplasia on their own. More than half (57%) of HIV-infected women with CIN 1, 42% of women with CIN 2, and 32% of women with CIN 3 have a natural "regression" of lesions. At least a third or more of all cervical intraepithelial lesions persist without progression or regression. Women with CIN 1 (low-grade squamous intraepithelial lesion [LSIL] or mild dysplasia) have an 11% chance of progression to CIS and a 1% chance of progression to cervical invasion. Women with CIN 2 have a 22% chance of progression to CIS and a 5% chance of invasive lesions. In cervical CIN 3 or HSIL (high-grade squamous intraepithelial lesion), all or most of the cervical epithelium shows cellular features of carcinoma; however, underlying tissue is not affected. At least 12% of women with CIN 3 (CIS) progress to cervical invasion.

CIS is generally a precursor of invasive carcinoma of the cervix. A number of factors, including tumor type, contribute to the rate at which CIS becomes invasive. Because of the ease of Pap smear screening, invasive cervical cancer is rare within the United States, but much more common in the developing world, where screening is not available. **Invasive carcinoma of the cervix** consists of cancer invasion into adjacent tissues and metastasis. Adjacent tissues most often involved are the ureters and structures of the lateral pelvic wall, the vaginal stroma and epithelium, and the lower uterine segment and myometrium. The internal, external, and common iliac lymph nodes and the obturator nodes are common sites of lymphatic involvement. Invasive cervical cancer is most often discovered through Pap smears, tentatively diagnosed with a biopsy during a colposcopy, and then further diagnosed using surgery and lymphangiography, CT scan, MRI, ultrasonography, or radioimmunodetection methods. The staging system for carcinoma of the cervix is shown in Table 24-6.

Treatment depends on the degree of neoplastic change, the size and location of the lesion, and the extent of metastatic spread. For premalignant cellular changes and CIS, the goal is to kill or remove abnormal cells; these procedures can be done in a clinic with local anesthetic. Invasive carcinoma requires surgery, including removal of the cervix and other affected tissues.

Common treatments can be classified as ablative, when the cells are killed without being removed, or excisional in which the abnormal cells are physically removed from the cervix. Ablative therapies are appropriate for lower levels of cervical dysplasia because the treatment does not produce a sample for analysis. However, ablative therapies leave the cervix intact, which may be beneficial for later childbearing. Ablative surgeries include cryotherapy and cold coagulation in which extreme cold is applied to the surface of the cervix. Carbon dioxide laser and electrocoagulation also are used to kill abnormal cells and coagulate vessels supporting their growth. Excisional therapies are appropriate if a more advanced lesion is suspected because they produce tissue for analysis. Excisional therapies include conization, in which a cone-shaped portion of the cervix is removed, and the loop electrosurgical excision procedure (LEEP), in which a small looped wire with electric current generates heat and burns off cancer cells. Heat, cold, or lasers are used in excisional procedures to simultaneously excise the tissue and obliterate abnormal blood vessels.

For invasive cervical carcinoma, treatment depends on the stage of the tumor. Surgical intervention may include a hysterectomy, pelvic lymphadenectomy, or pelvic exenteration (radical

removal of contents of body cavity). Multidrug chemotherapy regimens also have been used alone or in combination with radiation.[129] Smokers tend to have a higher stage of disease at diagnosis, and their cancer is more resistant to radiation treatment.

With early detection and treatment, prognosis is excellent. Overall, the 5-year survival rate is 95% for stage IA or lower (e.g., early detection). A cure rate of 100% is possible for women with dysplasia or CIS.[1] The prevention of HPV infection may be the key to substantially reducing the risk of cervical cancer. FDA-approved vaccines for two of the high-risk types of HPV show excellent promise, and studies are underway to quantify their benefit; however, it may take 10 to 20 years to see the full effect of widespread vaccination due to the slow progression of cervical cancer.[124,130]

TABLE 24-6 CLINICAL STAGING FOR CANCER OF THE CERVIX

STAGE	CHARACTERISTICS
0	Cancer in situ, intraepithelial carcinoma; earliest stage of cancer; cancer confined to its original site
I	Carcinoma confined to cervix (extension to corpus disregarded)
IA	Earliest form of stage I; there is very small amount of cancer, which is visible only under a microscope
IA1	Area of invasion is <3 mm (about ⅛ inch) deep and <7 mm (about ⅓ inch) wide
IA2	Area of invasion is between 3 and 5 mm (about ⅕ inch) deep, and <7 mm (about ⅓ inch) wide
IB	Includes cancers that can be seen without a microscope; also includes cancers seen only with a microscope that have spread deeper than 5 mm (about ⅕ inch) into connective tissue of the cervix or are wider than 7 mm
IB1	IB cancer that is no larger than 4 cm (about 1⅓ inches)
IB2	IB cancer that is >4 cm
II	Cancer has spread beyond the cervix to the upper part of the vagina; cancer does not involve the lower third of the vagina
IIA	Cancer has spread beyond the cervix to the upper part of the vagina; cancer does not involve the lower third of the vagina
IIB	Cancer has spread to the tissue next to the cervix, called the *parametrial tissue*
III	Cancer has spread to the lower part of the vagina or the pelvic wall; cancer may be blocking the ureters (tubes that carry urine from the kidneys to the bladder)
IIIA	Cancer has spread to the lower third of the vagina but not to the pelvic wall
IIIB	Cancer extends to the pelvic wall, blocks urine flow to the bladder, or both
IV	Most advanced stage of cervical cancer; cancer has spread to other parts of the body
IVA	Cancer has spread to the bladder or rectum, which are organs close to the cervix
IVB	Cancer has spread to distant organs beyond the pelvic area, such as the lungs

Vaginal Cancer

Cancer of the vagina is the rarest of the female genital cancers and accounts for less than 2% of gynecologic cancers.[131] Vaginal and cervical cancers are thought to have similar epidemiology. Both start as intraepithelial lesions, occur in sexually active women, and are associated with HPV infection. Prior carcinoma of the cervix places a woman at higher risk for developing vaginal cancer.[132] In utero exposure to nonsteroidal estrogens is a risk factor. It has been estimated that 100,000 to 160,000 women were exposed in utero to such nonsteroidal estrogens as DES, dienestrol, or hexestrol from 1960 to 1971.[133] Exposure to such hormones during the first 3 months of gestation inhibits the normal replacement of columnar epithelium by squamous epithelium in the vagina of the fetus. The columnar epithelium, which is not normally found in the vagina, may then undergo malignant transformation. Not all women exposed to DES in utero develop neoplastic changes in the vagina, however.[133]

Vaginal cancer is usually diagnosed in women in their 60s and 70s but the cellular changes begin many years prior to clinically visible signs of the disease.[131] The most common type of vaginal cancer is squamous cell carcinoma. About 90% of tumors are squamous cell–type cancers; the remaining 10% are adenocarcinomas, sarcomas (rare), and melanomas (rare). Nonsquamous types of cancer are more common in younger women. Vaginal sarcomas can develop in children younger than 5 years and adenocarcinomas are the most common in women less than 30 years old.[131]

Vaginal cancer is generally asymptomatic until fairly late in the disease process. The major symptom of invasive cancer is vaginal bleeding or bloody discharge. Other symptoms can include vaginal discharge, vulvar pruritus, rectal or bladder symptoms, pain, or leg edema.

Several mechanisms can be used to diagnose vaginal cancer including Pap testing of abnormal vaginal skin, colposcopy, and biopsy. Once a diagnosis of cancer is established, size and extent of the lesion are determined using MRI, prior to surgery.[131] Like cervical neoplasms, vaginal cancers are classified as intraepithelial neoplasia (dysplasia), CIS, or invasive carcinoma and are staged based on extension into local tissues and metastasis to distant organs. Treatment depends on the type and extent of the cancer and the overall health and expectations of the woman.[131] Potential treatment modalities include removal of the affected tissues (vagina, uterus, bladder, and rectum), excision of lymph nodes, radiation, and chemotherapy. Many women with invasive vaginal cancer develop recurrent pelvic cancer and need intensive monitoring for recurrence. Recurrence and survival rates vary greatly by the type and extent of cancer and the aggressiveness of the treatment regimen.[131]

Vulvar Cancer

Cancer of the vulva is responsible for about 3% to 5% of all gynecologic cancers; however, there has been a steady increase in the incidence of vulvar cancers over the last 30 years. The majority (90%) are squamous cell carcinomas, although melanoma (5%), Bartholin gland carcinoma (2%), sarcoma (2%), and adenosquamous carcinoma (1%) may occur. A history of HPV infection is a risk factor with 40% of lesions related to infection with HPV subtype 16.[134] Previous squamous dysplasia of the vagina or cervix also is a major risk factor, as are smoking and HIV infections.[135] Although it usually affects postmenopausal women (median age of presentation is women in their 60s), vulvar cancer has been diagnosed in women between ages 30 and 90.[134,135] Usually women have a history of vulvar irritation and pruritus (70%); urinary symptoms and discharge are less common. In addition, there may be a hard ulcerated area of the vulva, large cauliflower lesions, or lesions similar to those of chronic dermatitis. Biopsy confirms the diagnosis. Treatment options include primarily ablative or excisional surgery,

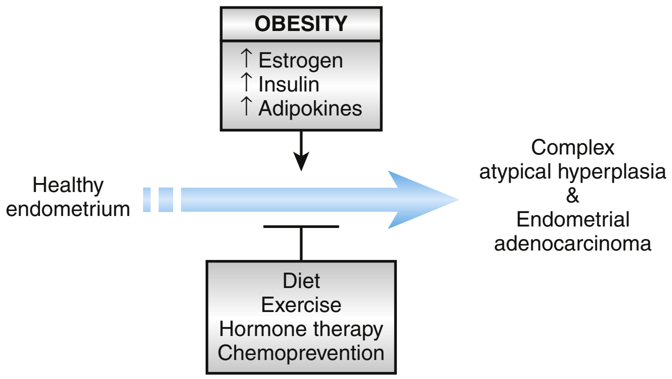

FIGURE 24-20 Endometrial Cancer. Overview of the contribution of obesity to endometrial cancer progression and preventive strategies. (From Schmandt RE et al: *Am J Obstet Gynecol* 205[6]:518–525, 2011.)

and sometimes radiation with or without chemotherapy. Less extensive removal of vulvar tissue is being studied to decrease postsurgical morbidity and maintain function.[136] Prognosis depends on lesion size and location, histology, and lymph involvement; risk of metastasis increases with tumor size. The 5-year survival rate depends on the extent of the lesion, the treatment, and the overall health of the woman. Cancer caught in the early stages has a greater than 90% 5-year survival rate with progressively poorer prognosis with advancing stages.[136]

Endometrial Cancer and Uterine Sarcoma

Endometrial carcinomas arise within the glandular epithelium of the uterine lining. Estimates include 49,560 new cases in 2013, with approximately 8190 deaths.[1] Most cases occur in postmenopausal women (Figure 24-20), with peak incidence occurring in the late 50s to early 60s.[137] Women have a 3% lifetime risk of developing uterine cancer. Although incidence rates are higher in white than in black women, mortality rates in black women are nearly twice as high. The primary risk factor is prolonged exposure to estrogen without the presence of progesterone. Estrogen causes endometrial proliferation, whereas progesterone changes the uterine lining to limit proliferation and encourage normal shedding. Estrogen without the presence of progesterone is known as *unopposed estrogen* because its proliferating effects are not restrained. Exposure to unopposed estrogen includes estrogen-only hormone replacement therapy, tamoxifen, early menarche, late menopause, never having children, and a failure to ovulate (i.e., PCOS and anovulatory cycles typical of the late reproductive years). Obesity also is a known source of endogenous estrogen and is a risk factor for endometrial cancer (see Figure 24-20).[138] Other risk factors not directly related to estrogen include diabetes, gallbladder disease, and hypertension, though obesity may be a mediating factor for these risks. A family history of colon, endometrial, or ovarian cancer could signal hereditary nonpolyposis colorectal cancer (HNPCC); women with this family history may wish to explore genetic testing and more aggressive screening.[139]

Although estrogen and obesity increase the risk of endometrial cancer, several interventions have been shown to decrease the risk of cancer. A review of modifiable risk factors and prevention for endometrial hyperplasia and cancer indicates that controlling obesity, hypertension, and diabetes may reduce an individual's risk of endometrial cancer.[140] Exposure to progesterone also decreases the risk of endometrial cancer both immediately and long term. Large amounts of progesterone are released during pregnancy. Smaller, but still effective, amounts of progesterone are in OCPs and the progestin-containing IUD. The use of birth control pills can decrease the risk of endometrial cancer by 80% even for more than a decade after use.[141] The progestin-containing IUD is used to prevent endometrial abnormalities in women who need to take tamoxifen as part of breast cancer prevention.[142]

About 75% of endometrial cancers are adenocarcinomas. Abnormal vaginal bleeding is the most common clinical manifestation of endometrial cancer. The bleeding is caused by disruption of the endometrial surface by neoplastic processes. Pain and weight loss are symptoms of late disease.

Screening methods for early detection of endometrial cancer are as effective as those for cervical cancer. Pap tests, which are highly effective in detecting cervical dysplasia, are ineffective in detecting early endometrial cancer. Transvaginal ultrasound (TVUS) may be used to measure endometrial thickness and screen postmenopausal and high-risk premenopausal women. If the endometrium is abnormally thick (defined as >5 mm), then further testing, such as endometrial biopsy, is warranted to rule out cancer, especially in high-risk women.[143] Endometrial biopsies can be performed in a normal clinic with minimal additional equipment. The biopsy involves placement of a small thin tube through the cervix to collect a specimen of the endometrium for analysis.[141] Once cancer is confirmed by biopsy, a laparoscopy and MRI may be performed to determine stage of disease.

Uterine cancers can be divided into two types by histology. Type I tumors are by far the most common and result from estrogen exposure leading to endometrial hyperplasia. Type II cancers make up 10% of endometrial cancers but are more likely to be invasive into the uterine muscle and metastasize beyond their original location resulting in a much greater risk for death.[144] Treatment is based on the cancer type and the extent of the disease. For women with simple hyperplasia, progestin therapy (orally or through LNG-IUD) may often suffice. However, treatment for atypical hyperplasia or invasive disease usually includes surgical intervention, such as curettage for carcinoma in situ, total abdominal hysterectomy with bilateral salpingo-oophorectomy, and lymphadenectomy.[141] Chemotherapy and radiation also may be used. The 1-year relative survival rate for endometrial cancer is 92%; the 5-year relative survival rate is 95% with early diagnosis and 16% if diagnosis occurred in the late stage. Survival rates for white women exceed those for black women by 8% at every stage.[1]

Uterine sarcomas are rare neoplasms that arise from mesenchymal tissues of and near the uterus, including myometrial smooth muscle, endometrial stroma, or adjacent connective tissues. Uterine sarcomas are rare, constituting up to 3% of all genital tract cancers and 3% to 5% of all uterine malignancies. The average age at diagnosis is the early 50s, though some sarcomas can form in childhood. Uterine sarcomas can be divided into endometrial stromal sarcoma, leiomyosarcoma, and adenosarcoma based on the involved tissue types. The

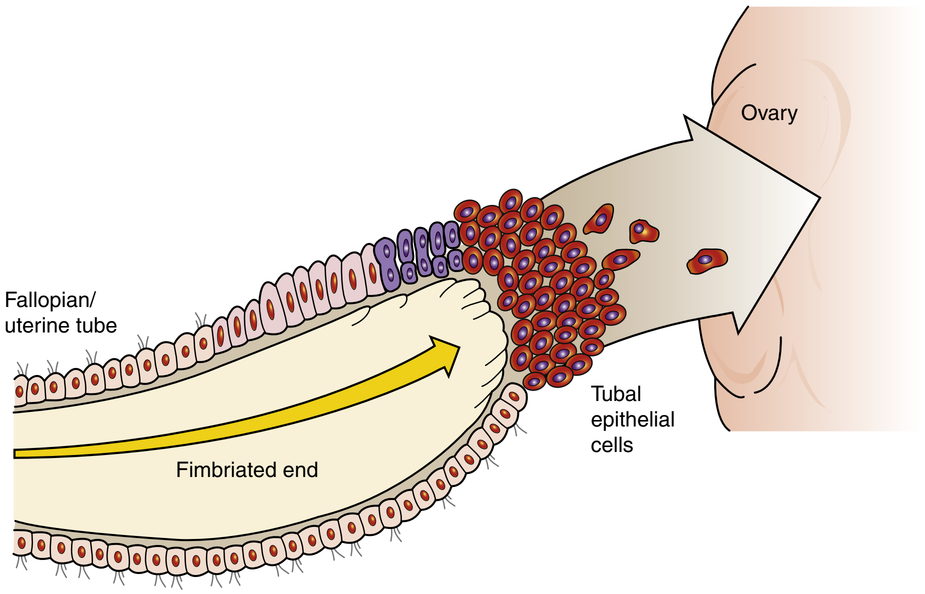

FIGURE 24-21 Migration of epithelial cells from the fallopian/uterine tubes to the ovary. (Adapted from Kurman RJ, Shih IM: *Am J Surg Pathol* 34[3]:433, 2010.)

very low occurrence and diversity of cellular composition of these tumors explains the lack of epidemiologic and treatment data.[145] Thus relatively few risk factors have been identified. However, chronic excess estrogen exposure, tamoxifen, and black race have been cited as risks. Symptoms include abnormal uterine bleeding, awareness of a mass, and pelvic pressure or pain. Vaginal discharge may be profuse and foul. Gastrointestinal and genitourinary complaints are common. Treatment consists of total hysterectomy, which may include bilateral salpingo-oophorectomy and selective lymphadenectomy followed by radiation therapy or chemotherapy, or both. Molecularly targeted therapies are also under investigation.[146] Five-year survival rates range from 50% in early disease to 5% in advanced disease. Like most cancers, stage and histopathology are the most important determinant of prognosis. The survival rate at 5 years for stage I disease is 50%. Few women survive advanced-stage disease.[145]

Ovarian Cancer

The incidence of ovarian cancer is estimated at 22,240 women in the United States in 2013. In 2013 ovarian cancer accounted for 3% of all cancers among women and caused more deaths (14,030) than any other female reproductive cancer in part because of the limited availability of early screening programs. From 2005 to 2009, the incidence declined at a rate of 0.9% per year.[1] Ovarian cancer in women older than 40 years is associated with conditions associated with increased ovulation over the lifetime, such as early menarche, late menopause, nulliparity, and the use of fertility drugs (especially in women who fail to carry a child after using fertility drugs).[146-148] Race and prior pelvic radiation also appear to increase risk.[147] Factors that suppress ovulation decrease the risk of ovarian cancer and include pregnancies, prolonged lactation, and the use of hormonal contraceptives that limit ovulation, including the birth control pill.[147,149]

PATHOGENESIS. There is controversy about the pathogenesis of ovarian cancer. The great majority (approximately 90%) of ovarian cancers are sporadic and not associated with a known pattern of inheritance.[150] Of the 5% to 10% that are familial, the majority are associated with the breast cancer susceptibility gene 1 *(BRCA1)* and a smaller number with mutations of *BRCA2* or mismatched repair genes (HNPCC syndrome). Various pathways have been proposed. Women and families who are more susceptible to cancer may have errors in the ability to repair cellular DNA, related to abnormalities in RAD51D, which is an enzyme crucial to DNA repair,[151] which allows aberrant cellular proliferation that occurs with repetitive ovulatory tissue repair in the ovary. In sporadic ovarian cancer, *BRCA1* and *BRCA2* are rarely mutated. A newer theory proposes that many spontaneous, nonhereditary ovarian tumors arise from the migration of cells from tissues of mesoderm origin to the surface of the ovary.[152,153] Cells from a variety of intra-abdominal locations, including endometrial tissue and epithelium of the fallopian/uterine tubes, can attach to the ovary (Figure 24-21). The local ovarian environment, including the ovarian stroma, may then interact with the transplanted cells to enhance cellular growth and encourage metastasis[154] (Figure 24-22).

The two major types of ovarian cancer are epithelial ovarian neoplasms and germ-cell neoplasms. Most ovarian malignancies are epithelial ovarian neoplasms that usually develop from the surface epithelium of the ovary or that which line cysts immediately beneath the ovarian surface, or may be cells that have migrated from the fallopian/uterine tubes.[153] Most epithelial cancers seem to arise from a single cell (i.e., clonal) because of a loss of tumor-suppressor genes and activation of oncogenes (see Chapter 12). Epithelial ovarian tumors may have cellular similarities to other tissues within the abdomen, including the lining of the fallopian/uterine tubes, or the endometrium, or be undifferentiated. Tumors are often classified as type I (low grade) and type II (high grade) based on their cellular type.

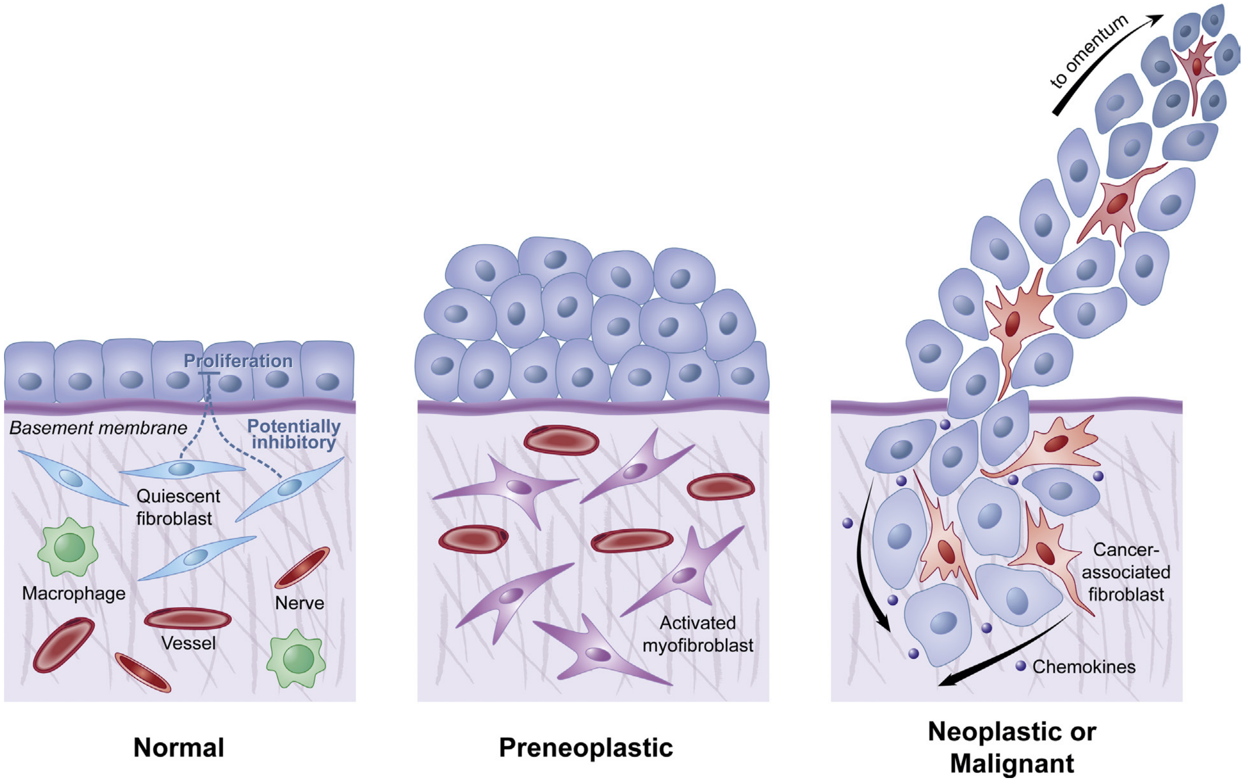

FIGURE 24-22 **Ovarian Stroma.** The ovarian stroma interacts with precancerous and cancerous cells within the ovary. (From Schauer IG et al: *Neoplasia* 13[5]:393, 2011)

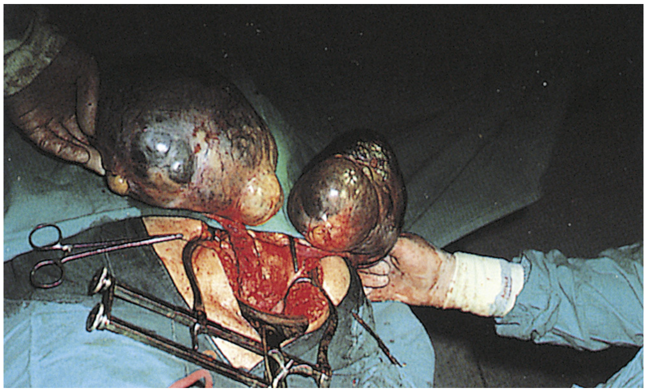

FIGURE 24-23 **Ovarian Tumors.** Bilateral multicystic ovarian tumors. (From Symonds EM, Macpherson MBA: *Color atlas of obstetrics and gynecology,* London, 1994, Mosby-Wolfe.)

Type I tumors grow more slowly but are more resistant to chemotherapy. Type II tumors often grow rapidly and aggressively but respond well to chemotherapy[153,155] (Figure 24-23). The 5-year survival rate is 92% if treated in stage I; however, only 15% of ovarian cancers are diagnosed this early. Five-year survival rates decline with stage of disease: women with regional spread of the cancer have a 5-year survival rate of 72%, whereas women with distant metastasis have only a 5-year survival rate of 27%.[1]

Germ-cell tumors are derived from the primitive germ cells (gametes) of the embryonic gonad and may be malignant or benign. The benign cystic teratoma accounts for approximately 10% of all ovarian tumors. These tumors represent an error in meiosis that results in the formation of ectoderm, endoderm, and mesoderm cell lines. Hair, teeth, and skin can be visualized within cystic teratomas. If the germ-cell tumor is malignant, it tends to be highly aggressive and rapidly growing with a poor prognosis. Cystic hygromas and other germ-cell tumors can occur on the ovaries of girls and women. Germ-cell tumors in children can be particularly aggressive.

CLINICAL MANIFESTATIONS. Ovarian cancer is commonly asymptomatic until the tumors have grown very large. Given the location of the ovaries, assessing abnormalities on routine gynecologic examination poses difficulty, especially in obese women. There is no sensitive and specific test for ovarian cancer for screening low-risk women, and routine screening of women without risk factors has not been shown to be beneficial and may cause harm because more women have unnecessary surgical procedures.[156]

Common first symptoms of ovarian cancer are vague and include persistent abdominal distention, loss of appetite due to early satiety, and pelvic pain. Screening is warranted if women have a new onset of these symptoms that persist for more than 12 days each month. However, many women fail to notice the very first signs of ovarian cancer because they are vague and fairly common in older women. The disease is most commonly diagnosed after metastasis has occurred. Consequently, ovarian cancer is often termed the *silent killer*. Symptoms of advanced disease include pain and abdominal swelling from the primary ovarian mass or ascites and abdominal distention (Figure 24-24). Gastrointestinal manifestations may include dyspepsia,

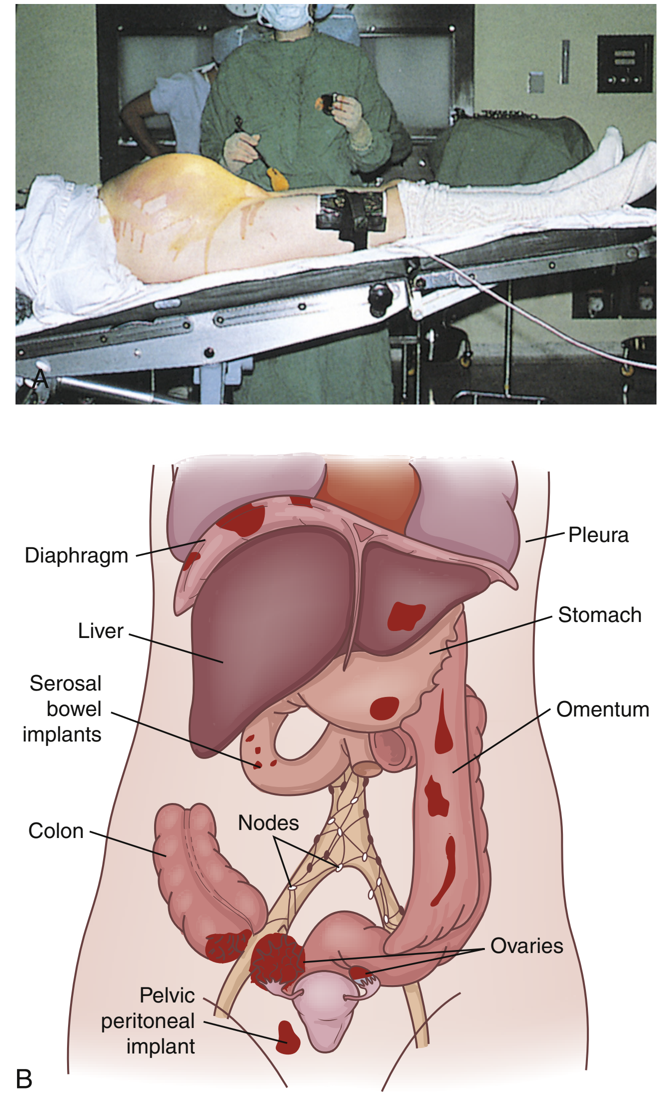

FIGURE 24-24 Large Malignant Ovarian Tumor and Metastasis of Ovarian Cancer. **A,** Tumor has caused massive abdominal distention. **B,** Pattern of spread for epithelial cancer of the ovary. (**A** from Symonds EM, Macpherson MBA: *Color atlas of obstetrics and gynecology,* London, 1994, Mosby-Wolfe.)

vomiting, and alterations in bowel habits caused by mechanical obstruction. Abnormal vaginal bleeding may occur if the postmenopausal endometrium is stimulated by a hormone-secreting tumor. The tumor also may cause ulcerations through the vaginal wall that result in bleeding. There also can be a feeling of pressure in the pelvis and leg pain.

Tumor obstruction of vascular channels can cause venous and, occasionally, arterial thrombosis. Alterations in coagulability also occur, contributing to clot formation. Metastasis often causes pleural effusion.

EVALUATION AND TREATMENT. Because ovarian cancer has no early symptoms and there is no cost-effective screening techniques for early detection, disease usually is advanced by the time treatment is sought. Women with symptoms of disease, as outlined earlier, should be assessed with minimally invasive tests first. Screening commonly begins with a CA-125 blood test looking for specific cancer markers and a transvaginal ultrasound.[157] Increased CA-125 levels are found in about 78% to 80% of nonmucinous ovarian cancers; however, elevated levels are produced in 29% of nongynecologic tumors and in a variety of noncancerous conditions, for example, endometriosis, PID, benign ovarian cysts, myomas, and pregnancy.

Women less than 40 years of age are more likely to have nonepithelial cells tumors and should be assessed with the blood tests to look for the CA-125 marker, alpha fetoprotein (AFP), and β-human chorionic growth hormone to screen for tumors of nonepithelial cell origin.[157] Some types of germ cells and, rarely, adenocarcinoma may be associated with increased levels of AFP, hCG, or CA-125.

If initial tests are suspicious for a cancerous mass, diagnosis is confirmed by biopsy and extent of the disease is determined by ultrasound, CT, MRI, or other imaging techniques. Women undergoing surgery for ovarian cancer staging receive a thorough assessment for metastasis. The International Federation of Gynecologists and Obstetricians (FIGO) staging system is described in Table 24-7. Other studies may be used to determine the extent of metastasis. These include an upper gastrointestinal series, barium enema, intravenous pyelogram (IVP), mammography, and lymphography.

TABLE 24-7 FIGO STAGING OF CARCINOMA OF THE OVARY

STAGE	CHARACTERISTICS
I	Growth limited to the ovaries
IA	Growth limited to one ovary; no ascites
IA1	No tumor on the external surface; capsule intact (90% 5-year survival with treatment)
IA2	Tumor present on the external surface, or capsule(s) ruptured, or both
IB	Growth limited to both ovaries; no ascites
IB1	No tumor on the external surface; capsule intact
IB2	Tumor present on the external surface, or capsule(s) ruptured, or both
IC	Tumor either stage IA or stage IB, with ascites present or with positive peritoneal washings
II	Growth involving one or both ovaries with pelvic extension
IIA	Extension and/or metastases to the uterus and/or tubes
IIB	Extension to other pelvic tissues
IIC	Tumor either stage IIA or stage IIB but with ascites present or with positive peritoneal washings
III	Growth involving one or both ovaries with intraperitoneal metastases outside the pelvis, or positive retroperitoneal nodes, or both; tumor limited to the true pelvis with histologically proven malignant extension to small bowel or omentum
IV	Growth involving one or both ovaries with distant metastases; if pleural effusion is present, there must be positive cytology to allot a case to stage IV; parenchymal liver metastases indicate stage IV
Special category	Unexplored cases that are thought to be ovarian carcinoma

FIGO, International Federation of Gynecologists and Obstetricians.

TABLE 24-8 POSSIBLE EFFECTS OF CHRONIC DISEASE ON SEXUAL FUNCTIONING IN WOMEN

DISEASE	SEXUAL FUNCTION
Cerebral palsy	Intact genital sensations, decreased lubrication; difficulty with sexual activity/positioning because of muscle spasticity, rigidity, and/or weakness; pain with positioning caused by contracture of knees and hips or because of increased spasms with arousal
Cerebrovascular accident (CVA)	Difficulties in sexual positioning and sensitivity because of impaired motor strength, coordination or paralysis; decreased sex drive with stroke on the dominant side of the brain
Diabetes	Diminished intensity of orgasm and gradual decline in ability to achieve orgasm; decreased lubrication and/or recurrent vaginal infections with resultant dyspareunia
Chronic renal failure	Decreased arousal; increasingly rare and less intense orgasms; decreased lubrication
Rheumatoid arthritis (RA)	Painful sexual activity/positions because of swollen, painful joints, muscular atrophy and joint contracture; decreased sex drive because of pain, fatigue, and/or medication; genital sensations remain intact
Systemic lupus erythematosus (SLE)	Similar to RA; decreased lubrication and vaginal lesions result in painful penetration
Myocardial infarction (MI)	Most literature male oriented; problems related to medications
Multiple sclerosis (MS)	Diminished genital sensitivity; decreased lubrication; declining orgasmic ability; difficulty with sexual activity because of muscle weakness, pain, or incontinence
Spinal cord injury	Reflex sexual response with injury above sacral area; disrupted response with lesion at or below sacrum; loss of sensation, decreased lubrication; spasticity, incontinence, or pain with arousal; continued orgasmic sensations or sensations diffused in general or to specific body parts, such as breast or lips

The initial approach to treatment is surgery, which is performed to determine the stage of disease and to remove as much of the tumor as possible. Future treatment is then customized based on the clinical stage of the cancer, the woman's desires, and the cell type and sensitivity of the cancer cells. Ideally treatment plans are developed and implemented by a multidisciplinary team from a variety of disciplines including surgeons, pathologists, and oncologists.[158]

Radiation therapy and chemotherapy with an agent containing platinum are common treatments.[159] Even after initially effective treatment, 55% to 75% of women relapse, and less than 20% survive long term with stage III or IV disease. New therapies under investigation include small-molecular-weight inhibitors, monoclonal antibodies, epidermal growth factor receptors, and gene therapy.[160]

Sexual Dysfunction

Sexual dysfunction is the lack of satisfaction with sexual function resulting from pain or a deficiency in sexual desire, arousal, or orgasm/climax.[161,162] Sexual function and dysfunction result from a complex interplay of the individual, culture, and physiology.[162] Sexual problems are multifaceted and often difficult to diagnose; adequate research is still needed. Sexual dysfunction can have organic or psychogenic causes or, more commonly, a combination of both.[162] Studies show that at any given time up to 45% of adult women have some form of sexual dysfunction.[163]

The sexual response cycle is complex, involving the brain/mind, sympathetic and parasympathetic nervous systems, the systemic and local vasculature, and local innervation. Any disruption in these systems can affect sexual response. Chronic medical conditions can greatly affect both sexual desire and sexual function (Table 24-8). Acute illness and infections also can affect the woman's desire and ability to engage in fulfilling sexual activity. Vaginal infections are especially problematic because they can lead to vaginal irritation and pain with friction. Medications also can disrupt the sexual response cycle. Antihypertensives and antidepressants are commonly associated with sexual problems.[161,163] Surgeries on the genital area can disrupt nerve pathways and hysterectomy may affect sexual function because the uterus, cervix, and vagina are involved in sexual response and orgasm. The mind is a large component of sexual response, and any stressor that affects the woman can affect her sexual response, including her feelings about her sexuality and relationship and past sexual abuse.[163] A thorough history is needed to assess for sexual dysfunction, and testing is appropriate to assess for organic dysfunction (Figure 24-25). The American College of Obstetricians and Gynecologists divide sexual dysfunction into four categories: disorders of desire, arousal, orgasm, and sexual pain.[161]

Disorders of desire (**hypoactive sexual desire, decreased libido**) is the most common sexual dysfunction in women.[163] The prevalence of hypoactive sexual desire increases with age and may be a biologic manifestation of depression, alcohol or other substance abuse, prolactin-secreting pituitary tumors, or testosterone deficiency. β-Adrenergic blockers used for heart disease also may inhibit sexual desire. Short-term treatment with testosterone has been shown to improve sexual desire and may be used to treat women who wish to improve their sexual interest.[161]

Anorgasmia, or **orgasmic dysfunction,** is the inability of the woman to reach or achieve orgasm. Dysfunction follows a continuum from difficulty in arousal to lack of orgasm. Any chronic illness may affect arousal. Diabetes, alcoholism, neurologic disturbances, hormonal deficiencies, and pelvic disorders, such as infections, trauma, and surgical scarring, may block orgasm. Narcotics, tranquilizers, antidepressants (especially SSRIs), and antihypertensive medications also can inhibit orgasm.[163]

Dyspareunia (**painful intercourse**) is common. Women may experience pain during arousal, at the time of orgasm, at

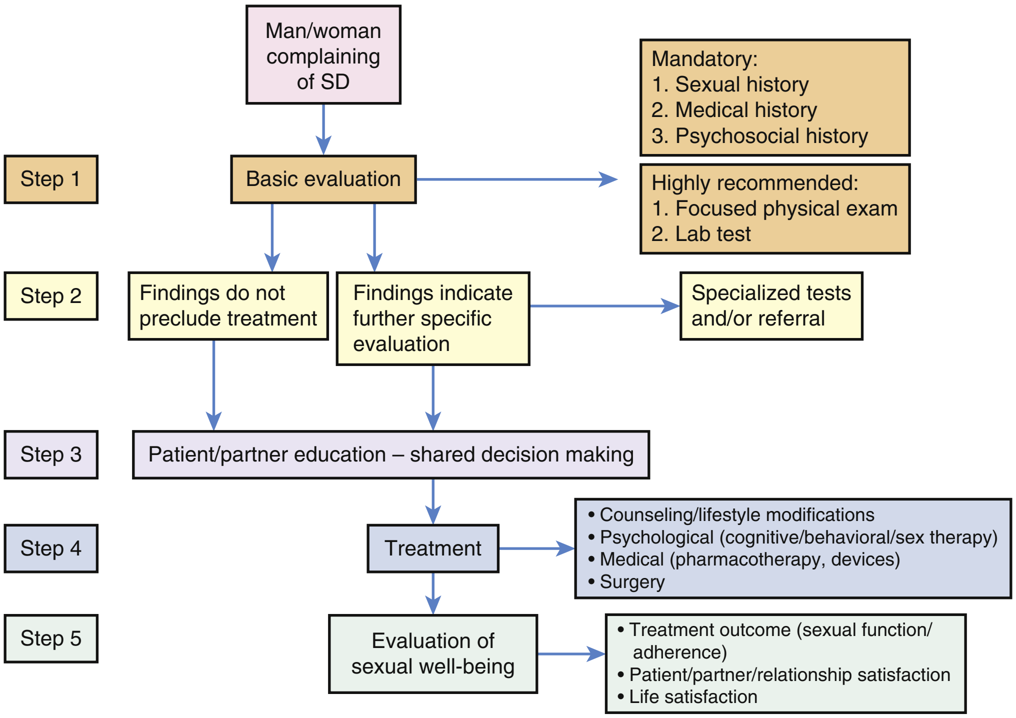

FIGURE 24-25 **Diagnostic and Treatment Algorithm for Sexual Dysfunction.** The International Consultation in Sexual Medicine (ICSM) stepwise diagnostic and treatment algorithm for sexual dysfunction in men and women. (From Hatzichristou D et al: *J Sex Med* 7[1pt2]:337–348, 2010.)

the initiation of intercourse, midway during intercourse, or after intercourse. The pain may have a burning, sharp, searing, or cramping quality and may be described as external, vaginal, deep abdominal, or pelvic. A variety of psychosocial and organic causes have been identified.

Inadequate lubrication may make penetration or intercourse difficult or painful. Low estrogen levels, as are common with menopause and lactation, can decrease vaginal lubrication. Drugs with a drying effect, such as antihistamines, certain tranquilizers, and marijuana, can decrease lubrication. Infections and skin problems of the vulva and vagina are a frequent cause of acute onset dyspareunia. The use of products such as spermicides and fragrances on the sensitive vaginal mucosa may increase the risk of irritation. Disorders of the vaginal opening, such as scarring from female genital mutilation, episiotomy, or an intact hymen, also can be problematic. Deep pelvic disorders such as infection, tumors, and cervical or uterine abnormalities can cause pain with intercourse.

Vaginismus is an involuntary muscle spasm in response to attempted penetration. Vaginismus is often a response to previous painful penetration. Common causes include prior sexual trauma or fear of sex; organic causes are less common and are similar to those that cause dyspareunia, including vulvovestibulitis. Even after the underlying organic problem is detected and successfully treated, vaginismus may persist.

Sexual dysfunction may develop as a coping mechanism. Women with a history of sexual trauma—rape, incest, or molestation—often have problems of desire, arousal, or orgasm or experience pain with sexual activity. In extreme cases total sexual aversion may develop.[163] At other times sexual dysfunction may be a symptom of marital or relationship problems. Because sexual dysfunction has many causes, assessment and treatment should be holistic and culturally sensitive.

Impaired Fertility

Infertility affects approximately 15% of all couples and is defined as the inability to conceive after 1 year of unprotected intercourse with the same, opposite-sex partner. However, many sources believe that medical intervention is indicated for women who are older than 35 years old if they fail to conceive after 6 months of unprotected intercourse.[164] The rate of infertility may be increasing because of an increase in sexually transmitted disease and a delay in the start of childbearing but the increase in incidence rates may also reflect the greater utilization of medical services for infertility.[165] Fertility can be impaired by factors in the man or the woman or both partners. The male is the sole cause of the infertility in 20% of cases, and a co-contributor to infertility in 30% to 40% of cases.[166] The majority of cases of infertility involve the female, caused in part by the complexity of the female reproductive cycle and tract. Ovulatory factors account for 40% of female infertility.[33] Regular ovulation occurs as a result of a functioning hypothalamic/pituitary axis. Ovulation can be disrupted by a wide variety of factors, including imbalances in a diversity of hormones (TSH, estrogen, progesterone, etc.), chronic conditions, and stress. Age is a major factor in female fertility because the regularity of ovulation and the quality of ova decrease with age (Figure 24-26). Abnormalities of the reproductive tract, including tubal pathologies, cause another 40% of cases of infertility.[33] Endometriosis and adhesions and scarring from PID are major

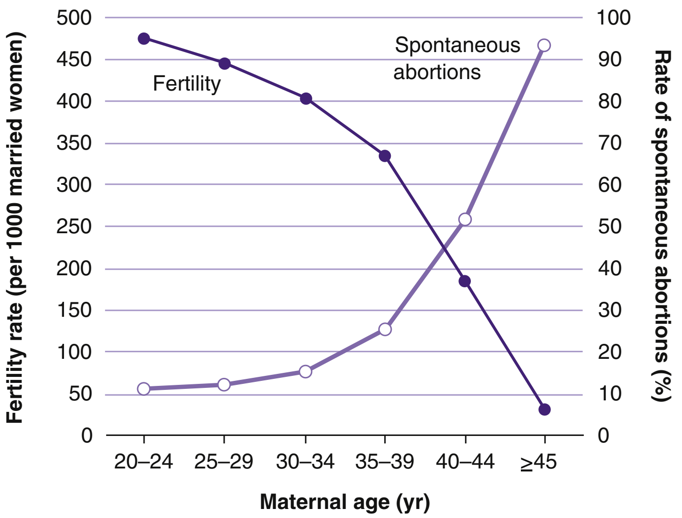

FIGURE 24-26 Relationship of Fertility and Miscarriage with Maternal Age. (From Heffner LJ: Advanced maternal age: how old is too old? *N Engl J Med* 351(19):1927–1929, 2004.)

contributors to blockages within the female reproductive tract. The remaining 20% of female infertility is caused by rare conditions or unknown etiology.[33]

Male infertility has a variety of causes, many of which can be corrected. Hormonal disorders, such as thyroid disturbances or low testosterone levels, can be diagnosed and corrected.[167] Throughout the 82 days of their creation and maturation, the sperm must be kept cooler than body temperature.[33] Elevations in temperature caused by illness, abnormal placement of the testes, varicoceles near the testes, or exposure to high temperatures in hot tubs or saunas may kill or disable sperm. Male infertility is also linked to abnormalities of the seminal tract and sexual dysfunction that disrupts ejaculation.[167] A number of diagnostic procedures are required in the routine investigation of the infertile couple (see Table 23-3). In many instances no cause may be identified.

Fertility Tests

Prior to the performance of even basic fertility tests, a complete history should be obtained that includes coital (sex) timing and frequency in relation to the menstrual cycle; an in-depth assessment and charting of the menstrual cycle; a reproductive history, including all previous pregnancies from both partners and their outcome; a medical history of systemic disease; current medications; past surgeries; a sexual history including any previous STIs; and any exposure to toxins.[168] The history allows the clinician to home in on the most useful tests. Testing starts with the least invasive test or procedure and increases in invasiveness and complexity as the duration of infertility increases. The types of tests and their normal values are summarized in Table 22-4.

The most common test for male infertility is the basic semen analysis, the man is evaluated for volume of semen and the concentration, morphology, and forward motility of sperm.[166,168] More advanced semen analysis also examines the function of the sperm including their ability to bind to and penetrate eggs. In-depth analysis may also analyze the sperm's DNA for number, fragmentation, and ability to merge with the egg's DNA.[168]

Tests for women determine whether: (1) ovulation occurs normally, (2) the endometrium is responding normally to hormones, (3) reproductive tissues are free of tumors or infections, (4) the woman does not have any chronic conditions interfering with fertilization or implantation, and (5) the reproductive tract (cervix, uterus, fallopian tubes) is adequately patent to allow for passage of ovum and sperm. Hormonal assays can be useful to detecting underlying abnormalities. The position and size of organs or the presence of tumors can be assessed by pelvic examination, ultrasound, or hysterosalpingogram that injects contrast dye into the reproductive tract to look for normal anatomy and patency of the fallopian/uterine tubes. Chromosomal analysis of the couple may reveal mutations or translocations that result in very early embryo loss.[33]

Treatment of infertility aims at correcting underlying pathologies or overriding the deficient system. Male infertility can be overcome through injection of the male DNA directly into the uterus or even the ovum. Anovulation in the female can be overcome with ovulation-inducing drugs. Blockages within the female reproductive tract can be bypassed with in vitro fertilization.

There has been a proliferation in assisted reproductive technologies (ART) that enable women and couples to conceive and bear children. ART results in more than 50,000 live births per year in the United States, and the rate is rising.[169] However, there are questions about the health and long-term safety of infants conceived with assisted reproduction; for instance, concerns about the high rate of twins and preterm birth in pregnancies conceived with ART. In addition, children born through ART have a higher rate of birth defects, even when other variables are controlled.[170] The many theories about the cause of this increase suggest that the birth defects may be the result of epigenetic changes when the expression of the embryo's DNA is affected by the very early environment of the blastocysts.[171] Research in this area and the field of epigenetics is ongoing.[171]

DISORDERS OF THE BREAST

Galactorrhea

Galactorrhea (inappropriate lactation) is the persistent and sometimes excessive secretion of a milky fluid from the breasts of a woman who is not pregnant or nursing an infant. It can occur in men, may involve one or both breasts, and is not associated with breast cancer.

Incidence is difficult to estimate because of differences among definitions of the condition, examination techniques, and populations of women who have been studied. Prevalence has been documented as 0.1% to 32% of all women.

PATHOPHYSIOLOGY. Galactorrhea is a manifestation of pathophysiologic processes in the body, rather than a breast disorder. These processes are chiefly hormone imbalances caused by hypothalamic/pituitary disturbances, pituitary tumors, or neurologic damage. Exogenous causes include drugs, estrogen, and manipulation of the nipples. When caused by hyperprolactinemia it is manifested by the spontaneous appearance of a milky secretion from multiple duct openings, usually from both breasts. Galactorrhea caused by oral contraceptives (OCs)

BOX 24-12 COMMON CAUSES OF HYPERPROLACTINEMIA

Physiologic Causes
- Exercise
- Idiopathic
- Pregnancy and postpartum period
- Sleep (rapid eye movement [REM] phase)
- Stress (trauma, surgery)
- Suckling

Drug Causes
- Amoxapine
- Amphetamines
- Anesthetic agents
- Butyrophenones
- Cimetidine
- Estrogens
- Hydroxyzine
- Methyldopa
- Metoclopramide
- Narcotics
- Phenothiazines
- Progestins
- Reserpine
- Tricyclic antidepressants
- Verapamil

Pathophysiologic Causes
- Acromegaly
- Chronic chest wall stimulation (e.g., post-thoracotomy, postmastectomy, herpes zoster)
- Cirrhosis
- Hypothalamic disease
- Hypothyroidism
- Pressure on pituitary stalk
- Prolactin-secreting tumors
- Pseudocyesis (false pregnancy)
- Renal failure (especially with zinc deficiency)
- Spinal cord lesions

is more likely to occur with high-dose use; is characterized by clear, serous, or milky discharge from multiple ducts; and is noticeable during the drug-free interval between OC packets. In premenopausal women, unilateral or bilateral spontaneous multiple duct discharge that increases before menstruation often is caused by fibrocystic change. Unilateral, spontaneous, serous, or serosanguineous discharge from a single duct usually is caused by an intraductal papilloma; bloody discharge suggests cancer; bilateral, sticky, multicolored discharge from multiple ducts is often caused by duct ectasia; and purulent discharge indicates a subareolar abscess.[172]

The most common cause of galactorrhea is **nonpuerperal hyperprolactinemia,** or excessive amounts of prolactin (the pituitary hormone that stimulates milk production) in the blood not related to pregnancy or childbirth. Nonpuerperal hyperprolactinemia can be caused by any factor that (1) stimulates or overstimulates the prolactin-secreting units of the pituitary gland; (2) interferes with production of **prolactin-inhibiting factor (PIF),** a neurotransmitter (probably dopamine) that inhibits prolactin secretion; or (3) interferes with pituitary receptors for PIF. A variety of exogenous agents (such as drugs) and disorders can trigger one of these three mechanisms, thereby causing hyperprolactinemia (Box 24-12).

Hypothyroidism causes increased secretion of hypothalamic TSH that stimulates prolactin release from the pituitary. Hypothyroidism also is associated with reduced metabolic clearance of prolactin, which prolongs its effects.

Many types of pituitary tumors cause hyperprolactinemia. Prolactinomas cause hyperprolactinemia by secreting prolactin, decreasing production of PIF, or putting pressure on the pituitary stalk such that delivery of PIF to the anterior pituitary is prevented. Growth hormone–secreting pituitary tumors may cause galactorrhea through the intrinsic lactogenic effect that growth hormone appears to have on mammary tissue. Prolactin-secreting lung and kidney tumors also cause hyperprolactinemia.

Chronic stress may cause hyperprolactinemia by inhibiting PIF release. Cervical spinal injuries, head trauma, encephalitis, meningitis, herpes zoster, or thoracotomy scars may stimulate the afferent portion of the suckling reflex arc, which is carried in the second to sixth thoracic nerves. The suckling reflex increases prolactin secretion.

CLINICAL MANIFESTATIONS. A small amount of breast milk expressed from the nipples of parous women usually is not a concern, and normal breast milk color can be other than white. Inappropriate lactation is manifested by the appearance of a milky breast secretion in nonpregnant, nonlactating women from one or both breasts. Most women with galactorrhea experience menstrual abnormality. If a pituitary process is involved, the woman usually experiences hirsutism and infertility; if a hypothalamic lesion is present, she may report such CNS symptoms as intractable headache, visual field disturbances, sleep disturbances, and abnormal temperature, thirst, or appetite.

EVALUATION AND TREATMENT. Galactorrhea requires evaluation when it (1) occurs in nulliparous women or in parous women who have not been pregnant or have not breast-fed for 12 months, or (2) is associated with amenorrhea, headache, visual field abnormalities, or other symptoms implying systemic illness. Evaluation includes a variety of diagnostic tests. When amenorrhea accompanies galactorrhea, the assessment is the same as for amenorrhea. Breast secretions are examined for fat globules and neoplastic cells to verify their source. Serum prolactin levels are measured. Because such variables as eating, sleeping, stress, and breast examinations increase prolactin levels, at least two positive results are needed for a diagnosis of hyperprolactinemia. Prolactin levels greater than 25 to 30 ng/ml (by radioimmunoassay) are elevated. Those in the range of 75 to 100 ng/ml are considered to be caused by a pituitary tumor until proved otherwise. Serum thyroxine and TSH levels are measured to rule out hypothyroidism, and LH and FSH levels are obtained if the individual is amenorrheic. MRI may assist in locating adenomas.

Treatment is specific to the underlying cause and occurs after identification of the cause. Medical therapy is usual and surgery or radiation therapy is rarely required.

Benign Breast Disease

Benign breast disease (BBD) is a spectrum of noncancerous changes in the breast. Numerous benign alterations in ducts and lobules occur in the breast, including irregular lumps, cysts, sensitive nipples, and itching. The most common symptoms reported by women are pain, palpable mass, or nipple discharge; the majority of these prove to have a benign cause. After a diagnosis of BBD, however, major determinants of breast cancer risk include degree of family history; histologic or biologic features, or both; and previous biopsy.[173] This risk varies according to the histologic category of BBD (moderate in women with proliferative lesions without atypia [deviation from normal]) and substantial in women with atypical (atypia) hyperplasia (AH)[174] (see p. 841). Among premenopausal women, the risk appears to be greater for

those with atypical lobular hyperplasia (ALH) than with atypical ductal hyperplasia (ADH) (see p. 841). For postmenopausal women, the risk of breast cancer was similar between those with ALH or ADH.[174] Family history is reported as an independent risk factor for breast cancer. Women with atypia and a family history had a breast cancer risk four times the expected risk.[175] Risk was lower among those with atypia and no family history.

The College of American Pathologists has classified biopsy tissue according to breast cancer risk. These classifications are listed in Box 24-13. Benign epithelial lesions can be broadly classified according to their risk of developing breast cancer as: (1) nonproliferative breast lesions, (2) proliferative breast disease, and (3) atypical (atypia) hyperplasia. Table 24-9 includes examples of benign breast tumors.

BOX 24-13 CLASSIFICATION OF BREAST BIOPSY TISSUE ACCORDING TO RISK FOR BREAST CANCER

No Increased Risk

Adenosis (sclerosing or florid)
- Apocrine metaplasia
- Macrocysts or microcysts
- Fibroadenoma
- Fibrosis

Mild hyperplasia
- Mastitis or periductal mastitis
- Squamous metaplasia

Slightly Increased Risk (1.5 to 2 Times)

Moderate or florid hyperplasia
- Papilloma

Moderately Increased Risk (4 to 5 Times)

Atypical hyperplasia (ductal or lobular)

Data from Dupont WD, Page DL: *NEJM* 312(3):146–151, 1985.

Nonproliferative Breast Lesions

The term *nonproliferative* has been used to discriminate from the *proliferative* changes commonly associated with increased risk for development of breast cancer. Nonproliferative breast lesions are generally not associated with an increase risk in breast cancer.[173] Terms such as **fibrocystic changes (FCCs)** or physiologic nodularity and cysts, fibrocystic disease, chronic cystic mastitis, and mammary dysplasia refer to nonproliferative lesions and are not clinically definitive because they encompass a heterogeneous group of diagnoses.[173] **Cysts** (fluid-filled sacs) are a specific type of lump that commonly occurs in women in their 30s, 40s, and early 50s. Cysts feel "squishy" when they occur close to the surface of the breast but when deeply embedded they can feel hard (Figure 24-27). An

TABLE 24-9 BENIGN BREAST TUMORS

BENIGN BREAST TUMOR	RISK FACTORS	PATHOPHYSIOLOGY	CLINICAL MANIFESTATIONS	TREATMENT
Fibroadenoma	Puberty, early adulthood; occurs earlier and more frequently in young black women	Slow-growing lesion composed of variable proportions of epithelial and connective tissue; thought to be under influence of estrogen	Painless, firm, elastic, solitary, well-circumscribed mass ≈1-5 cm in diameter	Excision with person under local anesthesia; or careful observation
Phyllodes tumor	Middle age	Fibroepithelial tumor characterized by marked proliferation of connective tissue stroma and great size; initially slow growing; 10%-25% may be malignant	Spheric, firm, usually well-circumscribed multinodular tumor with a diameter of 2-20 cm; trophic cutaneous ulceration is a late manifestation	Local excision of benign or small tumor; simple mastectomy if voluminous or malignant tumor
Intraductal papilloma	Ages 30-50 yr; relatively uncommon	Subareolar tumor consists of epithelial vegetation with central connective tissue axis; found in lactiferous duct	Spontaneous or induced watery, serous, or bloody nipple discharge; small soft, friable, yellow or red, ≈5 mm, papillomatous growth attached to duct wall by short, thin stalk; rare nipple retraction	Excision of involved duct
Mammary duct ectasia	After menopause or during pregnancy and lactation	Principal lactiferous ducts become dilated and filled with cellular debris; secondary inflammatory reaction; possible rupture of ducts	Subareolar induration or nipple retraction; spontaneous, bloody, sticky, thick, multiple duct discharge; burning pain and swelling of areolar area; palpable mass after rupture	Antibiotic and anti-inflammatory therapy
Fat necrosis	Ages 14-80 yr; average age 50 yr; increased in women with fatty, voluminous breasts; trauma	50% are posttraumatic; necrosis secondary to inflammation is more rare	Poorly circumscribed indurated area with yellow or gray necrotic foci	Leave alone or local excision

estimated 50% to 80% of women normally experience some of these changes. The prevalence of fibrocystic lesions is probably related to hormonal changes, which in turn are affected by genetic background, age, parity, history of lactation, caffeine consumption, and use of exogenous hormones.[176] Based on experimental animal studies, it is assumed that breast cysts are the result of ovarian alterations, but the exact mechanism is unknown. Calcifications, found in cysts and adenosis or an increase in the number of acini per lobule, can form mammographically suspicious alterations.[177] Cysts also can be associated with unilateral nipple discharge. A variety of substances are secreted into cyst fluid, including polypeptide hormones and male and female sex steroid hormones. Cysts often rupture with release of secretory material into the adjacent tissue. The resulting chronic inflammation and scarring fibrosis contribute to the palpable firmness of the breast.[177] Fibrous tissue increases progressively until menopause and regresses thereafter. Papillary apocrine (glandular) change, epithelial-related calcifications, and mild hyperplasia of the usual type are all considered nonproliferative breast lesions.[173] Genetic aberrations are more common in proliferative than in nonproliferative lesions.[177]

Proliferative Breast Lesions Without Atypia

These disorders are characterized by proliferation of ductal epithelium and/or stroma without cellular signs of **atypia** or deviation from normal. Criteria for the diagnosis of intraductal proliferative lesions have been the subject of much research and controversy and include the following structurally diverse lesions:

1. **Usual ductal hyperplasia (UDH).** In the normal breast, only myoepithelial cells and a single layer of luminal cells are present above the basement membrane.[177] UDH is defined by the presence of *more* than two cell layers above the basement membrane within the ductal space. Cytologically they are benign cells, not monoclonal, and cells can vary in size and shape.[173,178] The additional or proliferating epithelial cells fills and distends the ducts and lobules by both luminal and myoepithelial cells. Moderate to **florid hyperplasia** is more than four cell layers above the basement membrane. Ductal hyperplasia is usually found as an incidental finding on biopsy of mammographic abnormalities.
2. **Intraductal papillomas.** Solitary papillomas are a monotonous (sameness) array of papillary cells that grow from the wall of a cyst into the lumen of the duct. Growth occurs within a dilated duct often near or beside the nipple causing benign nipple discharge (Figure 24-28). These papillomas *can* harbor areas of atypia or ductal carcinoma in situ (DCIS) (see p. 841). Solitary intraductal papillomas may present as a breast mass (mammogram), a nodule (ultrasound) or image from MRI, or ductography (galactogram).[178] Hyperplasia and metaplasia can be present within the ducts. Atypical hyperplasia may be present within or adjacent to papilloma, making the distinction from DCIS difficult (see p. 866). The presence of

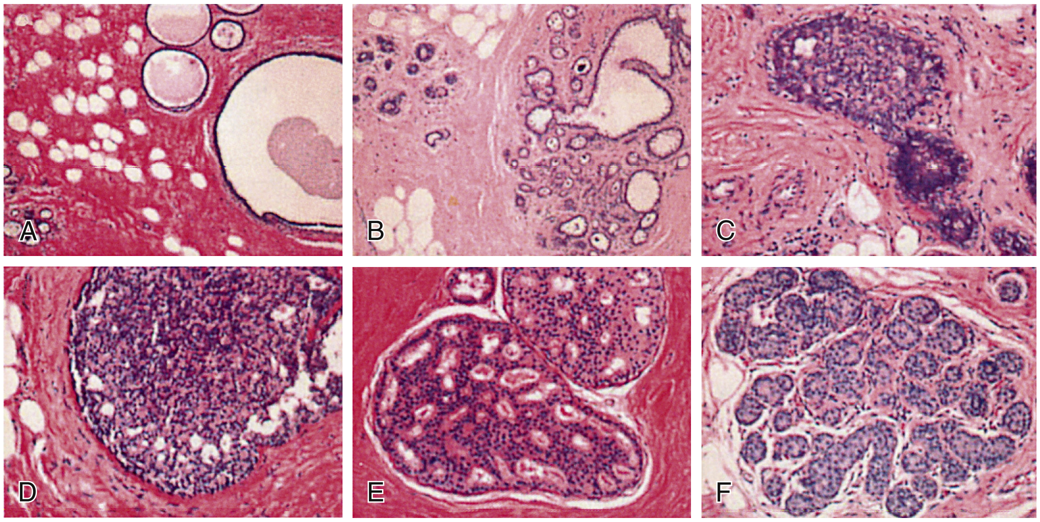

FIGURE 24-27 Benign Breast Disease. **A,** *Nonproliferative fibrocystic changes:* The architecture of the terminal-duct lobular unit is distorted by the formation of microcysts, associated with interlobular fibrosis. **B,** *Proliferative hyperplasia without atypia:* This is adenosis, a distinctive form of hyperplasia characterized by the proliferation of lobular acini, forming crowded glandlike structures. For comparison, a normal lobule is on the left side. **C,** *Proliferative hyperplasia without atypia:* There is moderate ductal hyperplasia, which is characterized by a duct that is partially distended by hyperplastic epithelium within the lumen. **D,** *Proliferative hyperplasia without atypia, which is florid ductal hyperplasia:* The involved duct is greatly expanded by a crowded, jumbled-appearing epithelial proliferation. **E,** *Atypical ductal hyperplasia:* These proliferations are complex and partially formed secondary lumens and mild nuclear hyperchromasia in the epithelial cell population. The peripheral spaces are irregular and slitlike. **F,** *Atypical lobular hyperplasia:* Monomorphic, small, rounded loosely cohesive cells fill the lumens of partially distended acini in this terminal-duct lobular unit (hematoxylin and eosin). (From Elmore JG, Gigerenzer G: *N Engl J Med* 353[3]:231, 2005.)

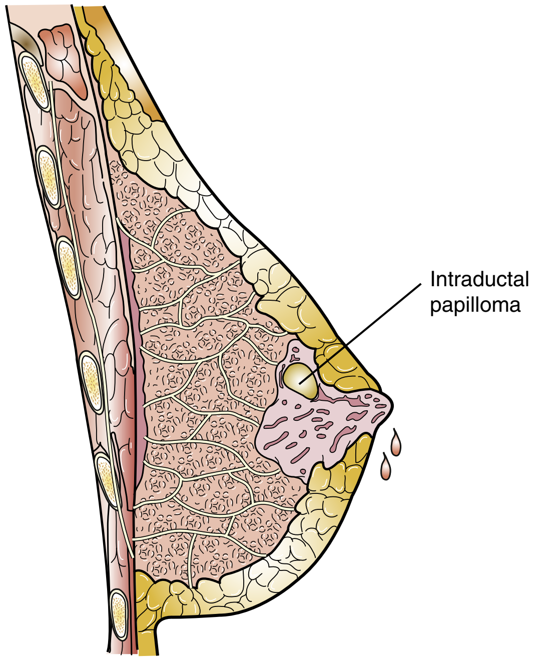

FIGURE 24-28 Intraductal Papilloma.

atypia (ductal or lobular) coexisting with a single papilloma (atypical papilloma) does not appreciably modify the breast cancer risk attributable to just atypia.[179] A solitary papilloma without atypia conveys a risk similar to proliferative fibrocystic lesions. Although the breast cancer risk is small, **multiple papillomas,** called **diffuse papillomatosis,** even without identified atypia, can increase breast cancer risk. Diffuse papillomatosis is defined as a minimum of five papillomas within a localized segment of breast tissue.[173]

3. **Sclerosing adenosis.** Sclerosing adenosis is a lobular lesion with increased fibrous tissue and scattered glandular cells.[173] Calcification is commonly present within the lumens; however, the normal lobular arrangement is maintained. It can present as a mass or suspicious finding from mammogram but requires no treatment. Occasionally, stromal fibrosis may mimic the appearance of invasive carcinoma.[177]
4. **Radial scar.** Radial scar (RS) refers to an irregular, radial proliferation of ductlike small tubules entrapped in a densely fibrotic stroma (Figure 24-29). The term *scar* refers to the structural appearance only because these lesions are not associated with scarring and fibrosis from a prior injury, biopsy, or surgery. RS also has been called *radial sclerosing lesions* and *sclerosing papillary proliferation.* RSs are usually discovered when a breast lesion or radiologic abnormality is biopsied or removed. Occasionally RSs are large enough to be detected by mammography, which, however, cannot reliably differentiate between these lesions and spiculated (spiky with pointed features) carcinoma. Controversy exists about the need for surgical excision when RSs are found. There is some evidence that RSs may be premalignant lesions, and the possibility of finding an unrecognized in situ or invasive component suggests that they be surgically excised.[173] Yet a retrospective study of 9556 women found that although RSs mildly elevate the risk of invasive breast cancer, the risk was largely attributed to the coexistent presence of proliferative disease.[180] Invasive breast cancer risk was further increased in women with AH.[180,181] No additional treatment is needed beyond excision and the risk of subsequent breast cancer is small.[173]

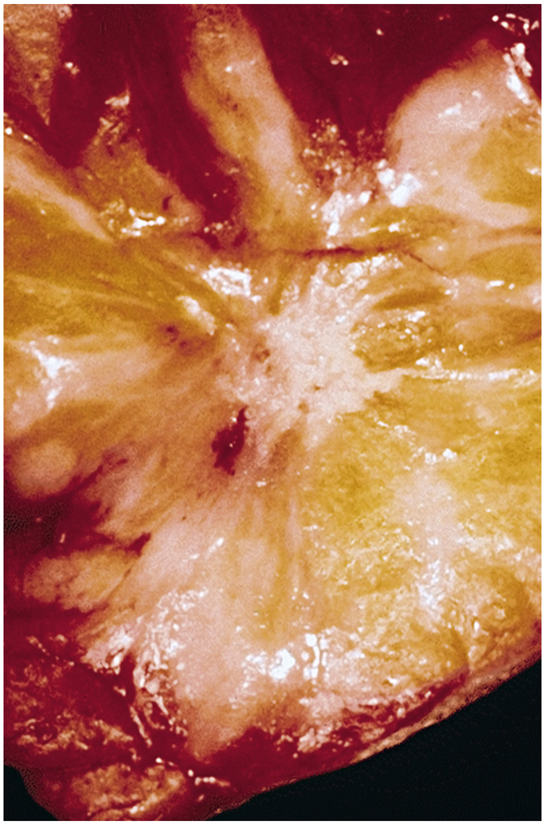

FIGURE 24-29 Radial Scar. Gross pathologic specimen of radial scar. (From the Armed Forces Institute of Pathology.)

5. **Simple fibroadenoma.** Simple fibroadenomas are benign solid tumors composed of both fibrous and glandular tissue.[178] Fibroadenomas are now considered proliferative lesions and the histologic features influence the risk of breast cancer.[178,182] If the fibroadenoma is complex with adjacent proliferative disease or if there is a family history of breast cancer the risk of breast cancer is slightly elevated. There is no increased risk of breast cancer in the majority of women with a simple fibroadenoma. Multiple fibroadenomas occur in the same breast or bilaterally in about 20% of cases.[178] Fibroadenomas are found most commonly in women between the ages of 15 and 35 years but they can occur at any age, especially in older women on hormone therapy.[183] The etiology is unknown, but a hormonal role is likely because they persist during the reproductive years, increase in size during pregnancy or with estrogen therapy, and usually regress after menopause. Fibroadenomas usually present as a well-defined mobile mass—smooth and hard like a marble—on physical examination or a well-defined solid mass on

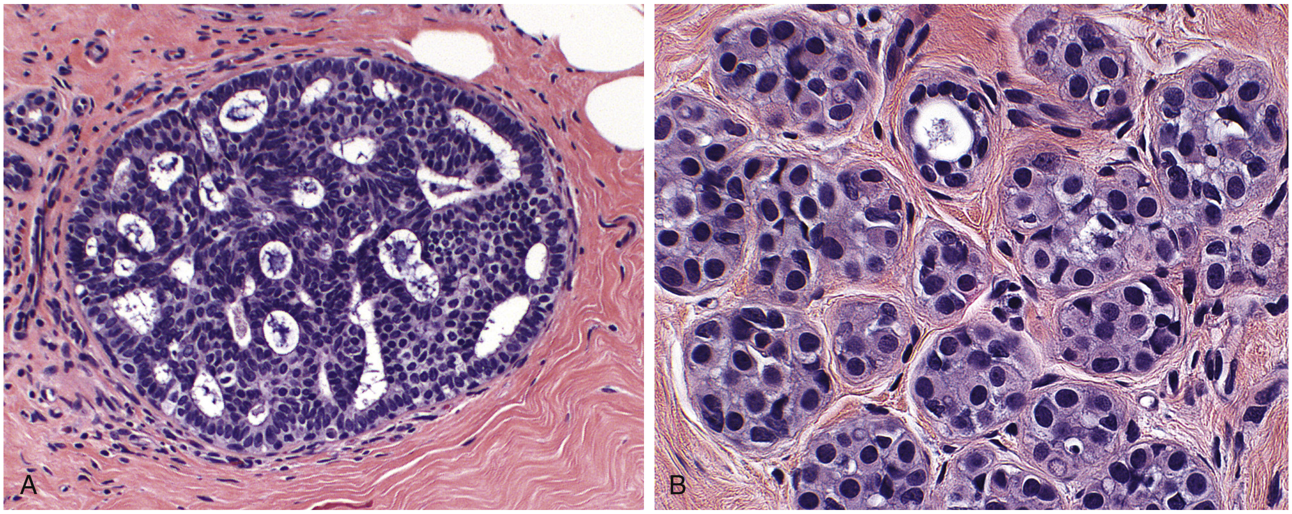

FIGURE 24-30 Atypical Ductal and Lobular Hyperplasias. **A,** Atypical ductal hyperplasia. A duct is filled with a mixed population of cells. Although some of the spaces are round and regular, the peripheral spaces are irregular and slitlike. These features are highly atypical but fall short of a diagnosis of ductal carcinoma in situ (DCIS). **B,** Atypical lobular hyperplasia. A population of monomorphic small, rounded, loosely cohesive cells partially fill a lobule. (From Kumar V: *Robbins & Cotran pathologic basis of disease,* ed 8, Philadelphia, 2008, Saunders.)

ultrasound. Not all biopsy-proven lesions require surgical excision. If a fibroadenoma increases in size or is symptomatic, surgical excision is mandated to know if the lesion is malignant.[178]

Proliferative Breast Lesions with Atypia

Proliferative breast lesions with some abnormal structure or *atypia* include **atypical ductal hyperplasia (ADH),** or abnormal proliferating cells in breast ducts, and **atypical lobular hyperplasia (ALH),** or abnormal proliferating cells in breast lobules.[177,178] ALH also can involve ducts.[178] **Atypical hyperplasia (AH)** is an increase in the number of cells with some variation in cellular structure but lacks sufficient qualitative or quantitative features of carcinoma. Studies continue to indicate that women with AH have an increased risk (about fourfold) of breast cancer compared with women who have nonproliferative lesions.[174] AH is associated with an increased risk of both ipsilateral (same side as lesion) and contralateral breast cancer indicating some evidence of underlying breast abnormalities that predispose to breast cancer.[178] Major determinants of breast cancer risk include histologic/biologic findings, degree of family history, and previous (age of) biopsy (see p. 843).[174] Recent findings from the Nurses' Health Study (NHS) found adolescent alcohol consumption is associated with increased risk of proliferative BBD.[184] Among premenopausal women at the time of their benign biopsy, the risk of breast cancer was substantially increased among women with AH (Odds ratio [OR], 7.3) than among women with ADH (OR, 2.72). The risks for women who were postmenopausal at the time of benign biopsy were similar for women with ALH and those with ADH.[174]

Ductal hyperplasia is an increased number of uniform epithelial cells within the lumen of the terminal ducts (Figure 24-30, *A*). Atypical ductal hyperplasia includes a continuum of changes—cell structure and placement—ranging from an increase in cellularity to features of DCIS (see p. 866). In ADH, the cells fail to completely fill ductal spaces as compared with DCIS.

Lobular hyperplasia refers to proliferation of small uniform cells in the lumen of lobular units. The abnormal cells of ALH and lobular carcinoma in situ (LCIS) share some of the cytologic and structural features, but the cells in ALH do not distend more than 50% of the acini within a lobule (see Figure 24-30, *B*). ALH can extend into ducts, and this is associated with an increased risk of invasive carcinomas.[177] Other benign conditions are summarized in Table 24-10.

EVALUATION AND TREATMENT. Breast problems should be diagnosed from a multimodal approach that combines physical examination, mammogram when applicable, sonogram, possibly MRI, and careful consideration of a biopsy. The principal mammographic signs of breast carcinoma are densities and calcifications. However, the dense breast tissue often seen in young women can make interpretation extremely difficult. Newer screening and diagnostic methods are being tested including those without compression and ionizing radiation such as different technologies using MRI. Ultrasonography (ultrasound) is used to differentiate a solid mass from a cystic (fluid-filled) mass, which is generally benign.

Treatment consists largely of relieving symptoms. Risk reduction for AH includes avoiding hormone therapy and oral contraceptives, careful diet choices, and exercise. Certain selective estrogen modulators, such as tamoxifen and raloxifene, or an aromatase inhibitor may be considered after a thorough discussion of risks and benefits.[178] Breast pain may be minimized by wearing a brassiere that provides good support. Reduction of caffeinated beverages, cola, root beer, and chocolate, which can cause overstimulation of breast tissue for some women, may reduce pain and nodularity. Given time the cysts may disappear without treatment. Although still controversial and possibly

dose-dependent, isoflavone exposure has been associated with a decreased risk of proliferative benign fibrocystic changes, nonproliferative changes, and breast cancer.[185,186]

Iodine deficiency may increase fibrocystic breast change, thus may be useful for relieving pain.[187] Although unknown, increasing omega-3 fatty acids may decrease associated pain caused by inflammation as well as the application of castor oil packs to the breasts. The use of anti-inflammatories also may decrease inflammation. Drugs used to treat severe breast pain are listed in Table 24-11.

TABLE 24-10 OTHER BENIGN BREAST CONDITIONS

TYPE	COMMENT
Developmental	
Milk-line remnants	Increase in number of nipples or breasts results from persistent epidermal thickening along the milk line
Accessory axillary breast tissue	Ductal system may extend into subcutaneous tissue of the chest wall and axillary region; this tissue can undergo lactational changes and give rise to tumors
Congenital nipple inversion	Is common and may be unilateral; can spontaneously correct during pregnancy; can be confused with retraction of nipple, which is sometimes part of invasive cancer or inflammation
Macromastia	Juvenile hypertrophy may be caused by unusual tissue response to hormonal stimulus
Iatrogenic	
Reconstruction or augmentation	Breast tissue can be replaced or augmented by skin and muscle flaps for synthetic prostheses; silicone implants, the most common, are rubbery silicone filled with either silicone gel or saline; a common complication of implants is formation of a thick fibrous capsule (i.e., chronic inflammatory responses) that can cause cosmetic deformity; the capsule can limit the spread of a ruptured implant but if the capsule ruptures silicone gel can escape; long-term consequences of rupture are unknown
Inflammation	
Acute mastitis	Inflammatory diseases of the breast are rare; acute mastitis is confined to the lactating period of nursing; the nipples can become dry, cracked, and fissured, increasing risk of bacterial infection; infection may lead to abscess formation
Periductal mastitis	Women or men present with a painful subareolar mass thought to be infectious; not associated with lactation; 90% of individuals are smokers; vitamin A deficiency associated with smoking may alter the differentiation of the ductal epithelium; keratin is trapped within the ductal system causing dilation and rupture; antibiotic therapy and surgery are usually indicated
Mammary duct ectasia	Affects 50- and 60-year-olds, usually multiparous women, not associated with smoking; dilation of ducts with chronic granulomatous inflammatory reaction; fibrosis may eventually lead to skin and nipple retraction, thus mistaken for cancer; may have white nipple secretions
Fat necrosis	Painless, palpable mass, skin thickening or retraction; mammographic density or calcification; may have hemorrhage; most women will give a history of prior surgery or trauma; can be confused with breast carcinoma
Lymphocytic mastopathy	Single or multiple hard, palpable masses; can be so hard that interferes with biopsy; lesion includes collagenized stroma surrounding atrophic ducts and lobules; the breast membrane is frequently thickened; a prominent lymphocytic infiltrate surrounds epithelium and blood vessels; most common in women with type 1 diabetes or autoimmune thyroid disease

Data from Lester SC: The breast. In Kumar V, Abbas AK, Fausto N, editors: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.

TABLE 24-11 DRUGS USED TO TREAT SEVERE BREAST PAIN (MASTALGIA)

AGENTS	COMMENTS
Definitely Effective	
Danazol	Causes a decrease in cyclic pain and nodularity believed to reduce estrogen; also used for endometriosis; some side effects include changes in menstrual cycle regularity, weight gain, acne, and flushing
Bromocriptine	Decreases cyclic pain, nodularity, and tenderness; decreases prolactin levels and may alter dopamine receptors; is also used to suppress lactation after childbirth; can cause nausea, vomiting, hypotension, and dizziness
Tamoxifen	As an antiestrogen it can decrease cyclic pain; increase clot formation (phlebitis, emboli, strokes); cause hot flashes, amenorrhea, weight gain, and increased risk of uterine cancers
Evening primrose oil (linoleic acid)	Can decrease cyclic pain, nodularity, and tenderness; women with mastalgia believed to have low levels of breast linoleic acid; reduces PGE2 prostaglandins and inflammation; too much oil, however, has been associated with increasing inflammation (>1000 mg/day)
Possibly Effective	
Iodine	Can decrease cyclic pain and nodularity (see Nutrition & Disease: Premenstrual Syndrome, p. 813)
Vaginal progesterone	Decrease in cyclic pain and tenderness; not as effective for decreasing tenderness; antagonist to estrogen; can cause weight gain
Insufficiently Studied	
Progestins	May decrease estrogenic effects; however, related to endothelial vasospasms, weight gain, and increased risk of breast cancer

TABLE 24-12 CHANCE OF BEING DIAGNOSED WITH BREAST CANCER

BY AGE (Years)	BY RATIO
30-39	1 in 238
40-49	1 in 69
50-59	1 in 38
60-69	1 in 27
Ever*	1 in 8
Never	7 in 8

Data from Reis LAG et al: *Cancer statistics review,* 1975-2005, Bethesda, MD, 2008, National Cancer Institute. Available at http://seer.cancer.gov/csr/1975_2005. Based on November 2007 SEER data, posted SEER website, 2008.

NOTE: These calculations are averages. An individual's risk may be higher or lower depending on several factors (e.g., family history, reproductive history, race/ethnicity, and others).

*Absolute lifetime risk.

Cancer

Breast cancer, the most common cancer in American women, is the leading cause of death in women ages 40 to 44 years and the second most common killer after lung cancer of women of all ages. The incidence of breast cancer has risen steadily since the 1970s and started leveling off from 1998 to 1999; incidence for all races combined is about 125 cases per 100,000 women per year. It is estimated that 234,580 women and 2240 men will be diagnosed with breast cancer, and 40,030 women and 410 men will die from breast cancer in 2013.[1] Age and the chance of being diagnosed with breast cancer are presented in Table 24-12. The breast cancer death rate in the United States has been declining from 1989 to 1990, peaking at a rate of 33 deaths per 100,000 women.[188] The age-adjusted death rate from 2005 to 2009 in the United States is 23 per 100,000 women per year. Breast cancer comprises clinically distinct subtypes. The National Cancer Institute (NCI) reported subtypes by race including estrogen receptor (ER), progesterone receptor (PR), HER2/neu, and triple negative (ER negative, PR negative, and HER2 negative). The luminal breast cancer subtype predominates across racial/ethnic groups with lifetime risk lowest in Hispanic women and highest in white women. Triple negative breast cancer is highest in black women compared with Asians, followed by Hispanics and whites.[189] Overall, black women have lower incidence of breast cancer but a 41% higher mortality than white women.[190] Black women in all age groups experience the highest mortality rates for breast cancer although the reason for this disparity is not clearly understood but includes diagnoses at later stages, excess obesity, and triple negative breast cancer, which has a more aggressive phenotype.[190] More than two thirds of breast cancer cases occur in women older than 55 years. From 2005 to 2009, the median age for breast cancer diagnosis was 61 years of age. The median age at death for breast cancer was 68 years of age.[191] Because DCIS is almost exclusively detected by mammography, the large increase in incidence of DCIS over the past 20 years can be attributed to screening (see What's New? Screening Mammography: Why It Has Not Lived Up to Expectations, Chapter 12, p. 393).

Risk factors and possible causes of breast cancer can be classified as reproductive, hormonal, environmental and lifestyle, and familial (Table 24-13). However, two factors emerging as important are postpartum involution of the mammary gland and breast density, which are not as easily classified.

Reproductive Factors: Pregnancy

A clearer understanding of mammary gland structure (morphology) and function from fetal development, to puberty, pregnancy, and aging will help elucidate fundamental changes to breast development and disease. A key element is "branching morphogenesis," in which the mammary gland produces and delivers copious amounts of milk by forming a rootlike network of branched ducts from a rudimentary epithelial bud.[192] Branching morphogenesis begins in fetal development, pauses after birth, starts again in response to estrogens at puberty, and is modified by cyclic ovarian hormonal action. This systemic hormonal action elicits local paracrine interactions between the developing epithelial ducts and their adjacent mesenchyme (embryonic) or postnatal stroma. Then the local cellular crosstalk directs the tissue remodeling, ultimately producing a mature ductal tree.[192] The gland is unique because it undergoes most of its branching during adolescence and not fetal development. This allows experimental manipulation of the gland not possible with any other organ.[193]
